Flap elevation is based on the superior epigastric supply. Care should be taken to divide the eighth intercostal nerve as it enters the muscle near the costal margin. This causes muscle atrophy, reducing epigastric bulk in the long term. A wide subcutaneous tunnel is made between the abdominal dissection and the mastectomy site allowing passage of the pedicle without compression. When using a contralateral pedicle, it is tunneled adjacent to the medial border of the normal breast. Ipsilateral flaps are passed straight up through the inframammary fold of the mastectomy site. If venous congestion occurs, repositioning may be helpful. Additionally, one may remove the LIGACLIP on the deep inferior epigastric vein stump and allow it to bleed for several minutes for venous decompression.

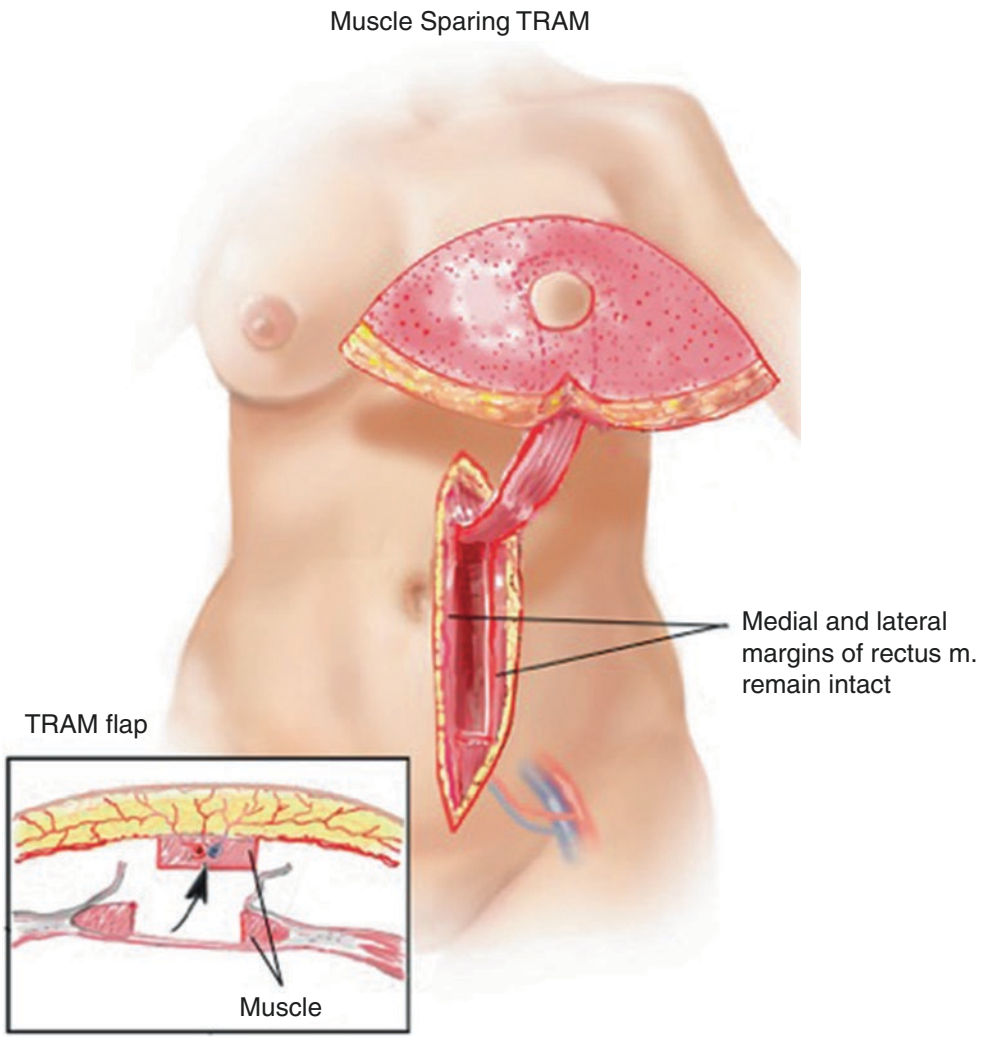

Fig. 36.6 Muscle-sparing unipedicled TRAM flap

Alternatively, Hartrampf's "mechanical leech" drainage system may be inserted into the deep inferior vascular system to aid in venous decompression [46].This involves inserting a pediatric feeding tube or venous cannula into the deep inferior epigastric vein and using this as a decompression valve which can be opened periodically to bleed the flap of congested, poorly oxygenated venous blood under pressure. The catheter can be flushed with dilute heparin solution to maintain its patency over a period of 2–3 days as needed.

Abdominal closure should be performed meticulously as poor closure dramatically increases the risks of hernia formation. It is essential to incorporate both the internal and external oblique aponeuroses into the sheath closure [47]. If fraying of the fascia occurs, it can be darned with a suture weave or covered with an onlay of AlloDerm®. Bucky and May have reported the routine incorporation of mesh into all TRAM flap abdominal closures with excellent success; one patient of 65 patients treated developed a mesh infection, and one patient developed hernia [48]. Once abdominal fascial closure has been securely closed, the upper abdominal skin flap is redraped over suction drains and closed. An umbilicoplasty is then performed. TRAM flap shaping follows and technical caveats are discussed later in this chapter. Careful attention should be paid to recreating the lateral inframammary fold with quilting sutures to prevent loss of definition at this site. This maneuver should be performed with the patient in the erect position to evaluate the effect of gravity on the final shape of the reconstruction.

36.10 Bipedicled TRAM Flap

The bipedicled TRAM flap is potentially indicated in:

1. Large-volume reconstruction
2. Patients with midline abdominal incisions
3. Smokers
4. Obesity
5. Patients with radiation injury to one pedicle

Most of the above represent indications for free TRAM flap transfer in many surgeons' hands. Bipedicled flaps are robust and probably have a better blood supply than free TRAM flaps due to the conversion of zones II and IV to additional zones I and III, respectively. They allow for more reliable survival of a greater proportion of the flap at the expense of greater abdominal donor site muscle loss. While this impacts the patient's abdominal strength in the short term, longer-term function appears eminently compatible with activities of daily living. Flap complications are less, and the procedure enables the non-microsurgeon to safely perform TRAM flap breast reconstruction in higher-risk patients [31].

Preoperative preparation and positioning are similar to those outlined for the unipedicled procedure. Initial flap elevation is identical in that both sides of the flap are dissected to the lateral perforators. Medial dissection differs in that a tunnel must be fashioned down the linea alba between the two pedicles (Fig. 36.7). This leaves a fascial strip on either side of the linea for fascial closure. As two pedicles have to pass up onto the chest wall, a more generous tunnel has to be fashioned causing more initial bulging about which patients should be informed. Once the flap is elevated, it is passed onto the chest taking care to prevent compression of the pedicles within the tunnel. I use a dou-

ble-layer mesh closure routinely in bipedicled flap procedures. The Prolene mesh is sutured from linea semilunaris to linea semilunaris using 0-Prolene. Abdominal wall strength is almost certainly more compromised when compared with the unipedicled procedure [49, 50], and it should be performed with caution in the younger patient. In the Emory review of bipedicled patient results, flap complications and abdominal wall complications were no worse than with unipedicled flaps, and flap blood supply was predictably better given the dual blood supply [31]. Our large experience with bilateral and bipedicled flaps has confirmed our initial experience with this procedure as being safe and reliable with remarkably few complications considering the higher-risk patients in whom it is performed. The abdominal strength objections voiced by some surgeons do not appear to be as significant as initially thought, and patients cope remarkably well with activities of daily living. While it is true that strength is diminished significantly initially, particularly with respect to patients' ability to perform sit-ups, abdominal wall function improves with time, and a remarkable number of patients achieve little or no negative impact on activities of daily living. Hernia rates are not significantly higher with this procedure when compared with unipedicled TRAM flaps. These issues will be discussed at greater length in the outcomes section. It is an excellent option for the non-microsurgeon who performs large numbers of breast reconstructions in higher-risk patients or those patients requiring large-volume reconstructions (Fig. 36.8b).

36.11 Bilateral Unipedicled TRAM Flap Breast Reconstruction

Bilateral reconstruction using two unipedicled TRAM flaps follows an identical operative sequence to that described for the bipedicled procedure, the exception being that the skin island is split down the midline during the initial dissection creating two flaps of equal size (Fig. 36.9a, b). The flaps are transposed to the chest wall through ipsilateral tunnels to prevent possible compression and kinking through a common central tunnel. Flap rotation on the chest wall is typically 90°. Abdominal closure is identical to that for the bipedicled TRAM flap.

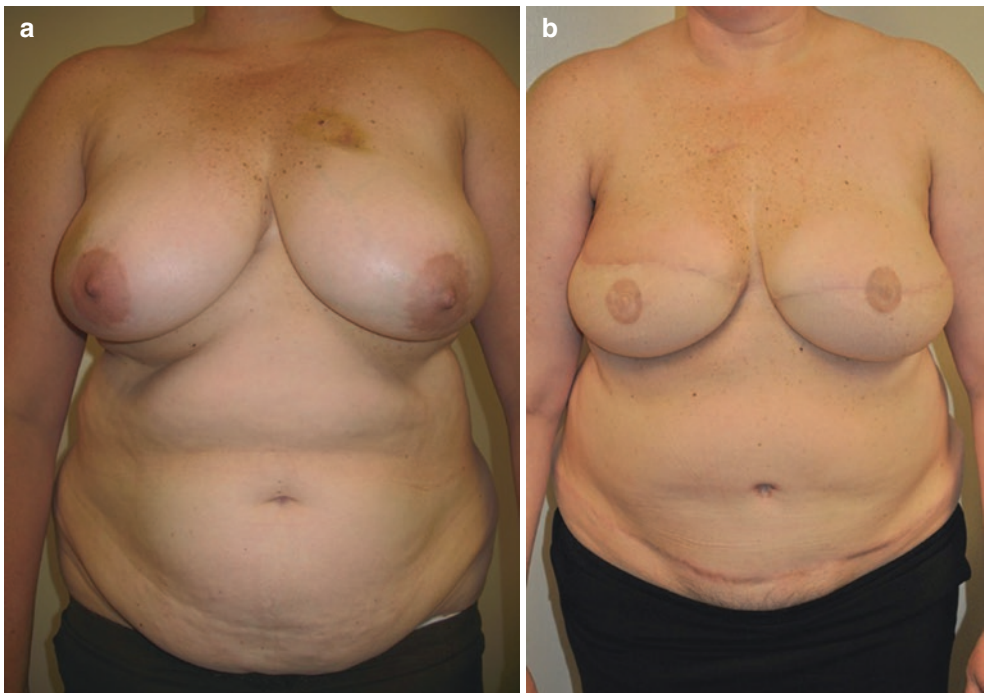

Fig. 36.9 (**a**) Preop view of obese patient requiring bilateral mastectomies and autologous reconstruction for breast cancer. (**b**) 1-year postoperative result after bilateral ipsilateral unipedicled TRAM flaps

36.12 Intraoperative Volume Assessment

During immediate reconstruction, the mastectomy specimen can be weighed off the surgical field. The problem becomes how to determine the volume of the TRAM flap available to achieve a match for the contralateral breast. Wagner devised a formula to calculate flap volume, $L \times W \times T \times 0.81 = V$ where L, W, and T represent the length, width, and thickness, respectively, of the TRAM flap [50]. Hudson has suggested the use of a simple hanging balance gas sterilized for intraoperative measurement of flap weight rather than volume [51]. Volumetric assessment by the hand is a simple but crude and somewhat inaccurate alternative.

36.13 Dealing with the Old Mastectomy Scar

The previous mastectomy scar, whether radiated or not, poses significant technical problems. If incised and used as the inset for the TRAM flap, its tight horizontal contraction tends to act as a band across the upper pole of the reconstruction, creating a linear groove. If this occurs, the scar should be excised completely, and a lateral modified Z-plasty should be created to soften the contour of the inset**.** The procedure is more of an oblique back-cut than a true Z-plasty, allowing a tongue of the TRAM flap skin island to angle up toward the axilla.

36.14 Flap Shaping and Positioning in Delayed TRAM Flap Reconstruction

The tip of zone I and all of zone IV should be discarded unless their blood supply appears unusually good. Many surgeons work primarily with ipsilateral tissue only in an effort to reduce fat necrosis. Flap orientation exerts a major influence on shape and symmetry. Secondary shaping is always feasible and often necessary [52], but time spent shaping the flap at the initial procedure is well spent, and it is possible to achieve excellent shape and symmetry at this first stage when adjustments are made most easily [33, 53–55]. The most common orientations used by the author are a transverse lie with a 180° rotation or an oblique orientation with a 120° or 80° rotation. Generally, it is preferable to place as much volume inferiorly in order to maximize projection and natural shape.

36.15 Donor Site Closure

Donor site closure is critical to the successful completion of TRAM flap breast reconstruction. A few words on donor closure are pertinent. Sheath closure should always incorporate both the internal and external oblique fascial layers to limit the risk of hernia formation. A deep layer of either running or interrupted #1Prolene suture followed by a second layer of running #1PDS suture is commonly used. Closure with double figure-of-8 #1Prolene interrupted sutures provides an extremely powerful closure with a built-in pulley-like

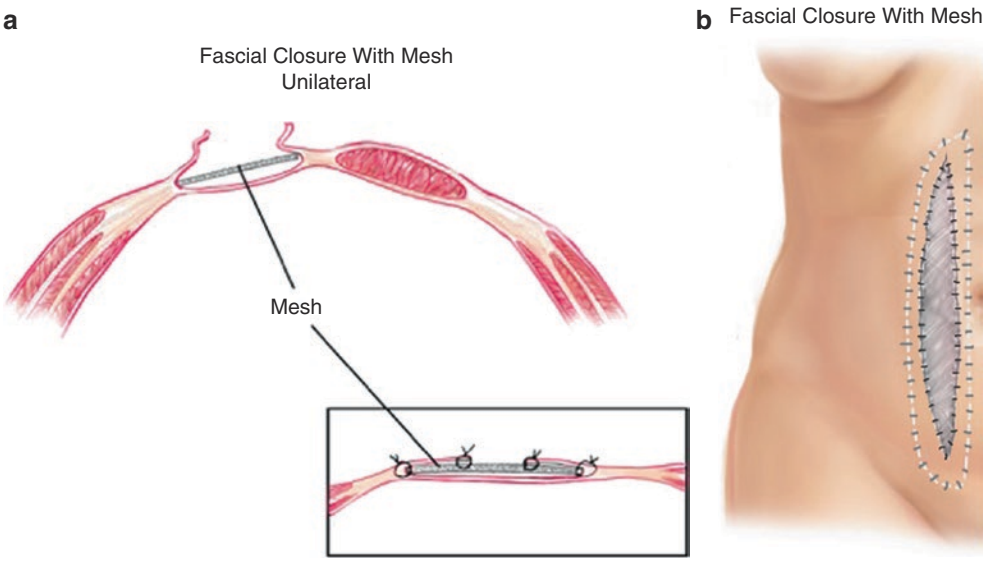

Fig. 36.10 (**a**) Unilateral mesh insertion within rectus sheath, (**b**) final anterior sheath overlay onto mesh inlay

mechanism to reduce fascial tearing as the fascia is closed. This is reinforced with a running #1PDS layer secondarily. Contralateral vertical sheath plication to centralize the umbilicus in unilateral pedicled flaps is unnecessary; if anything it simply raises intra-abdominal pressure unnecessarily and does little to move the umbilicus centrally. The skin pannus is defatted around the umbilicus inset, which the author prefers to reconstruct using the Avelar umbilicoplasty. Mesh should be used if there is extensive tearing of weak fascial components during closure or if tension seems high. If it is required, I use an inlay technique, suturing the mesh to the linea semilunaris internally within the sheath laterally and medially to the linea alba (Fig. 36.10a, b). The overlying anterior sheath leaflets are then sewn over the top of the mesh to cover about 50–60% of its surface area. Bucky describes excellent results with extensive inlay resulting in attractive abdominal contouring [48].

36.16 Timing of Nipple Reconstruction

It has been our policy to wait 6–8 weeks before performing nipple reconstruction. This allows the flap to settle under the influence of gravity, allowing nipple placement to be more accurately assessed. A C-V flap or modified skate flap is used for nipple reconstruction, creating a nipple some 50% longer than required, as atrophy will cause further slight loss of projection with time. In an effort to maintain nipple projection, I place the reconstructed nipple's free edge on a shelf of de-epithelialized adjacent TRAM flap skin to prevent the nipple from falling back into the donor site. Tattooing is usually performed 6–8 weeks later to minimize the effect of tattoo-induced atrophy of the nipple**.** Immediate nipple reconstruction has been advocated by some and is certainly more cost-effective than staged procedures [56]. The difficulty with using this approach is that settling of the TRAM flap may result in an incorrectly placed nipple reconstruction. The use of a traditional skate flap with surrounding skin graft unquestionably provides the best long-term projection in the author's opinion, but its requirement for a skin graft detracts from its value [57].

36.17 Secondary Shaping and Contralateral Breast Surgery for Symmetry

Secondary shaping is usually not necessary if careful attention to flap shaping and symmetry has been taken at the initial operation. Where possible, it is preferable to match the reconstruction to the unoperated contralateral breast unless this breast is in need of reduction or mastopexy at the patient's request. If secondary shaping is necessary, I prefer to perform it at the time of nipple reconstruction [52]. Careful contouring with 3–4 mm cannulae will help define blunted inframammary folds or lateral breast creases and effectively reduces minor contour defects produced by overfilling with excess flap bulk. Contralateral reduction, mastopexy, or augmentation will be necessary in some patients and can be performed either at the initial operation or subsequently at the time of nipple reconstruction.

36.18 Complications and Outcome Studies in TRAM Flap Reconstruction

The major complications of delayed TRAM flap reconstruction include scarring, skin and fat necrosis, flap loss, hernia formation, deep venous thrombosis, asymmetry, abdominal

tightness, and the psychosexual issues associated with breast reconstruction.

36.19 Skin and Fat Necrosis

Some degree of fat necrosis is common in any TRAM flap reconstruction whether free or pedicled. It should be less prevalent in free tissue transfers. The problem in assessing the available data is that authors differ in their estimate of "clinically significant" fat necrosis. Furthermore, many perforator flap surgeons only use ipsilateral tissue and discard any cross midline tissue. In our series at the Emory Clinic, we used a definition of 10% or more of the flap surface containing palpable firmness and included cross midline tissue in most of our reconstructions. This definition yielded a "significant fat necrosis" rate of 10.6% [32]. Risk factors associated with fat necrosis included prior radiation ($p < 0.001$), abdominal scarring ($p < 0.01$), and obesity ($p < 0.02$). Two or more risk factors increased the fat necrosis rate to 24.7% compared with 8.3% in patients without risk factors ($p < 0.002$). Patients with multiple risk factors having bipedicled flaps did not have an increased risk for fat necrosis suggesting that the bipedicled procedure eliminated the impact of the risk factors by boosting flap blood supply. Our review of bilateral unipedicled TRAM flap reconstructions demonstrated no increased risk of fat necrosis or flap loss among bilateral patients [31]. Bilateral procedures showed a very slight increase in general complications such as atelectasis. Abdominal complications were not increased significantly. Kroll compared clinical and radiologic evidence of fat necrosis between 49 free and 67 pedicled TRAM flaps. The size of the lesions was not clear but all lesions were visible mammographically. Predictably, free TRAM flaps demonstrated an 8.2% incidence of detectable fat necrosis compared with 26.9% in pedicled TRAM flaps ($p < 0.01$). While fat necrosis was more common in obese patients and smokers, this did not attain statistical significance [58]. Elliott confirmed similar findings for their series of patients, but in all of these studies, measurement of the amount of fat necrosis has been very subjective [59].

Radiation impacts TRAM flaps causing both fibrosis and fat necrosis. In 1997, Williams reported the Emory experience with radiation administered either before or after TRAM flap reconstruction. Fibrosis within the reconstruction was found in 31.6% of radiated TRAM flaps but not in patients who received preoperative therapy. Fat necrosis was similar in both radiated groups at 17.6% and 10% in the nonradiated patients. Not surprisingly, obesity further compounded fat necrosis rates when coupled with radiation therapy [42]. Rogers found a similar trend when free deep inferior epigastric perforator flaps were exposed to postoperative radiation [60]. By contrast, Zimmerman reviewed 21 patients with free TRAM flap reconstruction and claimed little negative impact in the majority of patients [61]. The question of whether or not it is worthwhile performing a microsurgical turbocharged anastomosis to reduce fat necrosis has been addressed in a small series of patients by El-Mrakby [62]. Turbocharged pedicled flaps had almost twice the rate of fat necrosis of free flaps although the fact that these patients required turbocharging suggests sample bias. Their conclusion is that free flaps are superior to turbocharged pedicled flaps.

36.20 Abdominal Wall Strength and Contour After Pedicled TRAM Flaps

There has been considerable debate about the impact of pedicled versus free TRAM and DIEP flaps on abdominal wall function. It would seem intuitive that a free flap would have far less impact on abdominal wall function than pedicled flaps with bipedicled flaps demonstrating the worst outcome. In practice, this is not strictly true, particularly when activities of daily living are evaluated by the patients themselves. It appears that there is considerable recruitment of adjacent muscle power, and this tends to improve with time. Furthermore, it appears that even with free flap harvest, the residual rectus muscle tends to atrophy significantly and hernia rates are not that much less than with pedicled flaps. Hartrampf [11] reported a 1.5% hernia rate in 351 unipedicled TRAM flap reconstructions, while the Emory group reported a hernia rate of 8.8%, a figure strongly skewed by one surgeon's use of small inlay mesh repairs; this figure has since been reduced to approximately 3.9% [31, 32]. This is similar to the data presented by Petit from Milan reporting 251 TRAM flap reconstructions with a hernia rate averaging 7% now reduced to 2% [63, 64]. Paige's review of the Emory experience with 257 bilateral versus unilateral pedicled reconstructions over a 7-year period revealed no significant difference between the two groups in terms of abdominal morbidity. In a review of 268 patients who had undergone either free TRAM (FTRAM) or conventional pedicled TRAM (CTRAM) flap reconstructions at least 6 months before, Kroll found similar hernia rates whether unipedicled or bilateral flaps were harvested (3.8% vs. 2.6%, not statistically significant). Single pedicle free TRAM flap patients were more likely to perform sit-ups than conventional unipedicled flaps which in turn were more likely to be able to do sit-ups than bilateral free or bipedicled patients. The conclusion was that the abdominal hernia or bulge rate is independent of the type of TRAM flap used and the number of muscle pedicles harvested. By contrast, measured abdominal strength was affected by these factors as far out as 6 months postoperatively. Nahabedian evaluated 108 women with free TRAM flaps, 37 women with pedicled flaps, and 10 women

with DIEP flaps. Lower abdominal contour defects were far more common after bilateral free TRAM flaps than with DIEP flaps [65]. Blondeel found that free TRAM flaps impacted far more negatively on abdominal strength than did free DIEP flaps [66, 67], but even free DIEP flaps create abdominal weakness to some extent [68]. To further confound the issue, Suominen has performed several elegant studies to accurately measure abdominal strength and function up to 12 months postoperatively [23, 24, 69]. In a magnetic resonance imaging study of the residual rectus muscles left after free and pedicled flaps, the donor rectus muscle on the free flap side had atrophied by at least 25% when compared with the non-operated side, and fatty degeneration was significantly higher in the donor muscle. No hernias were detected in either group [24]. In another study by the same author, long-term follow-up of the pedicled and free TRAM flap groups was performed with a mean follow-up of 23 months. By this time, there were no significant differences in abdominal flexion/extension strengths between either group [23]. In a prospective study of 19 free versus 23 pedicled TRAM flap patients, Edsander-Nord assessed strength at 3, 6, and 12 months postoperatively. Apart from an initial transient decrease in strength (worse in pedicled than free flap patients), the strength differences resolved almost entirely by 12 months. What is interesting is that free TRAM flap patients experienced a greater incidence of lower abdominal bulging (82%) than their pedicled counterparts at 48% [70]. In a meta-analysis of previously published data, Reece and Kroll attempted to collate the evidence concerning abdominal wall morbidity after TRAM flap reconstruction. The data is interesting, but firm conclusions are difficult to arrive at given the widely disparate data collected [30]. In conclusion, it appears that the more muscle one harvests, the greater the initial impact on abdominal strength. As time progresses, pedicled and free TRAM flap patients develop very similar functional outcomes with little impact on the activities of daily living. Abdominal bulge and hernia rates appear to be independent of the type of flap harvested and may relate to the care with which repair has been undertaken as well as the quality of the fascia to be repaired. The exact mechanism for these observed differences has yet to be explained satisfactorily.

36.21 Total and Partial Flap Loss

While complete flap loss is extremely rare in pedicled TRAM flap reconstruction (2 of 350 unipedicled and 0 of 39 bipedicled TRAM flaps in Hartrampf's series) [11], partial flap loss is more common. Hartrampf reported an 8.5% incidence in his series, while Kroll reported a 15.4% incidence in slim patients increasing to 41.7% in obese patients [71]. Elliott reported a 10% incidence in a series of 128 cases of unipedicled TRAM flaps [59], and Trabulsy noted a 6% incidence of partial flap loss and 4% complete flap loss in their series of 99 patients [1]. By comparison, Chang reporting on over 700 free TRAM flap breast reconstructions found total flap loss in 5.1% with a 6.2% partial flap loss [72]. This pushes total flap necrosis-related complications to over 11% in a center of excellence. These figures should be borne in mind when occasional microsurgeons are tempted to embark on complex free flap procedures in higher-risk patients. Given the high patient satisfaction with pedicled TRAM flaps compared with DIEP flaps [73], this may also explain why many surgeons who are comfortable with microsurgery are reluctant to convert to performing free TRAM or DIEP flaps routinely in their practices, given the time and cost restraints of these complex procedures.

36.22 The Impact of Obesity on TRAM Flap Viability

The most comprehensive study to date detailing the impact of obesity on human flap viability is that presented by Chang et al. [72]. In this study alluded to above, free TRAM flap results were evaluated based on the patient's body mass. Normal-weight patients ($n = 442$) had no total flap losses and a 1.6% partial flap necrosis rate. Overweight patients ($n = 212$) experienced 1.9% total flap loss with a 1.4% partial flap necrosis rate. By contrast, 64 obese patients had a 3.2% total flap necrosis rate and 3.2% partial flap necrosis. Fat necrosis rates were 6.1% in normal patients, 9% in the overweight group, and 7.8% in the obese category. Abdominal bulges were three times more common in overweight patients compared with normal, and seromas were ten times more common in obese patients. In the Emory University study of 556 patients, obesity correlated with both fat necrosis and general complications at the $p < 0.02$ level [32].

36.23 Smoking and TRAM Flap Viability

Watterson's study demonstrated a significant correlation between smoking and general complications ($p < 0.002$), but interestingly smoking did not correlate strongly with fat necrosis [32]. Hartrampf accorded heavy smoking a moderate risk in his scoring system for TRAM flap patient selection criteria [11]. Chang found a significant risk for both the reconstruction and the donor site in smokers compared with non-smokers, with those having more than a ten-pack-year history faring worse than those with shorter histories. Former smokers and non-smokers had similar complication rates [72]. In another study, Padubidri found overall complications to be greater in smokers at 39.4% versus 25% in ex-smokers and non-smokers [74].

36.24 The Timing of Reconstruction in Relation to Radiation Therapy

In the past, radiation therapy had been reserved for those patients with more advanced breast cancers and more than three positive axillary lymph nodes. The publication of two papers, one from Denmark and the other from Canada, initiated a major swing toward treating early breast cancer patients with adjunctive radiation in an effort to improve survival [75, 76]. The result has been that more and more patients with TRAM flap reconstructions are now facing postoperative radiotherapy and then facing the consequences of radiation's impact on the flap. Add to this the dramatic impact of skin-sparing mastectomy on breast reconstruction and one can see what a dilemma the reconstructive surgeon now faces. Should the patient who faces radiotherapy in her future proceed with mastectomy first and then have delayed reconstruction, or should we go ahead with a skin-sparing mastectomy with all of its benefits, reconstruct the breast with a TRAM flap, and then proceed to radiation accepting its negative consequences? This dilemma is the subject of constant debate at national and international meetings. All of us who frequently perform TRAM flaps are aware of radiation's impact on these flaps, whether pedicled or free. TRAM flaps tolerate radiation better than expander-implant reconstructions and with fewer complications [77]. Williams reviewed the Emory experience with radiation and found it to increase fibrosis as well as fat necrosis depending on the timing of treatment in relation to surgery [78]. Flap loss was not increased per se, a finding corroborated by Kroll's review of 428 flaps (of 1384 free flaps total) transferred to previously radiated beds [79]. It was Kroll's belief that radiation significantly impacts the feel and shape of TRAM flaps when administered after reconstruction as evidenced by William's data. His conclusion was that patients in whom radiotherapy is likely post-mastectomy should complete their radiation and then proceed to TRAM flap reconstruction, forgoing the benefits of skin-sparing mastectomy and immediate reconstruction. In this manner, the final reconstruction may be spared the deleterious effects of radiation injury in the long term even though there is a greater likelihood that such patients may need free or bipedicled TRAM flap procedures. There is certainly merit in this argument given the possible prospect of fibrosis, distortion, and fat necrosis that may supervene in a radiated TRAM flap.

36.25 Pregnancy Following Pedicled TRAM Flaps

Despite the loss of muscle function after pedicled TRAM flap harvest, it is still possible for patients to conceive and carry a pregnancy to term as well as achieve normal vaginal delivery [80]. Johnson described the successful vaginal delivery of monozygotic twins after bilateral pedicled TRAM flap reconstruction [81] indicating that patients can be reassured that their abdomens will in all likelihood perform satisfactorily even under the considerable stress of twin pregnancy. Parodi cautions against patients becoming pregnant within 12 months after TRAM flap surgery, reporting a single case of a woman becoming pregnant at 4 months postoperatively and developing a hernia. She delivered vaginally at term [82].

36.26 Patient Satisfaction Outcomes

A patient's emotional outcome after breast reconstruction is unpredictable and highly individual [83]. Several factors influence the aesthetic outcome [84]. In a study of 125 women diagnosed with breast cancer, Keith found that 49.6% of his respondents desired breast reconstruction if available. Young women and depressed women favored reconstruction more than older patients. In Keith's study, marital status, tumor size, extrovertism, neuroticism, and tough-mindedness were not independently predictive of the desire for reconstruction [85]. Of patients requesting reconstruction, 63% were concerned that reconstruction might mask recurrence, but 94% felt that it would greatly benefit their self-esteem. Age does not appear to be a significant risk factor for pedicled TRAM flap usage as evidenced by a study of 84 patients aged 65 years or older in whom successful reconstruction was achieved [86]. In another study evaluating patient acceptance of the procedure, Nissen found that while women were highly satisfied with their reconstruction, their greatest anxiety remained the fear of recurrence as well as a desire to be as informed as possible about complications and recovery [87]. This was reinforced in a study by Tykka who found most women were highly satisfied with their TRAM flap reconstructions, all of which in this study had been performed to replace inconvenient bra prostheses [88]. The patients were particularly pleased with the autologous nature of the reconstructions but had been surprised by the extent of the surgery and length of the recovery process. This highlights the importance of warning patients that recovery will take a minimum of 3 months before patients start to feel as if life is returning to normal once more. It appears that patients are more accepting of the quality of their reconstruction than are their surgeons as evidenced by a study of 20 patients whose level of satisfaction was much higher than that of their surgeons [89]. In another study of 60 inner city women undergoing breast reconstruction, demographic studies failed to show any differences in education, economic status, or insurance status in women undergoing reconstruction. In this study, reconstructed women had a higher satisfaction with their sex lives and body image than did non-reconstructed women [90]. While these trends are culled from relatively

small patient populations, it is apparent that breast reconstruction can be an immensely satisfying procedure for both patient and surgeon and can have a positive impact on a patient's daily life and convenience.

Conclusion

Pedicled TRAM flap breast reconstruction remains a common choice for autologous reconstruction and is readily learned by any competent surgeon. It provides excellent contour and softness in most patients and abdominal complications are few. Given the potential for free flap failure and the added cost involved in additional operating time for microsurgical procedures [91], pedicled TRAM flaps remain the most cost-effective method of autologous breast reconstruction in most surgeons' hands [91]. Although TRAM flap reconstruction is a major operative procedure, it provides both patient and surgeon with a unique tool to achieve a natural, soft, warm, well-integrated reconstruction after mastectomy.

Acknowledgment The author wishes to acknowledge the contribution of Bill Winn, a medical illustrator, without whose help this manuscript would not have been possible.

Breast Reconstruction with Free Flaps

37

Fabio Santanelli di Pompeo, Benedetto Longo, and Rosaria Laporta

37.1 Introduction

In 1973, Taylor and Daniel used the term "free flap" to describe the distant transfer of an island flap by microvascular anastomosis [1, 2]. They also carried out a detailed anatomical description of many of the more common free flap donor sites still in use to date [3].

The modern era of autologous breast reconstruction began with the free abdominoplasty flap introduced by Holmström in 1979 [4] and with the transverse rectus abdominis myocutaneous (TRAM) flap by Hartrampf in the early 1980s [5]. Both used the common pedicle flap concept to transfer autologous tissue from the abdomen to the chest wall for breast reconstruction using the inferior epigastric artery for the former and the superior epigastric artery for the latter with the rectus abdominis muscle as a carrier [4, 5].

Because of the complications correlated with the use of transverse rectus abdominis muscle such as abdominal wall weakness, abdominal bulging, frank herniation, and abdominal and lumbar back pain, the concept of donor-site muscle-sparing techniques was then embarked upon. On this basis Koshima used the skin territory overlying the rectus abdominis muscle to reconstruct head and neck defects [6]. The flaps were based on a single paraumbilical perforator vessel from the deep inferior epigastric artery. The perforator vessels were dissected meticulously leaving an intact rectus abdominis muscle and followed toward the deep inferior epigastric vessels to achieve adequate pedicle length. The resulting flap was thin, composed only by the skin and the vascular pedicle. The goal of muscle preservation became more apparent, and the next significant step was related to the work on perforator flap of the authors' group at Louisiana State University Medical Center. They injected fresh abdominoplasty specimens assessing that the skin and fat could be transferred without the use of the rectus abdominis muscle. This led to the realization of the first deep inferior epigastric perforator (DIEP) flap for breast reconstruction by Allen in 1992 [7]. By the use of this original procedure, 15 breasts were successfully reconstructed offering the same benefits as the TRAM flap but reducing the abdominal wall morbidity. The beginning of free tissue transfer allowed an infinite range of possibilities to appropriately match donor and recipient sites.

It is known that the type and timing of reconstruction is a multifactorial decision. It is based on the size and shape of the native's breast, location and type of cancer, patient's characteristic, patient's expectations whether adjuvant radiation and/or chemotherapy are needed, and the surgeon's preferences and skills. The commonly used autologous tissue flaps for breast reconstruction are free TRAM (muscle sparing) flap, DIEP flap, superior gluteal artery perforator (SGAP) flap, inferior gluteal artery perforator (IGAP) flap, transverse upper gracilis (TUG) flap, and superficial inferior epigastric artery (SIEA) flap. The alternative flaps, e.g., Ruben's flap (DCIA), anterolateral thigh (ALT) flap, and transverse fascia lata (TFL) flap, are occasionally used for breast reconstruction.

37.2 Free Flaps from Abdomen

37.2.1 Free TRAM Flap

The skin paddle of the TRAM flap is drawn between the umbilicus and pubic region and from the front of the iliac bone. Both deep superior and inferior epigastric vessels supply the muscle, while the skin and fat tissue are vascularized by perforators through the rectus abdominis muscle. The flap can be harvested either in a free microvascular or in a pedicled form. In the pedicled form, the caudal portion of the muscle is detached. Still left connected to the rest of the muscle, the flap is moved under the skin up to the mastectomy

site to reconstruct the breast. The modern free TRAM as "free abdominoplasty flap" for breast reconstruction was described first by Holmström in 1979 [4]. As a free microvascular flap, the TRAM flap is harvested with a small cuff of the rectus abdominis muscle and brought to the mastectomy site reestablishing the blood supply by microsurgical anastomoses between the deep inferior epigastric pedicle and the scapular circumflex vessels. Based on the amount of rectus abdominis muscle spared [8], the free TRAM is classified into four types: in MS0, full width (partial length) of the rectus abdominis muscle is harvested; in MS-1, lateral segment is preserved and as a result the innervated lateral rectus muscle is left intact. The middle/medial rectus muscle just enough to support the perforators with a narrow strip of anterior sheath is harvested with the flap. In MS-2, lateral and medial segment is preserved, while MS-3 is equivalent to DIEP flap because the entire muscle is left attached. The abdominal complications are significantly reduced with this technique compared to the pedicled TRAM flap as both the lateral innervated muscle and rectus sheath are preserved. Compared to the pedicled TRAM flap, reconstruction of breasts with the free TRAM flap offers a lower complication rate at the mastectomy site and a low donor-site morbidity rate as reported by Kroll [9] even if the ability to do sit-up from supine position was best retained in free TRAM (63%), followed by pedicled TRAM (57%) and free bilateral TRAM (46.2%), and worse in pedicled bilateral TRAM.

In literature, a lot of studies reported the impact of free flap breast reconstruction on the abdominal wall in order to minimize donor-site morbidity [10–14].

The planning of the free TRAM flap is similar to the DIEP flap. All details are reported in the next subheading.

37.2.2 DIEP Flap

The flap harvesting includes the identification of at least one reliable perforator. The average pedicle length is 8–15 cm and diameter is 2–3.6 mm. The first step is to assess the amount of skin and subcutaneous adipose tissue that should be transferred from the abdomen to the mastectomy site to achieve symmetry in ptosis and volume with the opposite breast. A simple pinch test can help the surgeon to estimate the amount of excess tissue available for reconstruction. The use of a complementary device in surgeon evaluation such as the BREAST-V [15] can be useful to predict preoperatively the volume of the breast that has to be reconstructed. An app entitled BREAST-V for both iOS and Android devices is currently available for free download in the Apple Store and Google Play Store.

Preoperative markings are done with the patient in upright position. The general surgeon indicates the oncological planning and the breast skin area that has to be removed with the mammary gland. Plastic surgeon then can plan the DIEP flap harvest. Standard abdominoplasty markings are made in the sitting or standing position, while the flap markings included vascular zones I–III for unilateral and zones I–II for bilateral reconstructions according to Holm et al. [16]. The side of the abdomen contralateral to the side to be reconstructed is usually preferred as it allows simultaneous operating by two teams. The inferior incision is marked in the natural suprapubic crease and extended to the level of the anterior superior iliac spine (ASIS) on both sides, while the superior incision is made joining the two ASIS passing over the umbilicus. The umbilicus is first dissected and the superficial inferior epigastric vein is identified and preserved if significant in size. Depending on the type of mastectomy that should be performed, the flap can be de-epithelialized during this step as planned. Then the flap dissection starts in a lateral-to-medial direction above the deep fascia until the first reliable perforator of the lateral/medial row is visualized. The number of selected perforators depends on the perforator's position, vein diameter, and flap volume to be transferred. The superficial inferior epigastric vein can be preserved and included in the flap as an extra-venous outflow.

Rectus sheath is opened around the perforator to facilitate further dissection following its course until its origin. Only the part of the rectus abdominis muscle that is found among the vessel is sacrificed in order to identify and dissect the course of the deep inferior epigastric pedicle running under the muscle until its origin from the external iliac vessels. Care is taken to preserve any intercostal nerves innervating the medial aspect of the muscle that might cross the pedicle. The superior end of the pedicle is divided above the perforator, and the zone IV of the flap is discarded. Once the recipient vessels are ready, the inferior end of the pedicle is ligated. The flap is then weighed and transferred, rotated 180°, and fixed temporarily to the chest wall. Great care is taken for the flap pedicle position without any twists or kinks; both arterial and venous end-to-end anastomoses are performed, while a second team carries out donor-site closure. The anterior rectus sheath is repaired with interrupted 1-0 vicryl sutures, and the umbilicus is relocated at a level above the ASIS. The Scarpa's fascia is approximated with interrupted 2-0 vicryl sutures, while the abdominal skin is sutured in two layers. The abdominal wall is supported by an elastic band, and the patient is positioned on the bed in half-sitting position in the immediate postoperative period. Next, the flap insetting is completed while the contralateral procedure is performed if already planned (Figs. 37.1, 37.2, 37.3, 37.4, and 37.5).

Although good and long-term aesthetic outcomes can be obtained in unilateral DIEP flap reconstruction, contralateral procedures are often required to achieve breast symmetry. Stevenson and Goldstein compared TRAM flap and immediate contralateral breast reduction/mastopexy with TRAM flap alone observing a satisfactory aesthetic result [17]. Haykel and Gay reported a single-stage autologous reconstruction by the use of both pedicled flaps and free

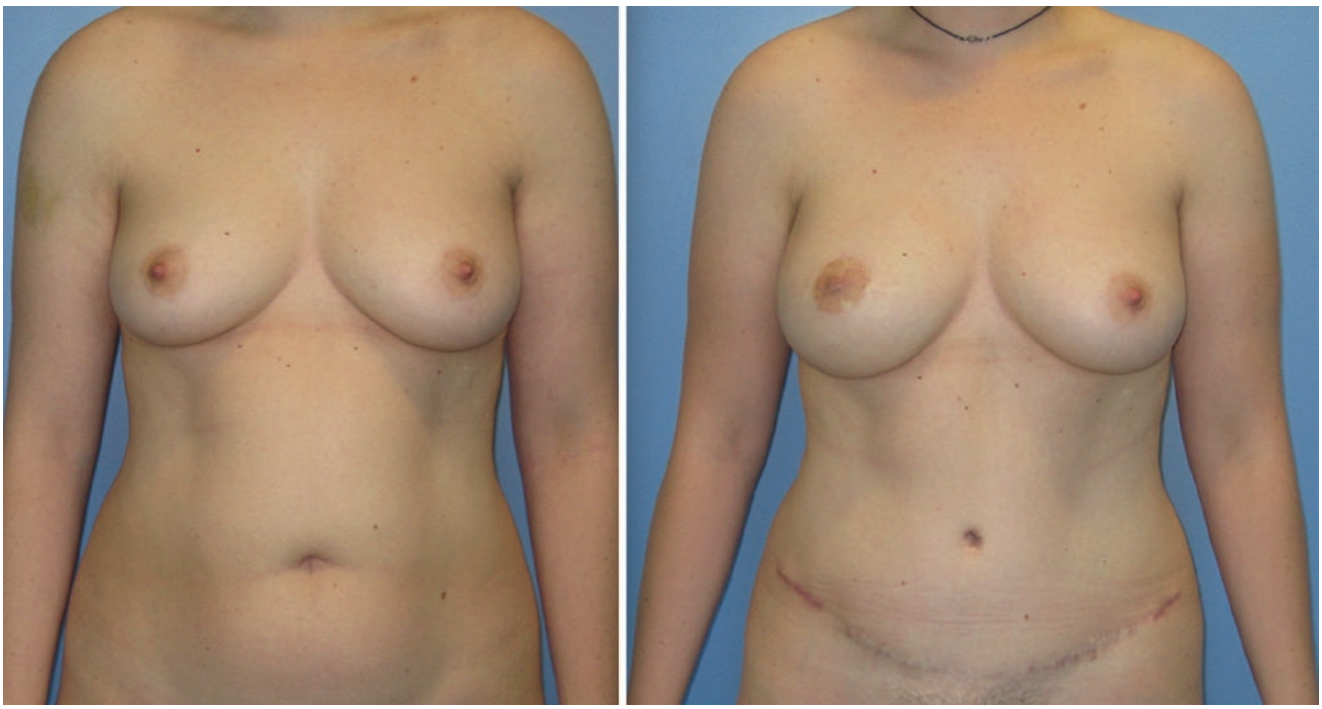

Fig. 37.1 A woman underwent immediate one-stage DIEP flap reconstruction following right nipple-sparing mastectomy. Preoperative (*left*) and postoperative (*right*) frontal view

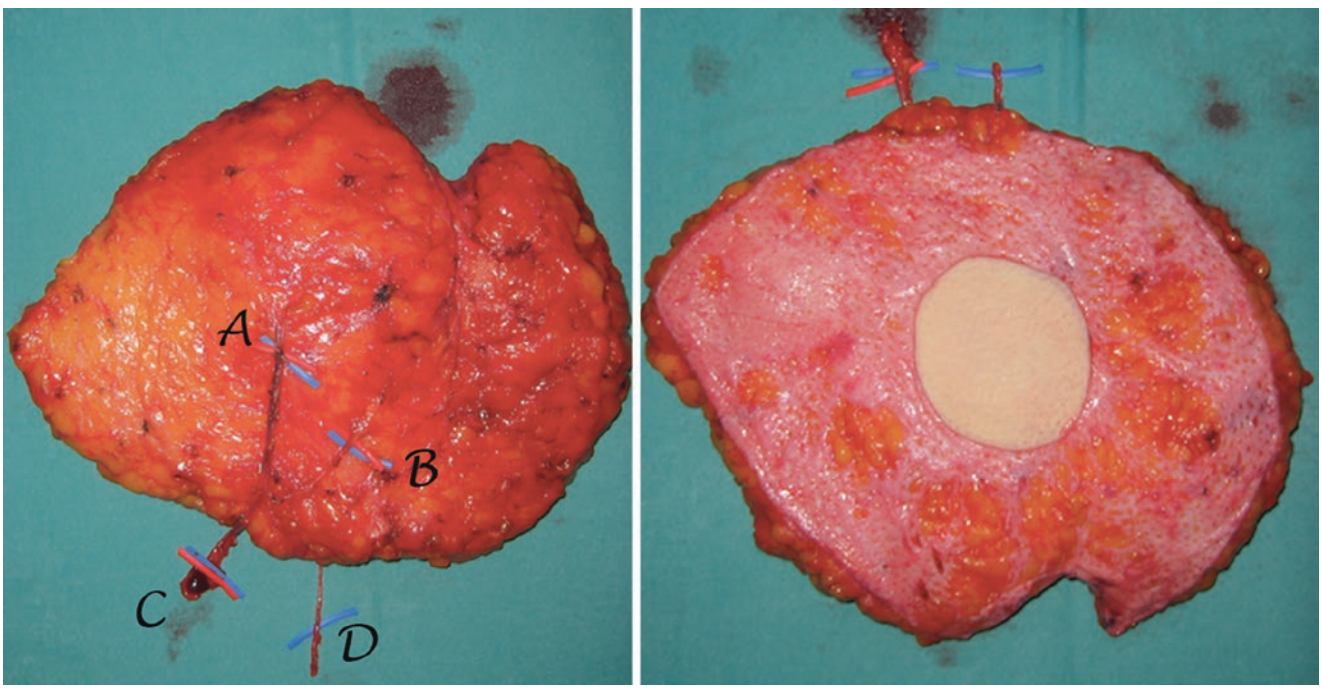

Fig. 37.2 Intraoperative DIEP flap. Posterior view (*left*) showing two perforators, superficial epigastric vein and deep inferior epigastric pedicle. Anterior view (*right*) showing sentinel skin island

flaps. They observed 11.3% of postoperative aesthetic complications in 141 patients by means of volume excess (5.7%), malposition (2.1%), volume loss due to weight loss (1.4%), shape asymmetry (1.4%), and volume deficiency (0.7%) [18].

Huang et al. observed greater patient satisfaction, minimal increase in operative time, and no increase in complication rates comparing clinical and aesthetic outcomes in immediate and staged contralateral surgery in DIEP and superficial inferior epigastric artery (SIEA) flap reconstruc-

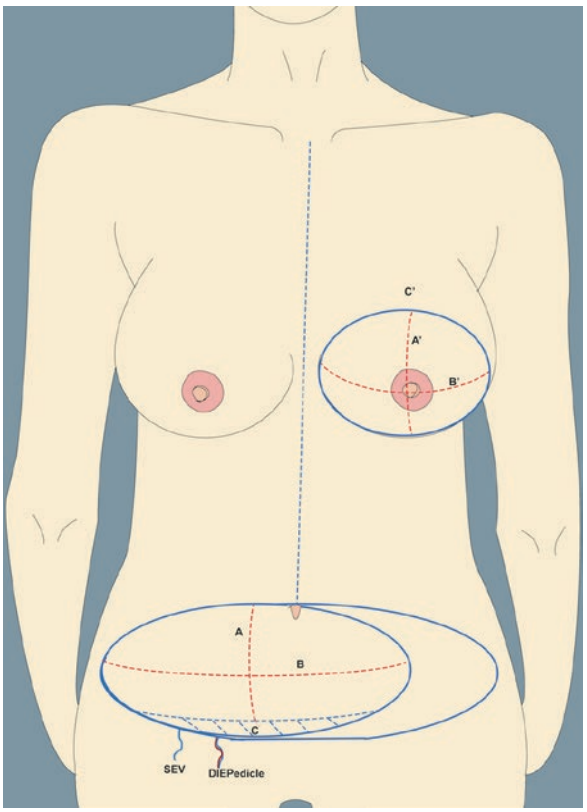

Fig. 37.3 DIEP flap breast reconstruction planning. Modified radical mastectomy is drawn on the affected breast (A = vertical axis, B = horizontal axis). tion [19]. One-stage DIEP flap reconstruction by means of the symmetrization algorithm was also described resulting in comparable aesthetic outcomes and patient satisfaction to a staged procedure [20].

37.2.2.1 Recipient Vessel Selection

The choice of recipient vessels is one of the key points in microvascular breast reconstruction, and it is largely up to the reconstructive surgeon and usually based on comfort level and experience, flow characteristics, chest topography, and patient comorbidities. In the recent literature, there is no unanimously agreed upon recipient sites for anastomoses. Both internal mammary vessels (IMV) and axillary vessels such as thoracodorsal (TDV) and circumflex scapular vessels (CSV) are usually easy to expose and of suitable caliber, allow an end-to-end anastomosis, and have demonstrated advantages and disadvantages in this setting. Some surgeons advocate the use of IMV as recipient vessels of choice [21–24], while others observed unpredictable quality and inconsistency of the internal mammary vein diameter at the level of the fourth rib, difficult anastomosis due to respiratory movements, risk of pneumothorax, and contour deformity due to rib cartilage excision [24]. Time for vessels' dissection and exposure in immediate reconstruction represents an issue in favor of the axillary vessels. The general surgeon following the lymphadenectomy or sentinel lymph node biopsy performs the preparation of these vessels, while the access to the IMV usually needs an extra "step" [25].

Previous reports have demonstrated that the flow rate of the flap is correlated to its size and therefore its flow rate is

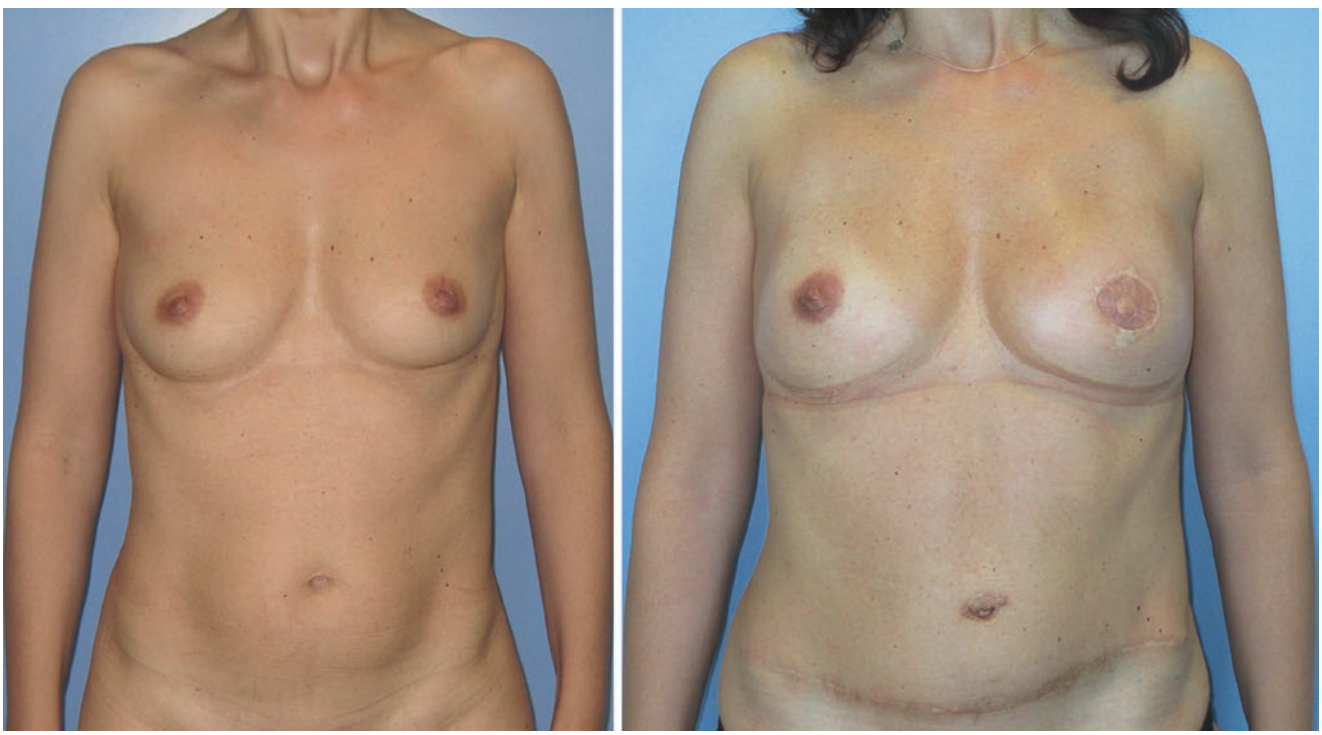

Fig. 37.4 A woman underwent immediate bilateral one-stage DIEP flap reconstruction following right nipple-sparing mastectomy and left skin-sparing mastectomy. Preoperative (*left*) and postoperative (*right*) frontal view

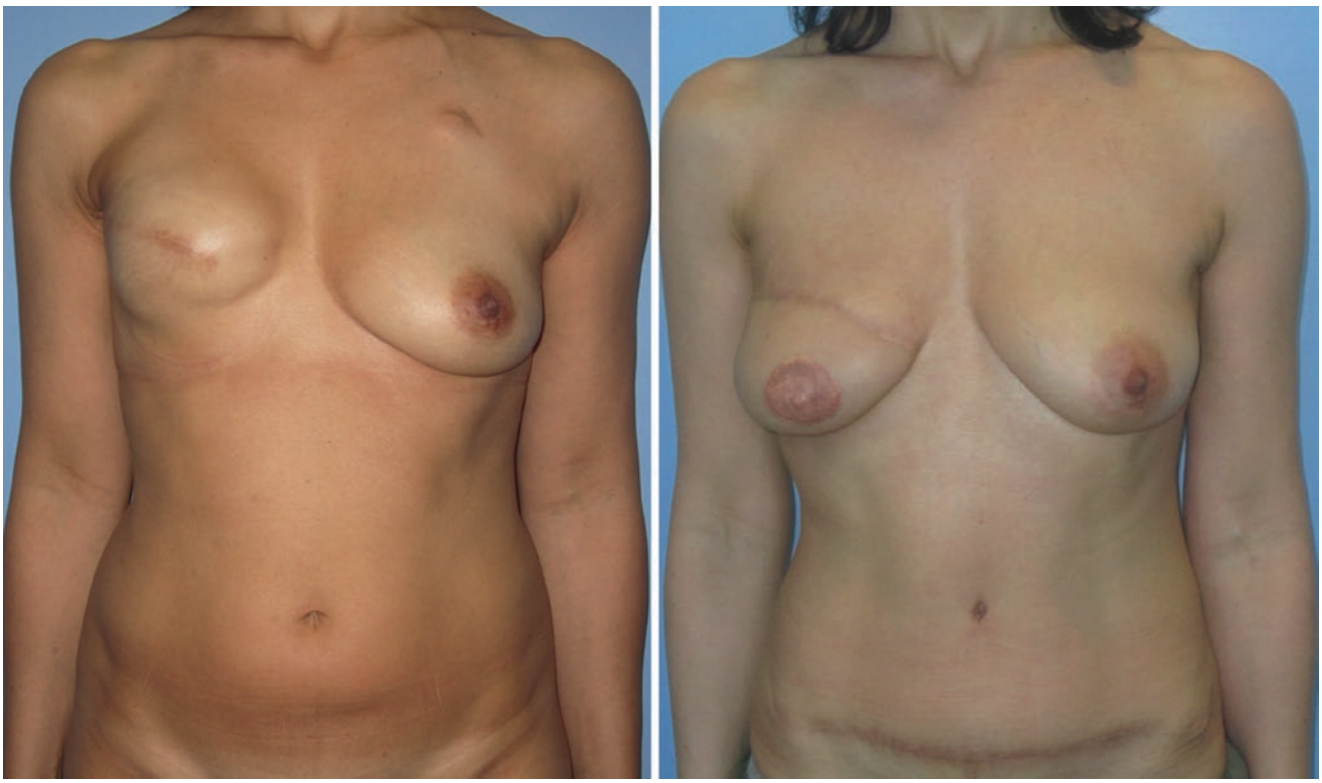

Fig. 37.5 A woman underwent secondary DIEP flap breast reconstruction after right modified radical mastectomy and failed reconstruction with breast expander. Preoperative (*left*) and postoperative (*right*) frontal view

correlated to its venous drainage [26, 27]. Adding veins in parallel and choosing veins with larger diameter can increase drainage from the flap and reduce risk of venous congestion. Both axillary and IMV have adequate negative vein pressure and drainage, but using IMV the main drawback is the difficulty to have two veins of adequate size and length compared to TDV and CSV [27, 28].

The perforators arising from the internal mammary vessels have also been used as recipient vessels avoiding many of the complications related to the use of IMV, but unfortunately their presence depends on anatomical variability and preservation by the general surgeon [29]. The absence of a proper and careful preoperative planning may cause an increased operative time and/or surgical errors.

We prefer the use of the CSV as a recipient pedicle [28]. Majority of our cases involve immediate breast reconstruction where the axillary vessels are already exposed during lymph node dissection. From our experience, vascular anastomosis, re-exploration, and revision are technically easier in the axilla. Complications such hematoma can be quickly identified and managed easily in the axilla. Moreover the use of CSV saves TDV pedicle to assure the viability of a myocutaneous latissimus dorsi flap, useful for salvage procedure in case of previous reconstruction failure. Furthermore, despite the possibility of accidental TDV injury by the general surgeon during lymph node dissection or radiotherapy damage in delayed reconstructions, the anatomical location of the CSV make it unlike for CSV [23, 30] as they are located in the omotricipital space and not embedded in scar tissue neither their lumen is never reduced nor weakened.

37.2.3 SIEA Flap

The procedure is similar to the DIEP flap, but the SIEA flap is harvested on the superficial inferior epigastric vessels just below the skin surface avoiding injury to the anterior rectus abdominis fascia or the muscle. Grotting first described it for breast reconstruction in 1991 [31]. The SIEA artery is a direct cutaneous vessel that arises from the medial side of the common femoral artery as a common trunk with superficial circumflex iliac artery or, independently, approximately 2 cm below the inguinal ligament. It travels up and pierces the cribriform fascia supplying the subcutaneous tissue and skin of the lower abdomen. The artery is accompanied by venae comitantes, and an additional prominent vein runs 3–4 cm medially to the artery. As previously described, this vessel is very useful as a second vein anastomosis in DIEP flap reconstruction.

By the use of the SIEA flap, there is no risk of abdominal hernia or bulge. Indeed, there is the significant saving of operating time because the vessels run above the rectus sheath avoiding any tedious intramuscular vessel dissection. Nevertheless, its major drawbacks are the inconsistent vascular pedicle anatomy, the shorter (6–15 cm) and smaller

diameter (1.4 mm) vascular pedicle, and limited flap territory. The skin area supplied by the artery is 140 ± 100 cm^2 running in a curvilinear way, 5 cm above the iliac crest. The flap spreads from the anterior superior iliac spine to the lateral border of the rectus abdominis muscle and below the umbilicus to the pubic hairline [32, 33]. A well-vascularized flap includes the zones I and II (ipsilateral hemiabdomen), while zones III and IV (contralateral hemiabdomen) are not considered reliable. Blondeel observed the inverse relationship between superficial and deep inferior epigastric veins [34]. The superficial inferior epigastric vessels may be dissected and preserved if more than 1.5 mm in diameter as previously suggested, irrespective of DIEP, SIEA, or MS-1 TRAM [35, 36].

37.2.4 Abdominal Free Flaps and Prior Abdominal Surgery

Despite the relative contraindications due to the supposed extensive vascular interruption [5, 37, 38], free TRAM, DIEP, and SIEA flaps can be harvested safely by tailoring the flaps previous abdominal surgery such as appendicectomy, hysterectomy, low cesarean section, subcostal cholecystectomy, midline laparotomy, laparoscopy, and other laparoscopic scars. Hamdi et al. proposed their clinical approach to maximize the perfusion to the upper abdominal flap by either widening/lengthening or "augmenting" the supply of the upper flap (with perforator preservation). A bipedicled free flap is also suggested in order to obtain an adequate amount of tissue when the anatomical condition does not allow harvesting ample tissue using standard flap markings [39]. Depending on the location and type of the scars, available vascular pedicle, perforator locations, and required flap tissue for breast reconstruction, Laporta et al. also suggested three clinical approaches by the use of standard abdominoplasty markings to ensure well-vascularized flap and to minimize abdominal donor-site complication [40]. If the Pfannenstiel or laparoscopic (hysterectomy or other gynecological operations) scars damage or interrupt the deep inferior epigastric vessels, the length of the pedicle is too short to reach CSV; they suggest the use of the serratus anterior pedicle (SAP) as recipient vessels. In patients with midline laparotomy scars, a simple but effective strategy is to vertically split the infraumbilical tissue into two hemi-DIEPs. To overcome the relative lack of volume, they propose a delayed fat graft session within 6 months after primary surgery. In all patients with a chevron or subcostal scars, the skin area caudal to the previous incisions is left attached to the periumbilical perforators.

In doubtful cases, a CT angiogram may be useful and can be arranged preoperatively to assess the status of perforators and the main vessels.

37.3 Free Flaps from Other Sites

In cases where abdominal tissue is not available for reconstruction, focus shifts on the gluteal or upper thigh region as donor sites. The SGAP, IGAP, TUG, and profunda artery perforator (PAP) flaps are usually considered flaps of second choice when abdominal tissue is not available. In a review of 31 cases of GAP by Granzow et al., 20 (65%) were performed due to inadequate abdominal tissue, 6 (19%) due to patients' donor-site choice, and 2 (8%) due to failed DIEP flaps [41].

37.3.1 SGAP Flap

The superior gluteal myocutaneous free flap for breast reconstruction was first described by Fujino in 1975 [42] and popularized by Shaw [43]. The main limitation of this flap is the short vascular pedicle, which frequently requires vein grafting, increasing the difficulty, complications, and the time required for this procedure. The SGAP flap for breast reconstruction was described by Allen et al. in 1993 [44]. Advantages of the gluteal artery perforator flaps versus the previous myocutaneous gluteal flaps include the preservation of the gluteus maximus muscle and additional length of the pedicle without the use of vein grafts for anastomosis.

The superior gluteal artery (SGA) is a continuation of the posterior division of the internal iliac vessel. It is a relatively short artery (6–8 cm) and emanates from the pelvis above the upper border of the piriformis muscle, where it immediately divides into both superficial and deep branches. The deep branch travels between the gluteus medius muscle and the iliac bone, while the superficial branch supplies the upper portion of the gluteus muscle and overlying fat and skin.

With the hip slightly flexed and rotated inward, a line is drawn from the posterior superior iliac spine to the posterior superior angle of the greater trochanter. The point of emergence of the superior gluteal corresponds to the junction of the upper and middle thirds of this line. An average of four perforators is usually found from the superior branch of the SGA to supply the skin.

The skin paddle can be designed as an oblique ellipse or horizontally producing a more favorable scar keeping the marked perforator in the center. The average flap height and length are 8 cm (range 5–12 cm) and 22 cm (range up to 30 cm). It should be noted that perforators located laterally would produce longer pedicles. The whole flap can be raised on single perforator and the donor site is closed primarily.

In unilateral cases, the patient is positioned in the lateral decubitus in order to perform mastectomy, recipient vessel

dissection, and the flap harvest simultaneously. If a bilateral procedure is scheduled in the primary setting, the patient is placed first supine during the mastectomy and exposure of the recipient vessels. Then, prone positioning, flap harvesting, and closure of both buttocks follow this dissection. The patient is returned in supine position and redraped in order to complete the anastomosis in this setting. The flap is elevated from the muscle in the subfascial plane, and the perforator's dissection starts from lateral to medial. It is preferred to use a single large perforator, if present, but two perforators in the same plane and direction of the gluteus maximus muscle fibers can be taken together as well. The muscle is then spread in the direction of the muscle fibers, and the perforators are followed through the muscle. The dissection continues until both the artery and the vein are of sufficient size to be anastomosed to the recipient vessels in the chest wall.

37.3.2 IGAP Flap

Higgins et al. subsequently introduced the IGAP flap for ischial pressure sore reconstruction in 2002 [45], while Guerra et al. introduced it for breast reconstruction in 2004 [46]. This flap uses the excess lower buttock tissue and preserves the muscle leaving the scar in the natural depression of the inferior gluteal crease. Its use is not widespread, and in literature, there are few articles encouraging this procedure for breast reconstruction [47, 48].

Inferior gluteal artery is the terminal branch of the anterior division of internal iliac artery and emerges through greater sciatic foramen below the piriformis muscle, with sciatic nerve and posterior cutaneous nerve of the thigh. The course of the vessel is more oblique providing a longer pedicle than the SGAP flap.

The gluteal crease is marked with the patient in the standing position. The flap is drawn as a horizontal ellipse with the major axis centered above the gluteal crease and the inferior incision located 2 cm inferior to it. The orientation of the skin paddle is usually parallel to the gluteal fold.

A second line is drawn from the posterior superior iliac spine to the outer part of the ischial tuberosity; the junction of the lower and middle third marks the point of emergence of the inferior gluteal arteries.

The dimensions of the flap usually are typically 8 cm (maximum 12 cm) in length and 18 cm (maximum 30 cm) in width. Flap dissection and patient positioning on operating table is similar to SGAP flap planning. Care must be taken to avoid injury to the posterior femoral cutaneous nerve of the thigh that travels with the inferior gluteal vessels. The sciatic nerve is never visualized because of the subfascial dissection. In small-breasted patients and large buttocks, the IGAP flap can give an excellent result, particularly with secondary liposuction of the lateral thighs. Nevertheless, if a unilateral small IGAP flap is harvested in a thin patient, buttock projection and the inferior gluteal fold may be distorted with unattractive outcomes. Painful donor-site scar and discomfort particularly in the sitting position are more common with the IGAP harvest than the SGAP.

37.3.3 TUG Flap

In 1992, Yousif et al. described the use of the transverse gracilis musculocutaneous flap for breast reconstruction with a transverse orientation of the cutaneous paddle in the proximal third of the muscle [49]. Arnez and Wechselberger popularized simultaneously the flap presenting their case series in 2004 [50, 51]. Compared to the common free flaps from the abdomen (TRAM, DIEP) and the buttocks (SGAP, IGAP), the size of the free TUG flap (25 cm × 10 cm) is smaller and the fat pad is usually thinner [51]. Because of the aforementioned, the flap provides inadequate tissue bulk to reconstruct large and ptotic breasts. Moreover, it is also considered less appropriate for secondary reconstructions where additional skin may be required for the excision of tissues in between the postmastectomy scar and the new inframammary fold.

With the patient in the supine position and the knee and hip flexed, the lower extremity is abducted. The flap is harvested from the ipsilateral side. This enables the reconstructive and general surgery teams to work simultaneously. The skin paddle is oriented transversely on the upper part of gracilis muscle just below the groin crease. The average pedicle length is 5–6 cm, with the vessel diameter around 1.6 mm. A line is drawn on the medial thigh from the pubic symphysis to the medial tibial condyle.

On this line, 8–12 cm distal to the symphysis, perforators from the main (proximal) vascular pedicle are identified by the use of a Doppler probe and marked. Around this marking, the width (vertical diameter) of the flap usually depends on the excess of skin/fat that allows primary skin closure avoiding the risk of wound dehiscence.

The flap is then outlined as a crescent shape with one tip in the lateral anterior groin and the other tip in the middle of the proximal posterior thigh. The superior incision of the crescent is parallel to the groin-gluteal crease (4 cm distal to it), while the inferior incision is drawn 10–12 cm distally.

The incisions are made along the preoperative markings, and the flap is dissected from an anterior to posterior direction in a subfascial plane until the intermuscular septum between the adductor longus and the gracilis muscle is visualized.

The greater saphenous vein can be included in the flap harvest allowing an extra-venous drainage. The fascia is incised anteriorly at the posterior border of the adductor lon-

gus muscle, which is then retracted. The dominant vascular pedicle is exposed traveling under the adductor longus and medially the undersurface of the gracilis muscle. The vascular pedicle dissection proceeds until its origin from the profunda femoris artery. The fascia is then incised at the posterior border of the gracilis muscle, and at the knee-joint level, the tendon of the gracilis muscle is divided and mobilized proximally. After checking vascular flap perfusion, the pedicle is divided and then ligated and the TUG flap is transferred to the chest wall. Both the artery and vein from the dominant gracilis pedicle are usually anastomosed end to end to the IMV or TDV. The donor-site closure is similar to the tight lift.

37.3.4 PAP Flap

An interesting recent advance of the TUG flap has been the description by Allen et al. of the profunda artery perforator (PAP) flap [52].

The ideal patient has a breast of small-medium size and excess tissue in the posterior thigh with contraindication for DIEP flap reconstruction. Preoperative imaging such as magnetic resonance or computed tomographic angiography of the pelvis and thigh with contrast can be useful to identify suitable posterior thigh profunda artery perforators. The posterior thigh tissue is bordered horizontally by the iliotibial tract and adductor muscles and vertically by the gluteal fold and popliteal fossa. The profunda femoris artery enters the posterior compartment of the thigh proximally to the knee giving three main perforators. The first perforator supplies the adductor magnus and gracilis, and the second and third perforators supply the semimembranosus, biceps femoris, and vastus lateralis. By the use of the imaging and a handheld Doppler, the perforators are identified and marked on the skin. Between medial and lateral perforators, the medial perforators are preferred because of the easier harvesting in the supine position and the perforator size. The skin paddle is drawn as an ellipse avoiding visible scar in the lateral or medial portion of the thigh outside of the gluteal fold. The superior marking is 1 cm inferior to the gluteal crease, while the inferior marking is approximately 7 cm below it.

Flap harvest can be performed in the prone or supine position. The supine frog-leg position offers the advantage of rapid dissection from a medial approach. Moreover, it is not necessary to reposition the patient to decrease the operative time. The prone position uses a lateral approach and gives the possibility to convert the PAP in TUG flap if no adequate perforators are identified. The elliptical incision is made and dissection proceeds in a suprafascial plane that helps with perforator identification. Once the key perforator is found, standard perforator dissection proceeds to harvest the desired pedicle length and vessels diameter. The donor-site closure is carried out in a multilayer fashion over a drain. After recipient-site preparation, the flap is transferred to the chest wall and the anastomoses are performed. The advantages on the use of PAP flap compared to TUG flap include the pedicle length as long as 13 cm (average, 9.9 cm) that provides versatility at the recipient site (IMV or TDV or CSV), the elliptical design that provides an ideal shape for coning to create a natural breast without the gracilis muscle harvest, and lower risk of lymphedema and seroma compared to the TUG because of the dissection near the lymphatic system that is not damaged. Moreover, the posterior femoral cutaneous nerve can be used to transfer a sensitized flap with branches from this nerve.

37.4 Complications

Vascular complications in free tissue transfer cannot be completely prevented; however a careful preoperative evaluation, prophylactic strategies, meticulous surgical technique, and meticulous postoperative monitoring may be significantly reduced the incidence [53]. Rapid exploration with revision is possible if an adequate flap monitoring is performed in the early postoperative period. Venous complications are more common than arterial likely due to the venous low-flow system being more prone to stasis or the easy vein kinking or compressing [53–56].

Kroll et al. reported that all microvascular complications occurred within the first 48 h and recommended that 3–4 days was the optimal length of time required for intensive postoperative microvascular monitoring [57].

Contralateral Breast Management

38

Marco Klinger, Luca Maione, Silvia Giannasi, Valeria Bandi, Barbara Banzatti, Alessandra Veronesi, Barbara Catania, Valeriano Vinci, Andrea Lisa, Guido Cornegliani, Micol Giaccone, Mattia Siliprandi, Fabio Caviggioli, and Francesco Klinger

38.1 Introduction

Breast reconstructive surgery techniques have increasingly evolved in the last decades both by a surgical and postoperative management point of view.

More and more attention has been paid on the quality of life of patients undergoing this kind of surgery. Nowadays a reconstructive result can be considered worth not only when an acceptable morphology of the reconstructed breast alone is achieved but symmetry with the contralateral breast in terms of volume and shape obtained.

As a consequence, oncoplastic surgeons are paying more and more attention to the management of the contralateral breast. In this chapter the authors will discuss and provide a systematic method to correctly plan and approach this kind of surgery.

38.2 Preoperative Evaluation

Preoperative evaluation is fundamental in order to choose the appropriate surgical technique for remodeling the contralateral breast after breast oncological procedure.

In order to obtain the best symmetry between the two breasts in terms of volume and shape, several features should be considered:

1. Type of oncologic resection.
2. NAC position: any asymmetry between the two NAC must be assessed.
3. Mammary ptosis: true ptosis or pseudoptosis must be discerned; the degree of glandular descent and of skin exceeding and stretching must be evaluated and distinguished in planning the correct mastopexy or reduction mammoplasty technique, when needed.
4. Volume: any difference and asymmetry in mammary volume must be assessed between the two breasts. If the affected breast is bigger than the contralateral one.
5. Breast shape: in particular stenotic and tuberous breast deformities should be recognized and assessed.
6. Symmetry.
7. NAC-inframammary fold distance.
8. Alignment of the NAC along the breast meridian. The NAC can be displaced both laterally and medially.
9. Thickness of the patient's skin. In patients with excessively thin skin, the breast implant contours may be easily visible giving an unpleasant and artificial appearance to the breast and leading to the loss of the natural harmonic breast profile.
10. Thoracic deformity deriving from a variety of conditions as prominent costal bones, sternal anatomical deformities or alterations, and scoliosis.
11. Patient's requests.

1. *Preoperative pictures:* pictures in six projections are made before surgery, as shown in images. To assess the precise position of the mammary crease, the patient is also asked to lift her arms above her head.
2. *Preoperative marking* is made requiring the patient to stand in front of the surgeon, with arms hanging relaxed along the body. A vertical median line is drawn running from the interclavicular junction to the umbilicus. The jugulum to NAC distance is then measured and compared between the two breasts. The areolar perimeter and the inframammary folds are marked. The breast meridians are finally drawn along with the base of the breasts. Mastopexy and reduction mammoplasty markings are modified during surgery when immediate reconstruction is performed, since the

contralateral breast will be adjusted to the diseased one after its reconstruction. The seatback of the operating table is lifted up to 45° during surgery in order to recreate the gravity effect and correctly adjust the markings. When a two-step reconstruction is performed, markings are made preoperatively, since the final volume and shape of the reconstructed breast are assessable previous to surgery.

The preoperative meeting with the patient is extremely important. During the encounter the goals of the surgical reconstructive procedure are clarified and explained: even if the main aim is to obtain symmetry between the two breasts, the physician must underline that equality between them cannot be guaranteed.

Patients' comorbidities and previous or current therapies must be considered too. Patients with a positive history for neoadjuvant chemotherapy or radiotherapy have an increased surgical risk for local infections and flap necrosis.

In order to correctly consider the entity of the oncologic resection planned for the diseased breast and consequently to correctly choose the technique to apply to the contralateral breast, a multidisciplinary approach is advocated. Thus the patient is evaluated together with the general surgeon previous to surgery.

Further preoperative and intraoperative considerations regarding the different techniques and situations will be discussed in the next sections.

38.3 Surgical Techniques

Depending on the oncological surgical technique employed on the affected breast, different reconstructive surgical techniques can be adopted to remodel the contralateral breast in order to symmetrize and adapt it to the former. A list of the employable techniques is here provided. In the next section, the authors will discuss in which case each technique is suitable and suggested.

38.3.1 Mastopexy

Mastopexy literarily means lifting up of the breast. Classically mastopexy is used to correct breast ptosis, which in turn can be due to a glandular ptosis, skin stretching and excess, or both. Actually by the employment of this technique, not only a lifting of the breast can be achieved but also a replacement of the NAC. Depending on the degree of breast ptosis, amount of breast tissue, and amount of skin excess, three main different mastopexy techniques can be used:

- Periareolar mastopexy: this technique can be used to correct low to medium degrees of mammary skin ptosis. In addition to the correction of a mammary ptosis, the goal in performing this technique is to centralize the NAC above the point of maximum projection of the breast mound and/or symmetrize it to the contralateral when the two NAC are not symmetrically positioned [1]. According to this the markings and consequently the incisions may be eccentric rather than concentric (Fig. 38.1). When a medial NAC repositioning is wanted, the markings and incisions will be elliptical having the major axis of the ellipse horizontal and having the lateral margin of the NAC corresponding to the lateral margin of the ellipse. The longer the major axis of the ellipse, the more the NAC will result medial in respect to the original position. The same method is adopted in order to lateralize, lower, or lift the NAC, accordingly

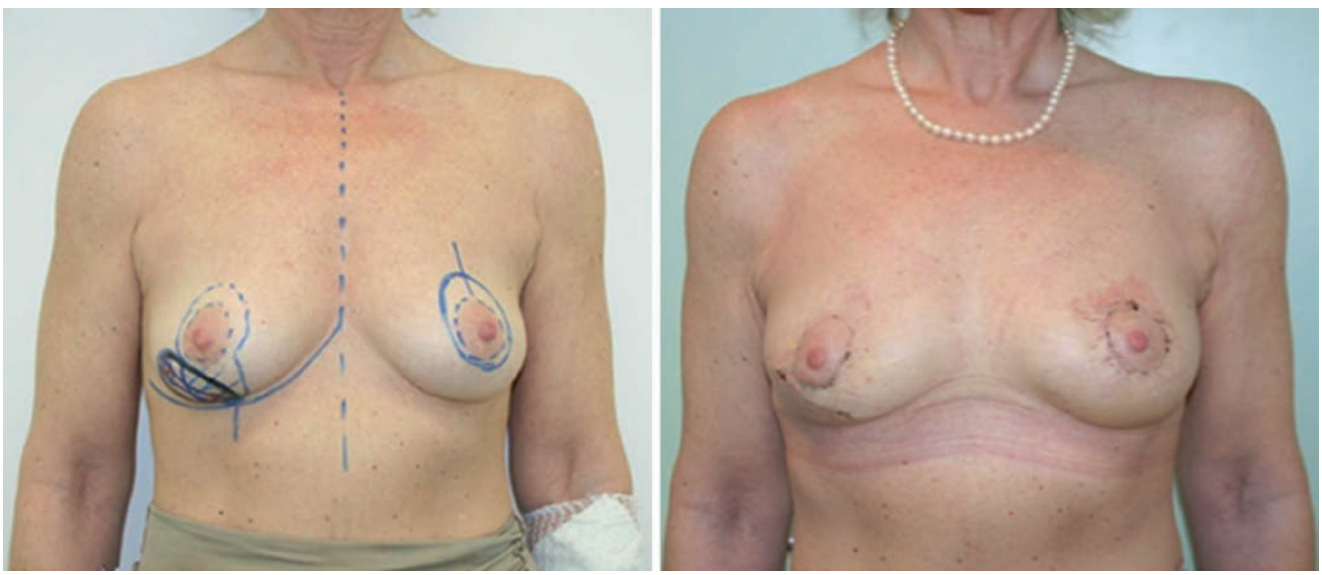

Fig. 38.1 Right breast inferolateral quadrantectomy. Periareolar vertically eccentric mastopexy is planned for contralateral breast management

changing the orientation and major axis of the ellipse. The wider the ellipse drawn, the more the amount of the skin that will be excided. Consequently the size of the ellipse should be increased along with the degree of skin excess.

The surgical incisions will follow the markings made in the preoperative evaluation. After the periareolar skin incision has been done, a second external cutaneous incision is made following the markings. The skin comprehended by the two incisions is then deepithelized. Consequently the dermal layer is incised circumferentially except for a small portion in the cranial part which will function as superior dermal pedicle. Dermal round-block sutures allow to reduce the diameter of the external incisions, thus reducing the skin tension affecting the eventual periareolar sutures. Reabsorbable Vicryl sutures are employed for the gland, and reabsorbable Monocryl intradermic sutures are used for the dermal layer.

- Vertical and inverted T mastopexy
  For medium to high and high degrees of mammary skin ptosis with breast volume and for glandular ptosis, an inverted T approach must be employed.

  Since the markings and techniques employed in performing a vertical or inverted T mastopexy are nearly the same of those employed in performing a vertical or inverted T reduction mammoplasty, these two approaches will be discussed and described in the reduction mammoplasty section.

In order to choose the correct mastopexy technique, the quality of mammary ptosis must be correctly assessed. When a true glandular ptosis is present and the mammary gland is majorly distributed at the lower quadrants, a reversed T mastopexy is usually advocated, allowing to reposition the gland upward and to remove the excess of glandular tissue. When the ptosis is purely glandular, repositioning of the NAC may not be necessary. When the ptosis is mainly due to a skin excess, a periareolar or vertical approach may be sufficient. In this latter case, a descent of the NAC secondary to skin stretching and descent is usually present and its repositioning is needed.

38.3.2 Reduction Mammoplasty

Reduction mammoplasty is employed to correct an excess in glandular volume. Since a variable degree of mammary ptosis and skin excess is always observed in hypertrophic mammary glands, lifting of the gland and excision of exceeding skin are also performed along with the excision of the exceeding glandular tissue. Three main different approaches are employed in reduction mammoplasty: periareolar, vertical, and inverted T approach:

- Periareolar reduction: surgical approach and markings are the same as described in the periareolar mastopexy section. By the use of this technique, small to medium volume reductions can be achieved. As a consequence this approach should be chosen when a smooth volume asymmetry is noted between the two breasts, after cancer excision and affected breast reconstruction. When quadrantectomy is performed, glandular reduction of the contralateral breast can involve the same quadrants as the ones resected in the affected breast or different ones, depending on the patient's preoperative anatomy. Volume symmetrization through this approach can be adopted also after mastectomy and reconstruction with similar indications obtaining good results with minimal scarring (Fig. 38.2).
- Vertical reduction mammoplasty: this technique can be employed when medium degree of glandular hypertrophy or exceeding is observed. Periareolar markings are first made. Secondly, the desired new position of the NAC is assessed: by holding the breast between the thumb and the third finger, the projection of the midpoint of the inframammary fold on the anterior surface of the breast can be marked; this point will indicatively correspond to the cranial margin of the NAC. The markings are consequently made. The two vertical lines connect the extremities of the circle to the midpoint of the inframammary fold. Indicatively the wider the vertical lines, the more will be the skin and glandular excision. The shape of the circle or ellipse allows to modify the quantity of the skin excised in the central and cranial part of the gland and allows to modify the position of the NAC in respect of the mammary mold, similarly to what has been previously described in the periareolar mastopexy section. The cutaneous incisions follow the markings described. The gland is also incised accordingly to the markings. A vascular pedicle cranially to the NAC is maintained and no glandular incision should be made in this region. A variable amount of glandular tissue can be excised in order to reduce the mammary volume. The amount of the skin excised not necessarily corresponds to the amount of gland removed: by increasing the depth of the glandular incision, increased amounts of glandular tissue can be removed. Dermoglandular detachment is usually performed along the margins of the incisions in order to avoid excessive tension on the suture lines. The dermoglandular flaps are eventually approached and sutured [2, 3].
- Inverted T reduction mammoplasty: this technique is usually employed when a medium to high degree of hypertrophy or mammary ptosis is observed. The length of the vertical lines is approximately 5–6 cm. This will be the final length of the NAC-inframammary fold distance. Depending on the degree of ptosis and hypertrophy of the mammary gland observed preoperatively, an upper or

Fig. 38.2 Left breast inferior quadrantectomy. Periareolar vertically eccentric reduction mammoplasty has been performed for contralateral breast volume symmetrization. Breast parenchyma has been removed in the lower quadrants of the right breast in order to balance volume asymmetry, already present before surgery, with minimal scarring

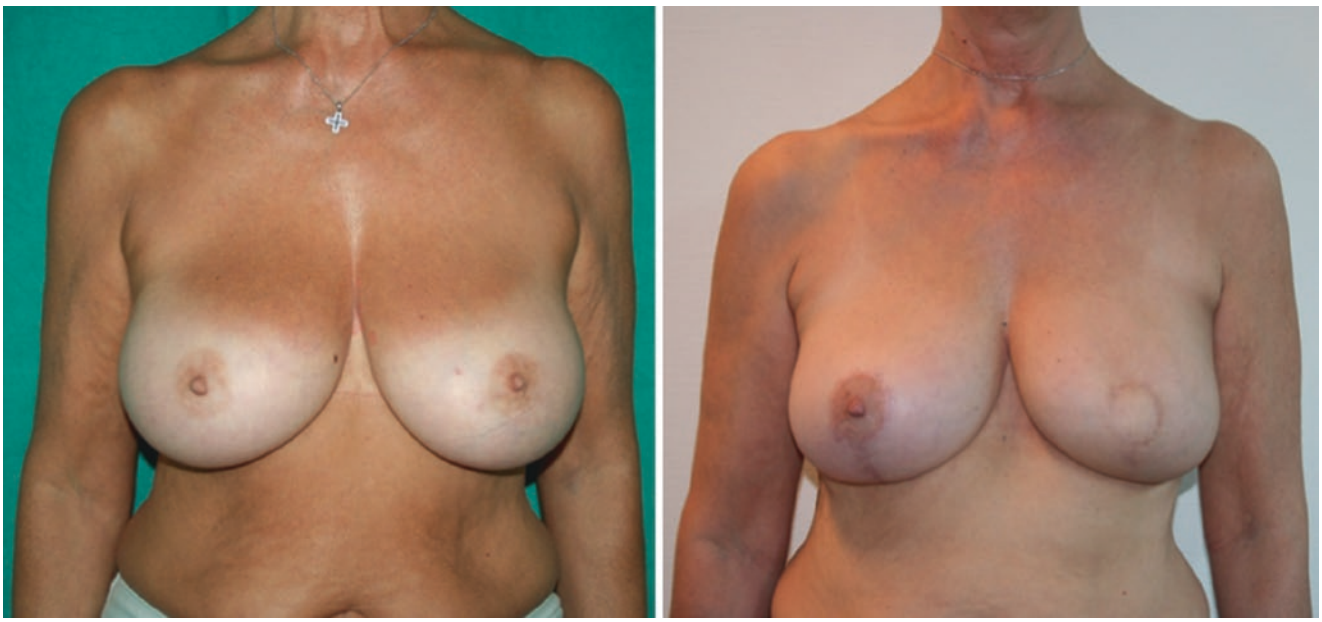

Fig. 38.3 Left breast central quadrantectomy. Inverted T reduction mammoplasty that is adopted has been chosen for contralateral breast volume symmetrization. A lower pedicle is adopted with a glandular excision in the lower quadrants

lower vascular pedicle is chosen. A lower pedicle is usually employed when a severe hypertrophy and degree of ptosis are present. In fact an upper pedicle in these types of breast would be excessively long and would need to be folded several times to allow the repositioning of the NAC cranially, thus increasing the risk of vascular necrosis of the NAC itself. The glandular excision involves mainly the lower quadrants. Comparing to the vertical technique, a wider amount of gland is removed. The glandular tissue remaining after the excision is usually rearranged and lifted: a detachment of the mammary gland from the muscular fascia allows to lift up the glandular tissue and to suspend it cranially by suturing it to the pectoral fascia (Fig. 38.3).

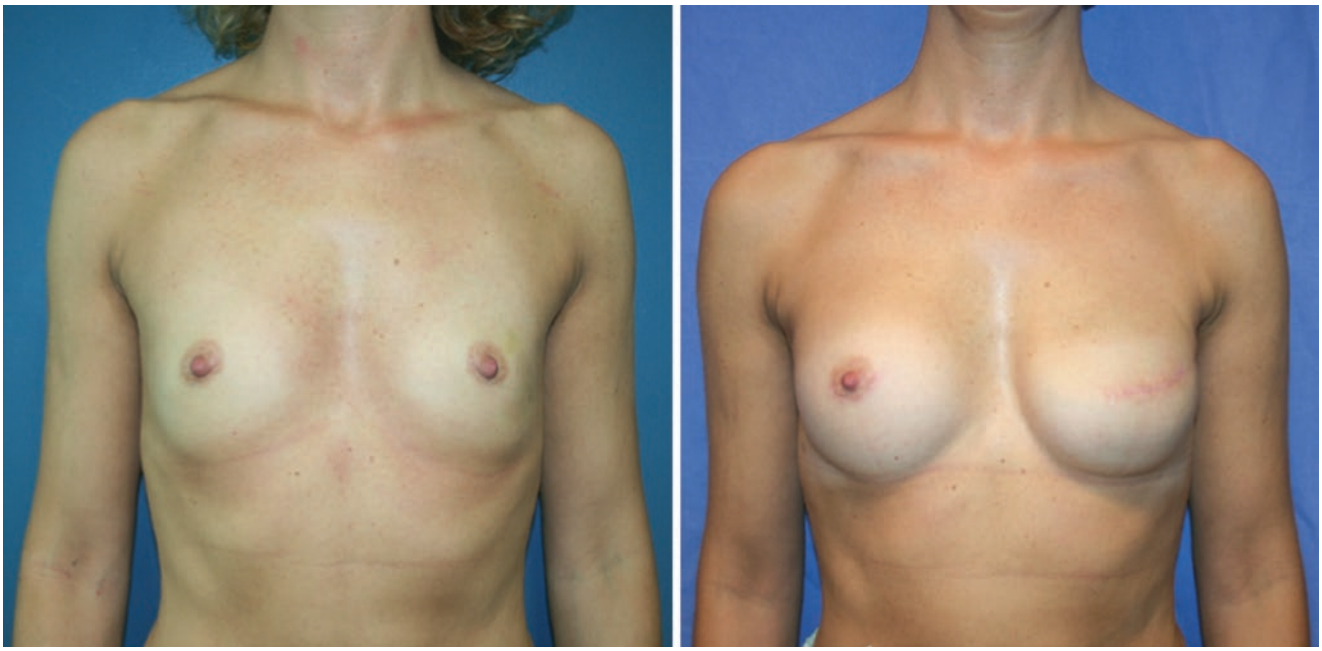

Fig. 38.4 Left breast mastectomy and immediate two-stage breast reconstruction. During stage II breast reconstruction, contralateral symmetrization has been performed with augmentation mammoplasty since unaffected breast was hypoplastic

When a residual excess of dermoglandular tissue is still present alongside the inframammary fold, a further dermoglandular excision can be performed. When an increase in breast projection is aimed, a portion of the lower quadrants' glandular tissue can be undermined and preserved: by flipping inward the resulting glandular flaps (autoprosthesis), the projection of the breast can be significantly increased [4–14].

38.3.3 Augmentation Mammoplasty

Augmentation mammoplasty assumes the use of breast prostheses. The cutaneous incisions can be periareolar or performed at the inframammary fold or axilla. The authors prefer the periareolar approach for several reasons. Firstly, when a periareolar mastopexy is necessary, the same surgical access can be employed for both techniques. Secondly, the scar can be camouflaged corresponding to the limit between the areolar darker skin and the breast lighter skin. Moreover when a modification or definition of the inframammary fold is needed, the periareolar surgical access allows to work on it more comfortably when compared to the inframammary surgical access. The prostheses can be implanted both in the subglandular plane or in the submuscular plane. If no anatomical abnormalities are found and the pectoralis major is normotrophic and integer, a submuscular approach is preferred. The dual plane technique is usually adopted: the pectoralis major muscle is interrupted at two thirds of its length parallel to the muscular fiber to avoid excessive bleeding and postoperative pain. When anatomical conditions are not optimal or the pectoralis muscle is hypotrophic or atrophic, a subglandular approach is preferred. In both the submuscular and subglandular techniques, the pocket is created by digital dissection in order to avoid excessive traumatism to nerves and vessels. The ideal pocket should be large enough to host the new implant without distorting it, being careful not to exceed cranially and medially which would lead, respectively, to riding high and symmastia deformities. A new inframammary crease is needed when the contralateral one is asymmetrical or if the previous mammary fold is aesthetically unpleasant. The new inframammary crease is defined by suturing the lower pole dermal and subcutaneous tissue to the costal perichondrium or to the caudal capsular tissue. Failure in performing this may lead to bottoming out or double-bubble deformities. The pocket is closed with interrupted sutures. A drain is always inserted in the pocket (Fig. 38.4).

38.3.3.1 Contralateral Breast Management in Case of Quadrantectomy

Quadrantectomy means the excision and removal of a part of the mammary gland. The volume and position of the glandular mass removed vary depending on the volume and the position of the tumor.

Quadrantectomy inevitably causes a reduction in the mammary volume of the affected breast leading to an

unavoidable asymmetry between the two breasts, if they are initially equal. Depending on the amount of tumorous and glandular tissue removed, the resulting asymmetry degree will accordingly vary. The location of the cancer and the affected quadrants do not importantly affect the approach on the contralateral breast, being the main variable counting the amount of tissue removed. The breast initial volume also influences the technique chosen to reconstruct both the affected and the contralateral breast.

When the patient's breasts are equal in volume or when the affected breast is smaller than the contralateral one, three main situations can be discerned:

1. A small amount of volume is removed from the affected breast. In this case no intervention on the contralateral breast may be needed. If an asymmetry derives from the excision of the tumor, a periareolar mastopexy is usually sufficient to symmetrize the contralateral breast and NAC.
2. A large amount of volume is removed from the affected breast and the patient's breast is normotrophic or hypertrophic. In this case a reduction mammoplasty and mastopexy are usually employed. If the resulting asymmetry is smooth, a periareolar approach may be sufficient for parenchyma reduction, while when asymmetry is more severe, a vertical or reverse T approach may be needed.
3. A large amount of volume is removed from the affected breast and the patient's breast is hypotrophic. In this case simply remodeling and reshaping the remaining volume on the affected breast do not allow a satisfactory reconstructive result, and a prosthesis implantation is needed to give the affected breast an acceptable morphology. If the affected reconstructed breast appears bigger than the contralateral one, a prosthesis implantation may be needed also in the unaffected side. The prosthesis chosen for the contralateral breast will be smaller than the one employed to reconstruct the diseased breast, since the glandular tissue is entirely preserved in the former. A circumareolar mastopexy is usually employed if a certain degree of ptosis is observed along with breast hypotrophy and in order to symmetrize the NAC.

When the affected breast is bigger than the contralateral one, no intervention on the latter may be needed: the reduction of the diseased breast derived by the quadrantectomy may adjust itself the affected breast to the healthy one. A simple periareolar mastopexy may be needed to symmetrize and reposition the NAC. If a large amount of volume is removed from the affected breast, the three previously reported situations are possible.

When radiotherapy consequent to surgery is necessary and programmed, any intervention on the unaffected breast should be postponed 3–6 months after the end of the radiotherapy cycles. Tissues undergoing radiotherapy may in fact suffer from chronic edema or fibrosis. In the first case, the breast will appear more and more swollen over time; in the latter it will progressively reduce. Thus modifying and adjusting the contralateral breast previous to radiotherapy may result useless and unsuccessful. Only when a great difference is observed between the two breasts after quadrantectomy, surgery is suggested on the contralateral gland.

When breast implants are adopted in reconstructive surgery by the insertion of a prosthesis in the breast undergoing quadrantectomy without a contralateral augmentation mammoplasty for symmetrization, a particular attention should be given. In such cases the aging processes will differ between the two breasts: the breast reconstructed by the implantation of a prosthesis will minimally change over time, while the contralateral one will vary in size, accordingly to the possible weight gain or loss of the patient, and will descend over time. Consequently asymmetry between the two breasts may turn out again over years after reconstruction and further surgery may be needed. The patient must be aware of this aspect, and the physician must clearly explain it at the preoperative encounter and consultation.

38.3.3.2 Contralateral Breast Management in Case of Mastectomy

Mastectomy means the removal of the entire mammary gland in the presence of a tumor. Depending on the different types of mastectomies and on the anatomical characteristics of the patient, two main reconstructive routes can be followed:

- Immediate reconstruction: the affected breast is reconstructed immediately after the oncologic resection by the use of a prosthesis or flaps.
- Two-stage reconstruction: the affected breast's volume is recovered over time by progressive expansions of an expander inserted at the time of the oncological resection. When the expansions are terminated, the expander is eventually replaced by a definitive mammary prosthesis.

When an immediate reconstruction is planned, contralateral breast reconstruction is made at the same time of the affected breast reconstruction. Since a portion of the skin may be removed together with the gland from the diseased breast, it may result smaller and lifted after the reconstruction. Thus a mastopexy and reduction mammoplasty are usually needed for the contralateral breast. Depending on the volume, degree of ptosis, and morphology of the unaffected breast, all the different mastopexy or reduction mammoplasty techniques previously described may be employed. If radiotherapy is to be performed on the affected breast, the reconstruction of the contralateral one should be postponed

3–6 months after the end of the last radiotherapy cycle, in order to appreciate any possible breast swelling or volume reduction.

When a two-stage reconstruction is planned, contralateral breast reconstruction is made at the time of the substitution of the expander with the definitive breast prosthesis. In fact the eventual appearance of the diseased reconstructed breast is not predictable at the time of the expander insertion. If radiotherapy is to be performed, the second stage of the reconstruction should be postponed 3–6 months after the end of the last radiotherapy cycle, in order to appreciate any possible breast swelling or volume reduction in the affected breast, as mentioned in the previous paragraphs. The possible situations at the time of a second stage reconstruction are listed as follows:

- *The contralateral breast has a major degree of ptosis and/or is greater in volume compared to the reconstructed breast:* this represents the commonest situation. Patients undergoing mastectomy are adult women, most of which over 40 years old. Consequently a certain degree of ptosis is generally present. Moreover when a mastectomy is performed, a variable amount of the skin may be excised along with the gland, as described before. As a result the contralateral breast usually proves to have a major volume when compared to the reconstructed one, even after the expansions have been completed. Depending on the severity of mammary ptosis and of the breast hypertrophy, different mastopexy and reduction mammoplasty techniques may be adopted, allowing to reduce and lift up the mammary gland, to excise the possible excess of the skin, and to reposition the NAC correctly.
- *The contralateral breast presents the same degree of ptosis and the same volume of the reconstructed breast:* in these rare situations, no intervention is needed on the contralateral breast. A periareolar mastopexy for minimal asymmetry between the glands or the NAC position may be performed.
- *The contralateral breast is smaller in volume compared to the reconstructed breast:* this may happen especially when a skin- or nipple-sparing mastectomy is performed, allowing a major expansion volume. The contralateral breast may be hypotrophic or atrophic. It may be or not be descended. This represents an extremely rare circumstance. In such case the implant of a prosthesis in the contralateral breast, along with a mastopexy (if necessary), is needed. As described in the quadrantectomy section, the prosthesis employed will be smaller than the one used to reconstruct the affected breast, since the mammary gland is spared in the contralateral breast and contributes to its final volume.

The previous consideration about aging processes in contralateral breast should be made for patients undergoing mastectomy breast implant reconstruction without a contralateral augmentation mammoplasty for symmetrization. In fact in these cases, which are the more frequent, the two breasts will differ over time. The breast reconstructed by the implantation of a prosthesis will minimally change over time, while the contralateral one will vary in size, accordingly to the possible weight gain or loss of the patient, and will descend over time. Consequently asymmetry between the two breasts may turn out again over years after reconstruction and further surgery may be needed. The patient must be aware of this aspect, and the physician must clearly explain it at the preoperative encounter and consultation.

Lipofilling

39

J.Y. Petit, V. Lohsiriwat, and M. Rietjens

Although lipotransfer is not a new technique [1], it can be considered a technical revolution in plastic surgery which is widely performed all over the world for aesthetic surgery [2]. More recently, the lipofilling has been indicated in breast cancer patients to improve the results of breast reconstructions, and [3–6] current literature underlines the efficacy of the technique as well as the safety of the procedure in cancer patients. Applications of lipofilling have been performed to improve the shape of breast reconstruction with prosthesis or with autologous musculocutaneous flaps. Fat injection can also be used to reshape the bad results of the conservative treatment. Most of the defects observed after conservative treatment can be easily filled up with fat tissue instead of glandular or distant flaps. Different teams are now investigating the possibility of refilling the defect of the quadrantectomy immediately at the time of the quadrantectomy. Total breast reconstruction with pure fat refilling is also performed as demonstrated in several studies [7, 8].

39.1 Application of Lipofilling in Breast Cancer Surgery

Lipofilling is being indicated for soft tissue defect correction in many sites. It is not only for corrective surgery but also for cosmetic purpose. For breast cancer surgery, lipofilling procedure might be proposed in the following situations:

- Correction of defects and asymmetry following wide local excision (or breast conservative surgery), with or without radiotherapy
- Improvement of soft tissue coverage following implant-based breast reconstruction
- Volume replacement of implants in unsatisfactory oncoplastic breast reconstruction outcomes
- Augmentation of volume and refinement after autologous breast reconstruction
- Whole breast reconstruction with serial fat grafting
- Scar correction

39.2 Technique of Lipofilling

Lipofilling can be performed under general or local anesthesia. Generally, the aim of the technique is to decrease cell damage and to promote survival of the fat tissue and its composition. Success is heavily dependent on the technique used for harvesting, preparing, and grafting of the fat (Figs. 39.1, 39.2, 39.3, 39.4, 39.5, 39.6, 39.7, 39.8 and 39.9).

39.2.1 Identification of the Donor Site

The most common site is the abdominal fat because it is one of the most fat deposit area. Moreover, there is no need to change the patient's position in the operation room. The second site is the trochanteric region (saddle bags) and the inside of the thighs and knees. The harvesting areas are outlined with a skin marker. But every location showing an excess of fat tissue on the body can be used for fat liposuction.

39.2.2 Preparation of the Solution

The tumescent solution (so-called Klein's solution) is prepared to be injected into the donor site: 1 cc of epinephrine (1:500,000) diluted in 500 cc of 0.001% lactated Ringer's solution (LRS). The 50 cc of mepivacaine can be added in

the solution if the procedure is planned under local anesthesia. It is injected through a small-bore 4 mm blunt cannula that was attached to a 60-cc syringe. The estimate volume of solution is 1 cc for each 1 cm^3 of target fat harvest volume. The surgeon should wait at least 15 min before starting fat harvesting; the adrenaline is added to the solution in order to achieve well hemostasis and to decrease postoperative pain.

39.2.3 Fat Harvesting

The most well-known technique of fat harvesting has been described by Coleman [9]. The procedure starts through a small incision made in the abdomen by blade no.11 and gradually applies a blunt tip harvesting cannula (3 mm in diameter and 15 or 23 cm in length). Manually, the syringe is drawn to create to low negative pressure during fat harvesting. The cannula is attached to 10-cc Luer Lock syringes. However, various techniques of fat harvesting with different cannula or liposuction machine system have been reported with different outcome assessments.

An "experimental solution" study by Ozsoy et al. demonstrated a greater number of viable adipocytes when harvested with a 4-mm-diameter cannula compared with 2- or 3-mm cannulas. Erdim et al. also recommended the use of larger cannulas to increase cell viability. Their study showed more viability of fat cells when using 6-mm-diameter cannula than using 2 or 4 mm in diameter cannula.

Different vacuum pressures and some assisted techniques have been used in many clinical series. Rohrich et al. compared traditional liposuction, internal ultrasound-assisted liposuction, external ultrasound-assisted liposuction, and massage-assisted technique liposuction. There was no significant histologic or chemical effect of external ultrasound-assisted liposuction on harvested adipocytes. Pu et al.

compared the Coleman technique versus conventional liposuction technique and found significantly higher viable adipocyte level in the Coleman technique. Crawford et al. examined the hand aspirate at low-force centrifuge versus standard power-assisted liposuction and showed higher cell counts which were observed when using the low-force centrifuge [10–20].

39.2.4 Fat Processing

The most frequently used methods for fat processing are centrifugation, washing, and decantation. The purified fat can be separated from cell debris by centrifugation, as described in the widely used protocol by Coleman. After centrifugation, the lipoaspirated specimen can be separated into four layers: (I) the oily fraction, leaked out of disrupted adipocytes; (II) the watery fraction consisting of blood, lidocaine, and saline, injected before the liposuction; (III) a cell pellet on the bottom; and (IV) the purified fat between the oily and the watery fractions. For washing technique, the fat is washed using normal saline or 5% glucose solution in order to wash out the blood and the oil part and cellular debris from the aspirated fat. The least popular technique is decantation, which uses the gravity effect to precipitate the cellular component from the oily and water component.

39.2.5 Fat Transfer (Injection)

At EIO, we are using modified Coleman technique by injecting the processed fat via 2-mm-diameter cannula attached to 1 mL to 3 or 10 mL disposable syringe. The fat is transferred directly to the breast, trying to avoid intraparenchymal injection and avoid creating the bolus injection. The entry site of the cannula can be made by sharp blade or a sharp 17-gauge needle to minimize the scar. It is mandatory to overcorrect the defects because 40–60% of the transferred fat is expected to be resorbed. Experimental studies have found that up to 90% of transplanted adipose tissue could be lost, while clinically reported figures range between 40% and 60%, and most of the volume loss occurs within the first 4–6 months following surgery. Despite, several novel techniques proclaimed that they produced more effective outcomes. Nonetheless, surgeon should calculate the quantity of fat preparation and injection before the procedure. The limitation of volume inject can be due to the recipient tissue quality such as in irradiation tissue or thick scar. If the target volume cannot be achieved by a single lipofilling procedure, then the patient should be informed for the possibility of repeated lipofilling. In general the overcorrection reaches an excess of around 40% of the amount of fat required to correct the defect.

39.2.6 Lipofilling in Reconstruction of Irradiated Breast

External radiation is required in breast conservative treatment and after total mastectomy in case of positive nodes. Salgarello et al. retrospectively studied 16 patients who underwent lipofilling to the chest wall after irradiation and then followed by prosthesis introduction and found high success rate of prosthetic-based procedure with no complication or oncological recurrence [21]. Sarfati et al. performed lipofilling prior to implant introduction after irradiation in 28 patients. They reported high success rate with only one prosthesis exchange due to prosthesis exposure after lipofilling [22]. Rigotti also demonstrated the efficacy of lipotransfer to improve the radiodystrophic sequelae [23].

39.3 Complication

39.3.1 Recipient Site Complications [23, 24]

- Fat necrosis, oil cyst formation, and calcifications can occur due to injection of large volumes into a single area or injecting fat into poorly vascularized areas resulting in failure of "graft take" with palpable mass formation resulting from fat necrosis which may be difficult to distinguish clinically from local recurrence in breast cancer patients and lead to a need for additional imaging and needle biopsy (3–15%). Moreover, post-lipofilling calcification can be found in mammogram (0.7–4.9%).
- Infection (0.6–1.1%).
- Under-correction or overcorrection of deformity.
- Damage to underlying structures, e.g., breast implants and pneumothorax.
- Intravascular injection with fat embolism.

39.3.2 Donor Site Complication

Complications appear to be minimal and related to liposuction technique. The possible complications include bruising, swelling, hematoma formation, paresthesia or donor site pain, infection, hypertrophic scarring, contour irregularities, and damage to underlying structure such as intraperitoneal or intramuscular penetration of the cannula.

39.4 Oncological Safety [4, 24–35]

Experimental studies have shown that adipocytes can stimulate breast cancer cells. Adipokines are factors that can stimulate breast cancerous cells through endocrine, paracrine, and autocrine pathways; theoretically, the "tumor stroma

interaction" can potentially induce cancer reappearance by fueling dormant tumor cancer cells in the tumor bed. There is increasing evidence that obesity, an excess accumulation of adipose tissue occurring in mammalians when caloric intake exceeds energy expenditure, is associated with an increased frequency and morbidity of several types of neoplastic diseases, including postmenopausal disruption of the energy homeostasis results in obesity, inflammation, and alterations of adipokine signaling that may foster initiation and progression of cancer. Other recent studies, some of which are based on endogenous WAT expressing a transgenic reporter, showed a significant level of adipose cell contribution to tumor composition. However, WAT contains several distinct populations of progenitors, and these data were obtained using crude or mixed cell populations. We therefore decided to purify by sorting the two quantitatively most relevant populations of WAT progenitors (endothelial cells and adipose stromal cells, ASC) and to investigate in vitro and in vivo their role in several orthotopic models of local and metastatic breast cancer. Compared with bone marrow-derived CD34+ cells mobilized in blood by granulocyte colony-stimulating factor (G-CSF), purified human WAT-derived CD34+ cells were found to express similar levels of stemness-related genes and significantly increased levels of angiogenesis-related genes and of FAP-α, a crucial suppressor of antitumor immunity. In vitro, WAT-CD34+ cells generated mature endothelial cells and endothelial tubes. In vivo, the co-injection of human WAT-CD34+ cells contributed to tumor vascularization orthotopic and significantly increased tumor growth and metastases in models of human breast cancer in nonobese diabetic severe combined immunodeficient (NOD/SCID) interleukin-2 receptor γ (IL-2Rγ)-null (NSG) mice.

The oncological safety should be considered as a priority problem for lipofilling. Many studies are showing the safety of lipofilling such as the multicentric study (Milan-Paris-Lyon) performed by Petit et al. dealing with 646 lipofilling procedures performed on 513 patients. The average interval between oncologic surgical interventions and lipofilling was 39.7 months. Average follow-up after lipofilling was 19.2 months. They observed a low complication rate; the overall oncologic event rate was 5.6 percent (3.6 percent per year). The overall locoregional event rate was 2.4 percent. Petit et al. reported a retrospective matched cohort study on 321 consecutive patients operated for primary breast cancer who subsequently underwent lipofilling for reconstructive purpose. The median follow-up of 56 months from primary surgery and 26 months from the lipofilling had shown no significant local recurrence when compared to 642 patients as a control group. However, there is a trend of higher risk of local event in subgroup of ductal carcinoma in situ. In 2010, Rietjens et al. reported a series of lipofilling procedures in breast cancer treatment and reconstruction. They followed 158 patients and found that postoperative complication rates are very low (3.6 percent) and that there is little alteration in post-lipofilling mammographic finding (5.9%). Seth et al. made a retrospective comparative study on 886 patients (1202 breasts) from 1998 to 2008 and revealed no significant differences in demographics, operative characteristics, tumor staging, or radiation therapy exposure between fat grafting (n = 90 breasts) and nonfat grafting (n = 1112 breasts) patients. Ninety-nine fat-grafting procedures were performed an average of 18.3 months after reconstruction, with only one complication (fat necrosis); they concluded that fat grafting did not affect local tumor recurrence or survival when compared with nonfat-grafted breasts. In 2007, the French Society of Plastic Surgery (SOFCPRE) announced that that they would not support the use of lipofilling for treating defects resulting from breast-conserving treatment (BCT) as a result of the lack of evidence on its oncological safety. A phase III multicenter randomized, controlled trial is currently taking place in France with the goal of investigating this issue. Also the American Society of Plastic Surgeons had set up a task force in 2009 (ASPS Fat Graft Task Force) to assess the indications, the safety, and the efficacy of autologous fat grafting on 283 patients; it showed the risk of malignancy with lipofilling could not be identified due to lack of standardized techniques and randomized controlled trials. Even though lipofilling seems to be a safe procedure in breast cancer patients, longer follow-up and further experiences from large multicentric oncological series are urgently required to confirm these findings [38–41].

Conclusions

Lipofilling in breast cancer surgery can be performed as a day surgery procedure, and it has acceptable efficacy in correction of deformities without compromising oncological outcomes. Although an apparent increase of local recurrences was observed at the IEO in the intraepithelial breast cancer patients, two recent match-control studies showed the cancer safety of lipofilling [36, 37]. More studies are needed to confirm that the risk of stimulation of local recurrences observed in the experimental setting is not observed in breast cancer patients. Moreover, application of experimental and fundamental researches on tissue engineering and stem cells can carry more hopes to augment the role of lipofilling in the future.

Breast Reconstruction with Biological and Non-biological Meshes and Matrices

40

Rachel Rolph and Jian Farhadi

40.1 Introduction into Meshes and Matrices in Breast Reconstruction

The terms mesh and matrix when applied to breast reconstruction are generally in reference to the composition of the material used in the manufacture of the product. The general consensus is that the term "matrix or matrices" refers to a product derived from biological sources (e.g. dermis), whereas "mesh or meshes" refers to a product wholly manufactured from synthetic materials (e.g. polypropylene). With the exception of SERI™, made from silk-derived bioprotein, the majority of products used in breast reconstruction can be divided into matrices and meshes.

The use of matrices in prosthetic breast reconstruction began with the publication of two papers in 2005 and 2006 by Breuing and Salzberg, respectively [1, 2]. Both authors reported small case series (n = 76; n = 20 breasts) using the human dermal-derived matrix Alloderm, in immediate single-stage implant breast reconstruction. Authors described a novel technique which aimed to shorten the reconstructive process by reducing prosthetic reconstruction from two-stage to one-stage immediate reconstruction. Since then, the use of meshes and matrices in breast reconstruction has gained in popularity and has provided the surgeon with the option for immediate single-stage implant reconstruction with mesh placement as a viable reconstructive option [3]. Single-stage techniques benefit patients by avoiding the need for repeated outpatient appointments for tissue expander fills and a second-stage operation. Meshes and matrices have been successfully employed both in single-stage implant-based breast reconstruction and in the setting of two-stage expander-based prosthetic reconstruction, nipple-sparing mastectomy (NSM) and skin-sparing mastectomy (SSM) [4–8].

40.2 Mechanics of Meshes and Matrices in Breast Reconstruction

Meshes and matrices in prosthetic breast reconstruction are placed at the inferior border of the reconstruction. Prosthetic devices (implant or expander) are placed submuscularly (pectoralis major ± proximal rectus abdominis, serratus anterior). When partial muscle coverage is performed, pectoralis major is released off the chest wall. The subpectoral plane is developed to the second rib superiorly and to the sternal muscle fibres medially. The pectoralis major is then released and the mesh/matrix can be attached. Meshes/matrices are sutured medially from the inferomedial border of the pectoralis major to the medial border of the inframammary fold (IMF). The mesh/matrix is then sutured from the inferior border of the muscle to the chest wall fascia at the level of the IMF to increase the inferior aspect of the subpectoral pocket; most commonly interrupted sutures are used. A hammock of mesh is created for the prosthesis (Fig. 40.1).

The mesh/matrix is sutured laterally to ensure minimal lateral migration of the device. Some surgeons will perforate the matrix (meshes are already porous) with the aim to minimise fluid pooling around the device [9]. Many surgeons will facilitate fluid evacuation by placing a vacuumed drain between the skin flap and the mesh/matrix to reduce the potential deadspace between the two layers. Drains are left in situ until there is minimal drainage (<30 ml/24 h) to prevent seroma formation. Soft tissue compression dressings can also be employed to help reduce seroma formation in the immediate post-operative period:

1. *Meshes act as an inter-positional graft between the pectoralis major and IMF.*

   In all cases, the mesh allows the surgeon to release the pectoralis major and use the mesh as an extension of this inner tissue plane between the pectoralis lamellae and the outer skin envelope. This is especially useful in patients where the muscle sits high on the chest wall or is too tight which would limit the reconstructive volume [10].

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_40

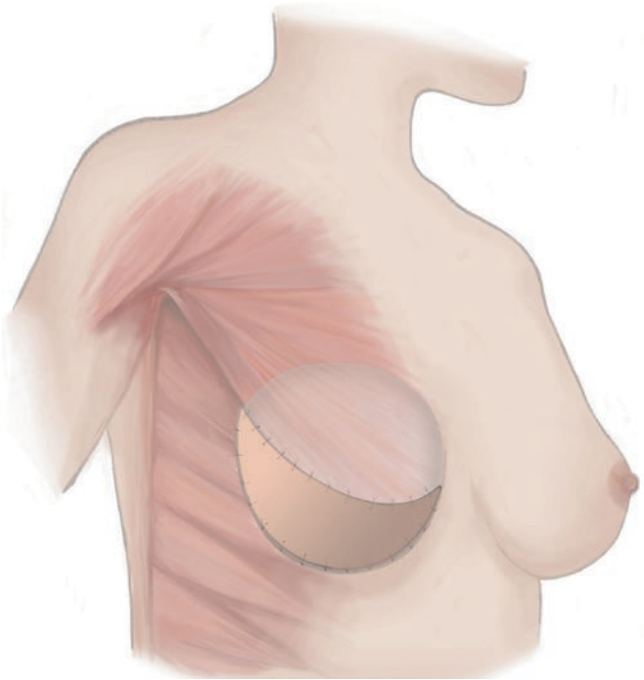

Fig. 40.1 Picture of mesh in breast reconstruction: schematic

The use of meshes enables a greater implant or expander volume to be placed at the original operation to either shorten the second-stage expansion process due to its ability to expand the subpectoral pocket or to remove the second stage entirely [11–13]. In obese patients with large ptotic breasts, there is often a discrepancy between the skin envelope of the patient and the underlying subpectoral pocket. Meshes be can be employed to redress this imbalance and improve the projection vector of the breast [10, 14].

2. *Meshes help to define and control the reconstructive pocket*.

   The use of a mesh along the IMF enables the surgeon to define the inferior aspect of the reconstructive pocket. This control can prevent implant migration and improve aesthetic outcomes by clearly defining the IMF [15–18]. The mesh also acts as a hammock to support the implant/expander and therefore maintain lower pole projection and a natural breast mound shape. Small case series have reported improvements in breast contour, implant placement, lower pole projection and IMF definition using blinded-surgeon assessors [18].

3. *Biological meshes may improve host neovascularisation of the mastectomy skin envelope*.

   Biological meshes may act as a stimulus to surrounding tissue including the skin flap, enhancing neovascularisation via the induction of growth factors in the surrounding host tissue (basic fibroblast growth factor [bFGF], vascular endothelial growth factor [VEGF] and transforming growth factor-beta 1 [TGF-β1]) [19]. Microcirculatory analysis in animal models demonstrated angiogenesis at 4 weeks post implantation on the skin-flap surface with established vasculature on the mesh observed at 8 weeks [20].

4. *Meshes confer additional soft tissue coverage to the prosthesis*.

   The position of the mesh at the infero-lateral pole enables the mesh to provide soft tissue coverage of the prosthesis. This reduces the need for extensive musculofascial dissection. Studies have reported that the increased soft tissue coverage supplied by the mesh can result in reduced capsular contracture around the implant with adjuvant radiotherapy [21, 22]. In addition, by increasing the tissue coverage of the prosthesis, the mesh can act to reduce contour irregularities (rippling, palpable implant) in patients with little subcutaneous fat in the mastectomy flap, thus improving aesthetic outcome [18].

40.3 Types of Meshes for Breast Reconstruction

Various companies have developed a number of meshes for use in breast reconstruction. Types of meshes in breast surgery can be divided into non-biological (synthetic) and biological types (Table 40.1). The majority of surgeons employ the use of biological meshes (also known as acellular dermal matrices/ADMs) in breast reconstruction as they provide a scaffold for host tissue ingrowth [23]. Training provided by manufacturers on the correct use of their product to surgeons and their continued support in its use can influence surgeons' choice of mesh, particularly when there is a learning curve associated with mesh use in breast reconstruction [24, 25].

40.3.1 Non-biological

Non-biological (synthetic) meshes have been used in breast surgery for over 20 years. They are manufactured using a variety of polyglactin, polyglycolic and polypropylene composites. By varying the composition of the mesh, manufacturers can alter its mechanical tensile properties and ability for the body to absorb the mesh. Non-biological meshes can be permanent or absorbable. Although the recent trend in reconstructive breast surgery has been in favour of biologic meshes, non-biological meshes still hold a role in prosthetic breast reconstruction.

Non-biological meshes can be divided into absorbable and non-absorbable meshes. Absorbable meshes in breast surgery include Vicryl (polyglactin 910), Dexon (polyglactin), GalaFLEX (poly-4-hydroxyalkanoate) and TIGR Matrix (copolymer of glycolide- and lactide-degrading fibres

Table 40.1 Soft tissue support meshes and matrices available for breast surgery

Type of soft tissue support	Product details	Clinical evidence
Synthetic		Case series
Absorbable		
Vicryl	Polyglactin 910	*n* = 24; 76 (Loustau et al. 2007; Tessler et al. 2014)

Autologous		
Dermal graft	Abdominal harvest site via mini-abdominoplasty	*n* = 21; 76 (Hudson et al. 2012; Lynch et al. 2013)

with trimethylene carbonate). Non-absorbable meshes include Seragyn BR (bicomponent polyglycolic acid (absorbable) caprolactone/polypropylene (non-absorbable)), TiLoop Bra (titanium-coated polypropylene mesh), PTFE (polypropylene) and Mersilene (polytetrafluoroethylene polyester) [26]. Recently, studies have revisited the use of non-biological meshes in breast reconstruction as they have an established safety profile and cost considerably less than biological meshes [27, 28]. There are no published comparative studies with synthetic versus biological meshes at present. A hybrid biological synthetic mesh, SERI surgical scaffold (Allergan Inc., MA) was recently introduced as a cross-over mesh between synthetic and biological. It is a scaffold made of silk bioprotein, fibroin (Biosilk), which provides strength mechanics similar to synthetic meshes whilst remaining absorbable [29].

40.3.2 Biological

Biological meshes are tissue-derived manufactured meshes. Tissue is processed from a variety of human cadaveric and animal sources to remove the epidermis and cells resulting in an "acellular" matrix (Table 40.1). This is also referred to as ADM (acellular dermal matrix). The majority of biological meshes used in breast reconstruction are derived from processed dermis (cadaveric, porcine, bovine). Other tissue sources include porcine small intestine mucosa (Surgisis) and bovine pericardium (Veritas). Proprietary processing, using a variety of techniques unique to each product, removes the epidermis (in the case of dermal-derived tissue) to leave a non-cross-linked acellular dermal matrix (e.g. Alloderm (LifeCell Corporation, NJ), FlexHD (Ethicon Inc., Somerville NJ), DermACELL (LifeNet Health, VA), DermaMatrix (Synthes, PA), Strattice (LifeCell

Corporation, NJ)) [23]. The resulting mesh is reported to have minimal antigenic properties; however, patients should be counselled in their consent process regarding the mesh composite and carefully screened for previous allergies. A "red breast syndrome" has been reported by Ganske et al. [30]. Patients presented with skin erythema overlying the dermal matrix with punch biopsies of the tissue revealing a delayed-type hypersensitivity reaction suggesting a localised immune host response requiring corticosteroid treatment [30].

Biological meshes have been widely used in immediate and two-stage breast reconstruction in recent years. No head-to-head randomised controlled trials have been completed to date to establish complication rates between the different meshes. Small case series comparing different meshes have been published although these are frequently underpowered and subject to reporting bias; therefore, no clear conclusions can be drawn between the different products on the market. A disadvantage to using biological meshes is that at current market pricings, the direct cost of biological meshes does not appear to offset economic savings related to greater expander fill volumes and a reduction in revision surgery [31, 32]. However, some argue that when the cost-effective incremental cost utility of biological meshes is calculated (due to an increase in quality-adjusted life years with mesh reconstruction), biological meshes can be considered cost-effective [33].

40.4 Why Choose Biological Matrices Over Synthetic Non-biological Meshes?

A recent survey of plastic surgeons within the USA demonstrated that the majority of respondents (84.2%, n = 361) used ADM in breast reconstruction in preference to synthetic meshes [34]. The reasons for this are multifactorial.

There is a paucity of clinical data on the use of synthetic meshes in breast reconstruction in the literature. The majority of data exists for the following meshes: TiLoop and TIGR meshes. The largest case series for TiLoop mesh was reported by Dieterich et al. [35]. Two hundred thirty-one breasts were operated on in primary and delayed implant-based reconstruction. The overall complication rate was 29%. Similarly the TIGR mesh case series by Becker and Lind [36] reported on 112 breasts with a complication rate of 19% in primary breast reconstruction. TiLoop Bra has been associated with a host granulomatous reaction in the skin flap (estimated at 4%) which in the context of recurrent DCIS can create an oncological challenge for cancer surveillance [37]. In addition, in patients with thin skin flaps, there have been reports of TiLoop mesh rippling and palpability [38]. The lack of clinical data on synthetic meshes limits the surgeons' ability to evaluate the product, and therefore it is less in use.

By contrast there are a much greater number of papers reporting on biological matrices in breast reconstruction with longer-term follow-up and larger numbers (n = 6199 cases) [58]. Pharmaceutical industry sponsored research on new biological meshes which influences the surgeons' choice of product. Marketing strategies and keynote speeches from industry-funded surgeons may influence the surgeons' choice of product although it is difficult to quantify. The overriding influence on product choice remains based on the reported lower complication rates with matrices compared with meshes.

Current estimates from meta-analysis of reconstructions with ADM give a pooled complication rate of 18%; however, more recent case series have reported lower rates in experienced surgeons of 5.3–8% [39, 40]. Moreover, the risks of total complications in a recent meta-analysis on ADM use in breast reconstruction concluded that the risks of implant loss and total complications were not significantly different from submuscular implant reconstruction without ADM [40].

40.5 Complications associated with Meshes in Breast Reconstruction

Amongst published literature there is conflict surrounding the overall complication rates associated with meshes in primary breast reconstruction. A number of meta-analyses have been performed by various groups in order to establish if the presence of mesh in the reconstruction confers an increased complication rate to the patient [12, 21, 41–44]. Unfortunately, there is a lack of level I evidence to evaluate this topic, with the majority of studies being small numbered comparative or case series [44] and limited by heterogeneity in study design, outcome measurement, selection and reporting bias [44]. As such, any pooled data from non-randomised studies for meta-analyses on complication rates with meshes has limited validity. In addition, a number of the studies published are funded by companies manufacturing the meshes which leads to considerable publication bias [44]. Only one randomised controlled study has been conducted to date which was stopped early due to poor recruitment [45]. The median complication rate following ADM-assisted immediate breast reconstruction was calculated by Potter et al. as 18% (6–64%), compared with 14% (5–45%) in a standard two-stage expander reconstruction without mesh [44]. There is a general consensus between the systematic reviews on this topic that the use of meshes in breast reconstruction does confer increased overall complication rates; however, the magnitude of this effect remains ill-defined. Comprehensive prospective randomised controlled trials are needed to investigate the true effect of meshes on complication rates. It has

been suggested that the differing complication rates may reflect not only a surgical learning curve for the technique [24, 25] but also variations in patient selection [11].

40.6 Complications Within the Post-operative Period Following Breast Reconstruction Using Matrices and Meshes and How to Manage Them Clinically

1. *Infection*

Despite the aseptic techniques used intraoperatively to prevent infection of the mesh (irrigation in antibiotic solution, changing of surgical gloves intraoperatively, minimal mesh and tissue handling, post-operative intravenous antibiotics) as a foreign body, the mesh can act as a nidus for bacterial ingrowth. Observational data suggests there is an association with infection rate and high intraoperative expander/implant volumes greater than 50%of the total volume; however, this needs to be corroborated [46].

Infection will present as classical signs of inflammation at the site of surgery with purulent discharge, wound swab or blood-positive cultures for bacterial infection and elevated white blood cells and C-reactive protein. This is in contrast to the observed and reported "red breast syndrome" [30] which may present with signs of inflammation without pain and infection markers and cultures will be negative. This condition will settle without antibacterial treatment and can be managed with close observation and simple anti-inflammatory agents.

If diagnosed early, infection may be treated conservatively with intravenous or oral antibiotics; however, if established the patient will require removal of the infected mesh as a secondary operation with removal of the prosthesis. Common organisms associated with implant infections include *S. epidermidis*, *S. aureus*, *S. marcescens* and *P. aeruginosa* [47]. There is no consensus in the use of prophylactic intraoperative and post-operative antibiotics; however, a 5-day course of oral antibiotics post-operatively is a common regimen. Removal of the matrix is surgeon dependent; however, it can be based on its intraoperative appearance. If the matrix appears partially hydrolysed, non-viable or inflamed, then the authors recommend its removal. A recent systematic review found infection rates with mesh reconstructions to vary from 0% to 31% with a combined average of 11.6%. Of note, in skin-sparing mastectomy the natural barrier to infection is compromised, and infection in the post-operative period must be considered [48]. There is a shift in practice to the use of sterile ADM (versus aseptic ADM), which involves terminal sterilisation in an attempt to reduce infection rates further [49].

2. *Haematoma and Seroma*

Although biological matrices are processed to prevent a host antigenic reaction to their implantation in the tissue, they do however cause a tissue reaction which predisposes this type of breast reconstruction to increase seroma formation. In addition, the increased reconstructive pocket volume created by the mesh at the lower pole can create an increased deadspace in the reconstruction which may predispose patients to haematoma and seroma formation. Interestingly, there is a correlation between increasing surface area of the matrix used and the odds of seroma formation [46]. A minimised surgical technique has been described (patching only the lateral area of the reconstruction with a small surface area of ADM; $n = 225$) which reports a reduction in seroma from 3% to 0%, although these results need further validation [50]. Extensive use of electrocautery has also been reported as a risk factor for seroma formation [51].

Judicious use of vacuumed drains post-operatively, soft compression dressings and surgical bras have been effective to reduce the incidence of seroma in these patients, although the drain site must be kept as clean as possible and ideally tunnelled in a long subcutaneous tunnel to minimise exposure of the implant and matrix to outside bacteria [52].

One study reported with these measures that a reduction of 18.6–4.7% ($p = 0.0022$) in seroma was achieved [53]. Seroma formation may also be due to insufficient intraoperative expansion when using a tissue expander as this will also allow fluid to collect in the reconstructive pocket. However, increased intraoperative fill volumes must be carefully considered as the risk of explantation increases with volumes over 300 cc due to increased skin-flap tension which can compromise vascularity especially if the patient has additional risk factors for complications [46].

Drains are often placed to prevent fluid accumulation and removed once drainage is less than 20–30 ml in 24 h. Low-grade seromas can be managed with percutaneous ultrasound-guided drainage; larger seromas and haematomas may require surgical evacuation.

3. *Mastectomy Flap Necrosis and Reconstructive Failure (Explantation)*

Skin-flap necrosis with mesh-assisted prosthetic breast reconstruction has been attributed to mastectomy flap thickness and disruption of the subdermal plexus during surgery. Prior to ADM use, mastectomy flap necrosis was as high as 15%. The additional burden of the mesh on tissue oxygenation demands has been postulated as a reason for the increased flap necrosis rates. Meta-analyses have reported an approximate twofold increased risk in recon-

structive failure with mesh-assisted reconstructions [54, 55] although their conclusions are based on limited evidence.

Minor wound dehiscence and matrix exposure can be managed in the outpatient setting with dressings and close monitoring, but may necessitate wound closure in theatres. Larger areas of skin-flap necrosis will require a return to theatres for debridement plus/minus removal of the matrix and implant in some cases. Placement of an expander will be required to facilitate wound closure.

Increased explantation rates observed with ADM-assisted breast reconstructions may also be in part due to prosthesis removal if mesh removal is required with severe infection. This may not be fully represented in the data reported. Although the mesh or matrix provides additional cover to the implant should skin necrosis occur and in smaller areas of necrosis, the implant can be salvaged. An alternative to explantation and delayed reconstruction in cases of matrix infection has been described. In this technique the implant and matrix are removed, and a negative pressure sponge is placed into the cavity. This maintains the reconstructive pocket until the infection is cleared and the patient can have replacement of the implant on the same hospital admission [52].

4. *Management of the Aesthetic Profile*

Clinical follow-up in the post-operative period includes clinical assessment of the reconstruction at 2 weeks, 3 months, 6 months and 12 months in general. During this time the reconstructed breast will begin to soften and develop into its long-term shape. Repeated aesthetic assessment is required to monitor for the need of further procedures to optimise the end aesthetic result. Autologous fat grafting (lipofilling) of the ADM-assisted implant reconstruction is often required to the upper pole to aid with implant coverage and volume especially in patients with a low BMI. Symmetrisation procedures on the contralateral native breast are often performed in unilateral reconstructions.

40.7 Risk Factors for Complications associated with Meshes in Breast Reconstruction

Since the advent of meshes in prosthetic breast reconstruction, a number of relative contraindications for the technique have been developed with increasing surgical experience [56].

Patients with a high body mass index (BMI) of over 30 and long ptotic breasts are at increased risk of poor wound healing as long skin flaps are prone to ischaemia and infection [11, 24, 46, 57, 58]. In addition, the thickness of the subcutaneous layer (>3 cm in some cases) can prevent significant projection from the prosthesis, impairing aesthetic results and adherence of the mesh to the subcutaneous layer [7]. Patients who have undergone pre-reconstruction radiotherapy to the chest wall are at increased risk of impaired skin-flap perfusion and post-radiotherapy fibrotic changes [7, 46]. The addition of mesh within a prosthetic reconstruction in these patients should be assessed on an individual basis intraoperatively based on skin-flap perfusion to prevent skin-flap necrosis (clinical assessment ± laser Doppler or laser-assisted indocyanine green imaging) [59]. Similarly, heavy smokers are at higher risk of necrosis due to impaired microvasculature and wound healing and therefore reconstructive failure with or without mesh [58]. This increased risk for reconstructive failure has been estimated at up to five times that of non-smokers in prosthetic reconstruction [60]. In addition, patients with non-nipple-sparing mastectomy, implant volumes of 600 ml or greater and age over 50 years are also at increased risk of post-operative complications ($p < 0.001$) [39]. Positive sentinel lymph node sampling and post-operative radiotherapy are not prohibitive to mesh use. Careful assessment of skin-flap perfusion intraoperatively is key to help minimise post-operative complications.

In all patients being considered for mesh-/matrix-assisted prosthetic breast reconstruction, an assessment of skin-flap perfusion should be made intraoperatively. If there is any concern regarding perfusion, the use of biological or synthetic meshes would be contraindicated. In patients with multiple risk factors for complications, an alternative reconstructive option must be considered.

40.8 Patient Selection for Mesh-/Matrix-Assisted Breast Reconstruction: Achieving Good Results

Patient selection is paramount in ensuring a good reconstructive result from ADM-assisted implant reconstruction. The technique is not without its pitfalls, and a considered approach should be used when deciding if the patient is suitable for this technique. The procedure is only 10 years from its conception, and as such, we have limited long-term data for this operation. Similarly, biological matrices in particular have unpredictable long-term characteristics, and as such, in young patients where the reconstruction will require longevity and consistency, autologous reconstructive options must be considered first. Although, as stated previously, the complication rates for ADM-assisted implant reconstructions have reduced with time and surgical experience, they are still considerable with a total rate ranging from 6 to 64%. With the experienced surgeon who is used to this form of reconstruction, the complication rate will be low; however, there is a considerable learning curve to this procedure [24]. This may explain the unacceptably high complication rates reported. Complications may delay adjuvant therapy and cause the patient considerable

psychological stress with repeated procedures especially if faced with reconstructive failure. Although the benefits and good outcomes with this technique are well documented and surgical practice has shifted to ADM-assisted implant reconstruction, it must be remembered that there is little level I evidence to support this technique.

A number of papers have been published presenting surgeons with treatment algorithms to aid the decision in placing mesh when performing prosthetic breast reconstructions [11, 25, 61]. Good aesthetic results with mesh-assisted tissue expander/implant reconstruction have been achieved in the following patients:

- Low BMI (<30)
- Non-smokers
- Small pre-operative cup size
- Patients <50 years old
- Patient unsuitable or refusing autologous reconstruction

In summary, careful patient selection is the most important step prior to ADM-assisted breast reconstruction and will determine in part, along with surgical technique and skill, the overall reconstructive outcome.

How to Manage Complications in Breast Reconstruction

41

Francesca De Lorenzi

Breast surgery is associated with a very low postoperative complication rate and even lower mortality rate. The reported morbidity rates range between 2% and 49% and are increased in cases of axillary surgery and immediate breast reconstruction [1, 2]. In case of reconstruction, the complication rate is still low and does not result in higher readmission rates compared with mastectomy only, therefore supporting the broadened access to reconstruction [3]. Furthermore, immediate reconstruction has been shown to be safe in terms of surveillance for recurrent cancer [3] and timing of systemic treatment delivery [4].

Even though complication rate is low, it represents an important indicator of the quality of surgical care, and, in an era of heightened patient awareness, healthcare providers are striving to identify and implement methods to reduce postoperative complications and ensure patient safety. An accurate preoperative planning is crucial to reduce surgeon's mistakes that can lead to complications. Preoperative evaluation includes drawings, measurements and pictures with the patient in the standing position and the assessment of comorbidities, smoking status and other potential risk factors for complications. These criteria lead surgeons to a tailored reconstructive option for every patient.

When complications occur, their quick identification and an appropriate management are mandatory to lower patient morbidity and improve final outcomes. Not all complications lead to surgical failure if adequately treated. Finally, a strict follow-up of patients with surgical complications is recommended, including an effective communication to patients and a good relationship, necessary to avoid legal litigations.

In this chapter we focus on the main complications after reconstruction and their management. Unsatisfactory results due to surgical mistakes or changing local situations, as volume and shape asymmetries, symmastia, dislocations of the inframammary fold and double-bubble deformities are not investigated.

41.1 Bleeding

It is the most common cause of reoperation in the early postoperative period, both in case of mastectomy and reconstruction or oncoplastic procedures, varying from 0.4% to 1.9% of the patients and generally within the first 4 days from the initial procedure [1].

Although in the vast majority of cases early postoperative bleeding requires surgical revision and haematoma drainage, in few cases a conservative approach may be sufficient, including compressive bandage and single intravenous administration of antifibrinolytic drug (tranexamic acid is the most used medication to prevent fibrinolysis). When fibrinolysis exceeds coagulation, unwanted surgical bleeding may occur despite adequate haemostasis. Because of uncertainty about the effect of tranexamic acid, particularly on vascular occlusive events, it is not recommended for routine use during most surgical procedures [5]. On the contrary, topical application of dilute tranexamic acid at the site of the wound reduces bleeding (Figs. 41.1, 41.2, 41.3) [6].

In case of implant reconstruction, haematoma formation enhances the risk of capsular contracture; therefore, surgical revision may be justified even in case of non-massive bleeding.

Patients with a bleeding disorder are at higher risk of return to operative room for haemorrhagic event, even though the vast majority of them can undergo surgery safely without complications. Balancing the timing of stopping or resuming anticoagulants, risk of embolic or thrombotic events and surgery can be challenging at times and often requires a multidisciplinary approach.

Late haematomas are also described both in case of implant reconstruction [7, 8] and flap donor site [9], presenting several months/years after the reconstructive procedure. Patients with implant present breast swelling and asymmetry generally associated to pain and no bleeding disorders. Many of these

Fig. 41.2 Late haematoma of the left breast, no breast swelling is present, not requiring surgical revision

cases do not have a definitive mechanism of injury or develop symptoms immediately after the triggering event. Sudden enlargement onset or progressive expansions are both described. Ultrasound is an appropriate and cost-effective tool for differentiating between fluid collection and haematoma. Moreover, percutaneous ultrasound-guided needle drainage of fluid collection can confirm fluid nature, and the aspirate can be sent to pathology to rule out malignancy or infection. However, definitive treatment of late haematomas involves surgical drainage and capsulectomy and implant change (implant reconstructions) or sac excision (flap donor sites).

Fig. 41.3 Haematoma of the right breast after oncoplastic surgery conservatively managed

41.2 Surgical Site Infection

Surgical site infections at the donor or mastectomy site are the predominant cause of postoperative morbidity following mastectomy and immediate reconstruction [10]. Significant independent risk factors for infection were identified as BMI greater than or equal to 25 kg/m^2, chronic alcohol use, American Society of Anaesthesiologists classification of 3 to 5, flap failure in autologous or hybrid cases and operative time greater than 6 h [11]. The overall incidence rate of surgical site infection is 3.53% according to the US National Surgical Quality Improvement Program database (years 2005–2009). Patients within the dataset were divided in three groups according to the method of reconstruction: autologous procedures, prosthetic and hybrid type. Adjusting for confounding factors, there is no statistical difference in rates of surgical site infection among the three methods of reconstruction [12]. However, the gravity of surgical site infection is different among the three groups. In implant-based reconstructions, there is a risk of device loss and need for intravenous antibiotics. It generally requires reoperation with either removal of the implant or removal and replacement. Surgical site infection in autologous reconstructions typically does not result in loss of the flap but may result in deformity, the need for prolonged dressing changes and/or later reoperation (Fig. 41.4).

Focusing on infected implants, there is strong evidence that previous radiation therapy confers a significant risk of implant infection and suggestive evidence that simultaneous lymph node dissection increases the risk [13].

In the past, common practice was the immediate removal of the infected breast prostheses. However, the more recent literature has explored options for device salvage [14, 15, 16], changing surgical dogma that dictated foreign body removal in instances of infection. Methods for salvaging an

Fig. 41.4 Infection of the right breast after implant-based reconstruction

infected device have included systemic antibiotics combined with either conservative wound drainage or antibiotic lavage, capsulotomy/capsulectomy and device exchange, capsule curettage and continuous antibiotic irrigation. Treatment strategy is based on the response of the infection to initial antibiotic therapy and on the availability of soft tissue coverage (possible association to threatened or actual implant exposure). The severity of infection is an important factor in predicting the outcome of attempted salvage. The nature of infection may influence the ultimate outcome as well [17]. Organisms such as common skin flora may be treated with a high success rate, but organisms such as *Pseudomonas* species or Gram-negative rods may not be easily treated, and device removal is more likely indicated. Finally, if overwhelming localized infection or systemic sign of infection persists, further salvage attempts should be abandoned.

Finally, a further management strategy successfully indicated in case of mild infection and exposed implant is prosthesis explantation and immediate autologous reconstruction [18].

41.3 Necrosis and Wound Dehiscence

41.3.1 Managing Skin and Fat Necrosis After Oncoplastic Procedures

Glandular necrosis is the most challenging complication of oncoplastic procedures. Aggressive glandular undermining from both the skin and pectoralis muscle (dual-plane undermining) can lead to glandular necrosis in fatty breasts. Its incidence varies up to 13.4% [19, 20] in the literature. Imaging evaluation after oncoplastic surgery revealed fat necrosis in 18% of the cases on clinical examination, in 15% with ultrasound and 7% confirmed on pathology [21]. Non-healing wounds are recorded in 8.6% of the patients undergoing oncoplastic surgery [22]. These rates can be considerably reduced, incorporating the evaluation of breast density into the decision-making process [23]. In fact breast density predicts the fatty composition of the breast and determines the ability to perform extensive breast undermining and reshaping without complications. Breast density can be classified into four categories based on the Breast Imaging Reporting and Data System (BIRADS): fatty (1), scattered fibroglandular (2), heterogeneously dense (3) or extremely dense breast tissue (4) [24]. Low-density breast tissue with a major fatty composition (BIRADS 1/2) has a higher risk of fat necrosis after extensive undermining. Other risk factors for fat necrosis are diabetes, smoking habitus and previous irradiation of the breast.

Areas of fat necrosis can become infected and cause wound dehiscence resulting in postoperative treatment delay. They are usually managed conservatively, with daily dressing and antibiotic therapy. Surgical debridement is sometimes necessary to accelerate the healing process.

Fat necrosis can lead to scar retraction and deformities in the long term, therefore requiring surgical correction of sequelae.

41.3.2 Managing Flap Necrosis

It is due to an insufficient blood supply or drainage of the flap. Different mechanisms are responsible in case of pedicled or microvascular flaps, and the final result is the loss of part or the whole flap.

In case of pedicled transfer, flap necrosis is generally associated to peripheral venous congestion rather than arterial ischaemia. Important flap loss (greater than 25% of the transfer) is exceptional, and it may be related to preoperative risky factors as pre-existing scarring, smoking, obese and diabetic patients or thrombotic disorders. Massive abdominal flap necrosis can be also related to technical errors during the flap harvesting (traction of the pedicle) or insetting (twisting or torsion of the pedicle). Moderate flap loss (between 5% and 25%) occurs more frequently, and it is often related to venous congestion that will be the cause of necrosis. In both situations early surgery is recommended as soon as the limits of cutaneous venous congestion are well defined (generally on second postop day) and before thrombosis spreads to a larger portion of the flap. These situations generally require also late revisional surgery to correct the sequelae of the necrosis and eventual asymmetries with the contralateral breast (Fig. 41.5).

In case of minimal skin necrosis of pedicled flaps (less than 5% of the transfer), reoperations are not necessary, and the wound spontaneously evolves. Postoperative care is simple and generally managed by patients themselves.

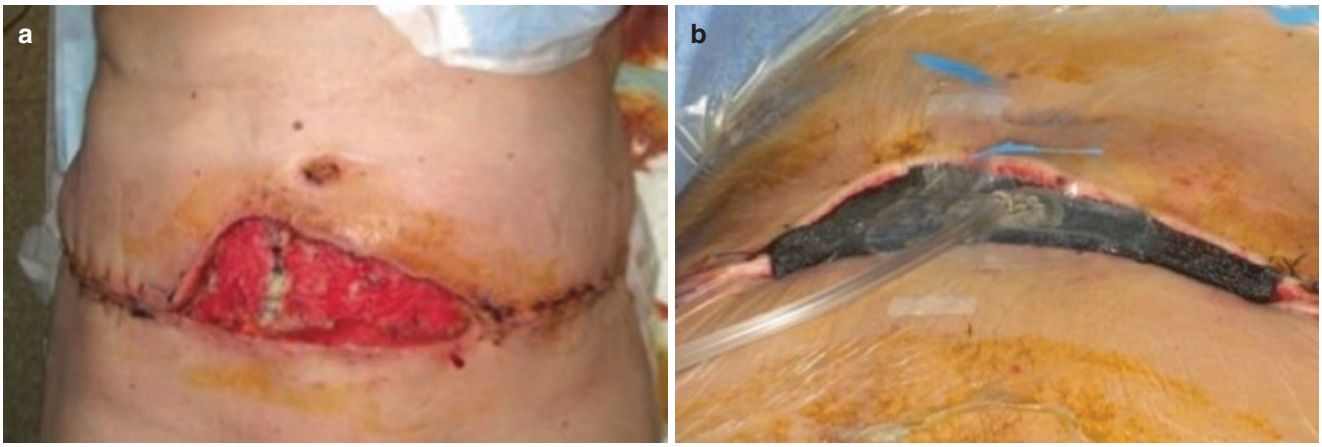

Fig. 41.5 Necrosis of the abdominal wall (**a**) after pedicled TRAM breast reconstruction. After debridement primary closure is not possible and negative-pressure wound therapy is a good solution (**b**)

In case of microvascular transfers, thrombotic complications are the major barrier to successful reconstruction, and they may be responsible of whole flap loss. For this reason, those patients candidate to microvascular transfers should be questioned about hypercoagulable history at the first consultation (family history of abnormal blood clotting, thrombosis in unusual sites, idiopathic or recurrent blood clots, a history of miscarriages, stroke at a young age). Unfortunately, thrombophilias remain a preoperatively silent and frequently undetected physiologic status against microvascular tissue transfer [30].

Routine postoperative care generally includes aspirin daily administration for coronary thrombosis risk reduction and potential enhancement of vascular patency as well as venous thromboembolism prophylaxis with subcutaneous heparin and sequential compression devices [31]. Microsurgical exploration is necessary for thrombotic events in about 7% of the cases [31]. It is due to arterial insufficiency (white and cold flaps, without turgor or Doppler signal) or venous insufficiency (blue and cold flaps, with fast capillary refill). Overall microvascular salvage rate is about 89% with a combination of intra-arterial, subcutaneous/intramuscular and intravenous tissue plasminogen activator, microvascular explorations and therapeutic multiagent anticoagulation/antiplatelet therapy.

41.3.3 Managing Mastectomy Flap Necrosis

It is a significant clinical morbidity after skin sparing and nipple and areola sparing mastectomies, related to the mastectomy itself and not to the reconstructive procedure. The incidence of native mastectomy skin necrosis after breast reconstruction ranges from 6% to 30% in retrospective series [25]. It is significantly higher in patients with higher mastectomy weight and body mass index, which correlates with breast size and subsequent mastectomy weight and in cases of diabetes. It is significantly more frequent in smokers, regardless of the type of reconstruction [26, 27]. Therefore, smokers undergoing reconstruction should be strongly urged to stop smoking at least 3 weeks before their surgery. Mastectomy incision type may influence its incidence [28].

Skin flap necrosis can be defined as mild (no intervention needed), moderate (requiring at least office debridement) or severe (surgical debridement needed, implant loss or healing not complete at 8 weeks) [29]. A not healed wound by 8 weeks postoperatively indicates a severe degree of ischaemia or wound-healing problems, which may be associated with infection and increased risk of dehiscence and can potentially delay adjuvant chemotherapy or radiotherapy (Figs. 41.6, 41.7, 41.8).

A different management is recommended in case of autologous or implant reconstructions. The benefit of autologous reconstruction is the possibility of healing by secondary intention with a well-vascularized flap at the base of the wound. This is in contrast to implant-based reconstruction where mastectomy skin loss increases the risk of implant exposure, necessitating earlier and more aggressive intervention with debridement and closure.

41.3.4 Managing Necrosis at the Donor Site

Necrosis of the anterior abdominal wall is observed typically in the infraumbilical region, which occasionally involves the umbilicus as well, and it is more frequent in smokers and obese patients [26, 32]. In fact, abdominal flaps are widely undermined and depend on a random blood supply unlike the axial vascular source of TRAM and DIEP flaps.

Similarly, in case of latissimus dorsi reconstruction, marginal necrosis of the dorsal wound may occur especially in case of closure with tension (extended latissimus dorsi flap).

According to different degrees and the extent of necrosis, wound care treatment modalities include debridement, wet-

Fig. 41.8 Total flap necrosis after left reconstruction with microvascular transfer. Early microsurgical exploration failed

to-dry dressing changes and negative-pressure wound therapy. In case of massive necrosis, when primary closure is not possible after debridement, negative-pressure wound therapy may be an appropriate solution. The system generates negative pressure resulting in approximation of the wound edges, aspiration of infectious debris and exudates, reduction of oedema, increase in blood flow, promotion of granulation tissue generation and preservation of a wound-friendly moist environment [33].

In case of long-term chronic abdominal wound conservative treated, the risk of acute infection increases, and it may require the removal of the underlying abdominal mesh if present. If not, a chronic skin fistula may occur. If germs affect the mesh located behind the anterior rectus fascia, superficial wound debridement, even combined with adequate antibiotic therapy, is not adequate. The removal of the contaminated mesh is mandatory, which can weaken the abdominal wall.

In any case of healing problems at the donor site, revisional surgery may be necessary to correct scarring and deformities.

41.3.5 Pyoderma Gangrenosum

It is an inflammatory neutrophilic dermatosis characterized by painful, sterile ulcerations, bullae or pustules [34]. The aetiology is unclear, but it is thought to involve autoimmune dysfunction with dysregulation of the innate immune response. It is often associated with other autoimmune diseases as inflammatory bowel disease, rheumatoid arthritis, hematologic dyscrasias and connective tissue diseases. The so-called postoperative pyoderma gangrenosum is defined as the pathergic development of pathognomonic lesions in the surgical incision [35]. The typical presentation is an initial erythema of the recent surgical site, and afterwards the wound may dehisce or develop small punctate ulcerations that eventually coalesce, often associated with fever and leukocytosis. A wound infection is often diagnosed and antibiotics are initiated, as disproportional rapid wound breakdown is the typical presentation of necrotizing fasciitis. Even with negative wound cultures, the clinical presentation of postsurgical pyoderma gangrenosum still seems to favour the diagnosis of wound infection. Unfortunately, this misdiagnosis tends to result in prolonged courses of ineffectual antibiotics and surgical debridement that exacerbate and accelerate the problem by perpetuating the pathergic response in skin that was yet unaffected. Biopsies tend to show non-specific neutrophilic inflammation (Fig. 41.9) [36].

Fig. 41.9 Initial erythema and small punctate ulceration at the surgical site 6 days after right mastectomy and immediate reconstruction with implant (**a**). A wound infection is often diagnosed and antibiotics are initiated. The ulcerations coalesce (**b**—8 days postoperatively and **c**—9 days postoperatively). After systemic corticosteroids therapy, surgical debridement was necessary and successful (**d**—13 days postoperatively)

Awareness of postoperative pyoderma gangrenosum can help early diagnosis and an appropriate management to decrease patient morbidity. Systemic corticosteroids and immunomodulation agents are the first-line therapies; surgical wound debridement and reconstruction (skin grafts) are often necessary to expedite the healing process only if appropriate medical therapy has already initiated [37]. Postoperative pyoderma gangrenosum is a diagnosis of exclusion but should be considered in the differential diagnosis of postoperative wound dehiscence and infection.

41.4 Seroma Formation

Seroma is defined as a fluid collection that can occur both in case of flap reconstruction (at the donor site) and implant reconstruction (around the prostheses).

41.4.1 Managing Seromas at the Donor Site in Flap Reconstruction

Donor site seroma is the most common complication after latissimus dorsi reconstruction reported in the current literature with rates varying from 6% to 95% [38]. Postoperative seroma occurs in a lower percentage of breast reconstruction with abdominal flaps (2–13.5%) [39]. Seroma formation inevitably complicates any extensive surgical dissection and disruption of tissue planes that results in a dead space.

The consequences of developing a donor-site seroma are additional visits to the outpatient clinic for percutaneous aspiration as well as an increased risk of infection.

Several techniques have been described to prevent seroma formation. They minimize the "pocket" created at the donor site. Fibrin glue and quilting sutures are both performed for this purpose [40]. The principle of quilting is to promote flap apposition that facilitates healing. Finally, specially designed supportive garments may reduce seroma formation by applying external pressure on the donor site without jeopardizing the donor vessels.

41.4.2 Managing Seromas Around Breast Implants

Fluid collection around implants is a common event in the immediate postoperative period after drain removal. In case of small amount of serum, it could be asymptomatic, and the excess fluid spontaneously reabsorbs. In case of moderate or large seromas, breast swelling occurs, and percutaneous puncture and drainage are necessary. Ultrasound-guided drainage represents another solution.

The occurrence of late seromas, developing at least 12 months after the most recent breast implant surgery, is a rare event, reported in 0.6% of anatomical silicone form-stable implants [41]. It ranges from 0.4% in primary augmentation patients to 0.9% in reconstruction revision subjects. Late seromas appear as clinically symptomatic breast swelling. They are arousing increased interest in both cosmetic and reconstructive surgery since recent reports describe a possible rare connection between breast implants and anaplastic large cell lymphoma (ALCL), as these tumours often present as late seromas [42, 43, 44, 45].

Late seromas are often related to some sort of trauma and shearing forces between the capsule and textured implants (mechanical theory) [46] or low grade, subclinical infections (e.g. mycobacterium or biofilm—infectious aetiology) [47, 48]. In the vast majority of cases, they appear to be idiopathic, without a clear evidence of infection or malignancy [49].

There are a variety of recently described methods to manage late seromas [50]. Early acquisition of seroma fluid is recommended to rule out infection and malignancy with microbiology and cytology evaluation. The surgeon must decide whether to proceed with percutaneous (ultrasound-guided drainage) versus open therapeutic drainage of the fluid collection. If the decision is surgical drainage, the capsule needs to be inspected to determine whether local biopsy or total capsulectomy is necessary. Implant replacement also needs to be considered. A standard oncological evaluation is recommended to detect associated palpable or radiological masses in the breast or capsule or in the axilla. In fact, although the most common presenting sign of implant-related ALCL is late seroma, in some cases it presents as a mass adherent to the capsule, with or without associated fluid [45].

In our experience, the first approach is percutaneous puncture with culture and cytology. If no suspicious mass is present and fluid drainage resolves the problem, nothing further needs to be done. On the other hand, in case of recurrent seromas, the more definitive and reliable approach appears to be the surgical drainage associated to implant change and possible capsulectomy. In fact, implant-related ALCL tumour cells are usually found both in the fluid and the capsule, but occasionally they are found only in the capsule. In these cases, capsulectomy is essential for diagnosis [45].

41.5 Flap Reconstructions: Donor Side Morbidity

41.5.1 Abdominal Hernia and Bulging, Abdominal Asymmetries

After pedicled TRAM flap reconstruction, parietal complication may occur due to rectus muscle and fascia harvest and relaxation of the fascial suture. Even in cases of DIEP flaps,

Fig. 41.10 Abdominal hernia after right breast reconstruction with a pedicled TRAM flap

sparing the muscle and the fascia, intramuscular perforator dissection may lead to morbidity [51]. Chang et al. [52] reported an overall hernia/bulge incidence of 5.9% after abdominal-based free flap reconstruction, varying from 3.3 to 9.9% depending on the type of free flap and if these were unilateral or bilateral reconstructions.

Weakness of the abdominal fascia is responsible of laxity and bulging in the infraumbilical region. It can be corrected by plication of the fascia (re-tension) and reinforcement with a preaponeurotic mesh (Fig. 41.10).

Most troublesome are abdominal hernias, which can be localized in the epigastric region (pivot point of the pedicled transfer) or below the umbilical region (anatomical fascia weakness below the arcuate line). They should be treated as if they are symptomatic. A reinforcing mesh is generally used.

41.5.2 Shoulder Function

Latissimus dorsi muscle primarily contributes to shoulder adduction, extension and internal rotation. There is a general consensus that after latissimus dorsi rotation or removal, the actions of synergistic muscles of the shoulder joint compensate for the missing muscle when it comes to the mobility of the shoulder and to carrying out daily activities [53, 54, 55]. Conversely, there are several reports of decreased shoulder strength, but the severity of this loss varies [56].

41.6 Implant Exposure and Extrusion

It is due to insufficient soft tissue or muscular coverage of the implant, and many reasons might be responsible: thin mastectomy flaps or necrosis of the mastectomy flaps and/or deficit in the muscular pocket or wound dehiscence.

It occurs in 0.25–8.3% of implant-based breast reconstructions [57]. In case of actual exposure, the assumption is made that contamination or mild infection is present even though there may be no clinical evidence of infection. Therefore, all exposed devices are treated accordingly. Salvage attempts and decision-making process is based on the severity of local infection and on the availability of soft tissue coverage. Thus, initially the patient is covered with antibiotics, the device is removed, a capsulectomy is performed, the pocket is curetted, a new device is placed and closure is performed with local or distant tissue [17]. If sufficient local tissue is present, local tissue rearrangement may be adequate. If local tissue is not adequate, a distant flap should be used for coverage. If a flap has been used in the initial procedure before implant exposure and this distant tissue is unavailable for a salvage procedure, the implant should be removed in favour of a delayed reinsertion (Fig. 41.11).

Fig. 41.11 Left implant exposure and extrusion after necrosis of the mastectomy flaps and wound dehiscence

41.7 Implant Rupture

It is defined as a gap in implant envelope leading to silicone gel or saline diffusion outside the implant itself. Saline prostheses are almost abandoned nowadays; in case of rupture, the implant deflates, and it is clinically evident. Conversely, the majority of implants on the market are silicone ones composed of a textured silicone elastomer shell and filled with cohesive silicone gel. Cohesive gel is formed by increasing the number of cross-links between gel molecules, with results in form-stable implant less likely to fold or collapse.

Rupture occurs as a result of biochemical degradation of silicone, physical trauma to the elastomer at the time of implantation or as a result of mechanical injuries during mammograms, closed capsulotomies or accidents. Intracapsular rupture is defined by the presence of silicone outside the implant shell and within the intact fibrous capsule. Extracapsular rupture is defined by the presence of silicone into surrounding tissues and lymph nodes.

The incidence of implant rupture widely varies in the literature [58, 59], and its prevalence increases over time. It depends on the type and generation of implants, different detection methods, mean implant life span and different follow-up period. In 2015, 10-year results from the Natrelle 410 anatomical form-stable silicone implants have been published. The overall rupture rate (suspected and confirmed) in those patients who underwent bi-annual MRI to screen for silent implant rupture is 9.7% of implants at a 10-year follow-up [41]. Rupture rates are even lower using Mentor MemoryShape implants, but results at a 10-year follow-up are not yet available, and patients have been screened with MRI at 8 years [60, 61, 62].

The majority of silicone implant ruptures are asymptomatic and are detected during routine follow-up ultrasounds. In case of suspicious images with ultrasound, MRI is recommended. MRI is the most accurate technique to evaluate implants integrity. Its sensitivity for rupture is between 80% and 90% and its specificity between 90% and 98% [63].

Explantation is the gold standard, with the removal of the capsule to include eventual silicone residuals.

41.8 Capsular Contracture

The pathologic process of capsular contracture manifests from excessive peri-implant fibrosis or capsular formation beyond the normal state. Clinically, it can manifest as pain, hardening of the breast and distortion of the reconstructed breast. The rate and risk of capsular contracture remain controversial. It increases over time [64], and it is reported as baker III and IV in 14.5% of the patients at 10 years after reconstruction with the Natrelle 410 anatomical form-stable silicone breast implant [41]. A meta-analysis (level Ib evidence) demonstrated that textured implant shells clearly reduce the risk of contracture for subglandular implants [65]. Review of randomized controlled trials found a significantly increased risk of contracture for smooth subglandular implants [66]. Its incidence is significantly higher in cases of irradiated beasts [67].

Despite advances in breast implant surgery, it is the most frequent cause for implant revision, and capsulotomy and capsulectomy represent the standard treatments.

The exact cause for capsular contracture has yet to be determined. Several theories on the pathomechanism and origin of capsular contracture have been suggested. These theories underpin the pivotal role of an inflammatory reaction, which leads to induction of fibrosis and shrinking of the capsule. A non-specific inflammatory process directed against silicone and periprosthetic bacterial contamination is considered to be the primary pathogenic mechanism leading to excessive local inflammation [68]. Therefore, treatment strategies also include the use of targeted inhibitory molecules as the leukotriene inhibitor zafirlukast to affect capsule formation [69, 70]. These drugs are also used in the prophylaxis of contracture. Implant insertion with a funnel may also decrease capsular contracture reducing skin contact and potential contamination of the implant pocket with skin flora [71].

Finally, more recently, acellular dermal matrices have been proposed to decrease the incidence of capsular contracture in implant-based reconstruction. They are hypothesized to block the inflammatory process suspected to be the trigger in the pathogenesis of capsular contracture, and several animal models support this statement [72]. In the clinical setting, the higher level of evidence (level III) is represented by a study comparing capsular contracture rates in a cohort of women who had acellular matrix-assisted implant reconstruction against a cohort who underwent standard implant reconstruction [73]. This study concluded that acellular dermal matrix is associated with less capsular contracture.

41.9 Systemic Complications

41.9.1 Pneumothorax

Pneumothorax remains a serious although rare complication of breast reconstruction. Most cases in the plastic surgery literature relate to breast augmentation, but they are described also in case of tissue expander/prosthesis placement [74] and autologous reconstruction [75]. The American National Incidence of pneumothorax after expander reconstruction is 0.55% per patient [76].

When pneumothorax occurs, it may cause significant morbidity. Delay of diagnosis may be fatal as the patient can quickly become hemodynamically unstable.

Clinically it can be classified as spontaneous (no obvious precipitating cause present) or traumatic. In patients with breast implant, it may be a direct complication of surgery (pleural damage) or secondary to pulmonary blebs. The mechanism of damage to the parietal pleura during surgery may include intraoperative pleura laceration during capsulectomy or creating a new muscular pocket, needle puncture for anaesthetic infiltration and pleural rupture due to high anaesthetic ventilation pressure. Falling SpO_2 levels despite oxygen supplementation generally occur. Chest auscultation reveals reduced air entry on the affected side, and chest X-ray can confirm the diagnosis. Chest drain insertion is required for successful treatment, determining good reinflation of the lung seen on check chest X-ray.

41.9.2 Pulmonary Embolism

Incidence of symptomatic pulmonary thromboembolism postoperatively after breast reconstruction is low, and it is reported in 0.7% of the patients after pedicled TRAM reconstructions [39]. Unfortunately, however, this number underestimates the true value because asymptomatic events may not have been identified. These accidents may present a dangerous and dreaded complication, even towards mortal pulmonary embolism.

Both latissimus dorsi and pedicled TRAM are associated with risk factors for deep vein thrombosis and pulmonary embolism including underlying malignancy (immediate reconstructions), operation time and transient immobilization in the postoperative period [77]. Abdominal flaps, however, have been thought to decrease venous return of the pelvis and lower extremities in superficial veins, increasing the risk of deep vein thrombosis and subsequent pulmonary embolism. In addition, an abdominal flap generally has a longer period until full ambulation in comparison with latissimus dorsi reconstruction [78]. This further supports the importance of proper deep vein thrombosis prophylaxis. The combination of the type of reconstruction (immediate vs. delayed procedures, abdominal flaps, dermolipectomy) and the predisposing individual patient risk factors (age, obesity, varicose veins, venous thromboembolism history, coagulation disorders) defines the level of thromboembolic risk that can be mild, moderate or high [79]. Prevention is based on general guidelines (early mobilization) and, at every level of potential risk, on the use of low molecular weight heparin and/or wearing antithrombosis stockings. If thromboembolic complications occur, their surveillance with duplex venous scanning of lower limbs is recommended at an early stage as well as appropriate systemic treatment to avoid evolution towards pulmonary embolism.

Medical Oncology

Adjuvant Systemic Therapies by Subtypes: Guidelines

42

Antonella Palazzo and Marco Colleoni

42.1 Introduction

The adjuvant treatment of breast cancer involves a multidisciplinary approach including surgery followed by medical treatments and radiotherapy as clinically indicated. Adjuvant systemic treatment aims to reduce the risk of breast cancer relapse, in terms of locoregional and distant events, and to prolong survival. Adjuvant treatment options for primary breast cancer include chemotherapy, endocrine therapy, biological therapy, or combination of these. Decision on adjuvant systemic therapy should be balanced on the risk of relapse, patients' comorbidities and preferences, and the potential absolute treatment benefit. It should be tailored according to tumor burden and biological behavior of cancer.

Invasive breast cancer has been historically classified according to histopathological parameters such as histomorphologic features, tumor size, nodal involvement, and presence of metastases. Recently, it has been more evident that breast cancer heterogeneity reflects a high complexity of molecular composition with different subtypes varying in their characteristics and natural history.

Perou et al. described different gene expression patterns of breast cancer. Through an extensive genomic analysis of breast cancers, authors identified four molecular subtypes (luminal A, luminal B, HER2 enriched, and basal-like) with different prognoses [1, 2].

In order to better define treatment decision, breast cancer subtypes can be defined by the use of multiparameter molecular tests such as MammaPrint (Agendia BV, Amsterdam, Netherlands), Oncotype DX (Genomic Health Inc., USA), PAM50 risk of recurrence (ROR) score (Prosigna Breast Cancer Prognostic Gene Signature Assay; NanoString Technologies, Seattle, WA), EndoPredict (EP) assay, and Breast Cancer Index [3–7]. Although in selected areas of the world multigene assays are readily available, due to their costs, their use is not possible in many countries. Surrogate pathological classification of subtypes has been studied by immunohistochemical (IHC) determination of estrogen receptor (ER), progesterone receptor (PgR), human epidermal growth factor receptor (HER2) status, and proliferative index (Ki-67 index). Even if similar to the intrinsic subtypes, the pathological classification is not entirely the same. About 72% of triple-negative tumors are basal-like, 9% HER2 enriched, 6% luminal B, and 5% luminal A [8].

The future of breast cancer treatment is based on developing regimens that provide the greatest clinical benefit with lower side effects. Molecular diagnostic tests can provide prognostic information about cancer in its early stages. International guidelines recognize the assay's ability to predict a patient's risk of recurrence or benefit from chemotherapy. The assays are all considered usefully prognostic for years 1–5. PAM50 ROR® score is considered to be clearly prognostic beyond 5 years, whereas only Oncotype DX showed its value in predicting the usefulness of chemotherapy [9, 10, 11, 12].

According to the widely used immunohistochemistry classification of subtypes, adjuvant treatment guidelines will be examined for hormone receptor-positive HER2-negative disease that include two distinct prognostic groups, "luminal A-like" and "luminal B-like," based on Ki-67 expression level or on the expression of PgR; the "HER2-positive" group (which expresses HER2 by IHC or amplification detected by fluoresce in situ hybridization [FISH]) and the "triple-negative" group (which is negative for ER, PgR, and HER2).

42.2 Luminal-Like A and Luminal-Like B HER2-Negative Subtypes

The luminal-like subtypes are characterized by tumors that are clinically described as ER positive and a relatively high expression of many genes expressed by breast luminal cells.

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_42

The Cancer Genome Atlas Research Network described ER-positive (luminal) breast cancers as the most heterogeneous in terms of gene expression, mutations, and copy number changes. The heterogeneity is not only for the luminal genes expression. In fact, luminal subtypes were further distinguished into at least two subgroups on the basis of their "proliferation cluster": luminal A and luminal B tumors. The proliferation cluster is a group of genes whose levels of expression correlate with cellular proliferation rates. The TP53 pathway is differently activated in this subtype, with a low TP53 mutation frequency in luminal A (12%) and a higher frequency in luminal B (29%). Other differences between luminal A and B included the hyper-activation of some transcriptional activity as c-MYC in luminal B breast cancer. This cluster also included the genes encoding the widely used immunohistochemical markers of cell proliferation as Ki-67 index [13].

The luminal A subtype of breast cancer has the best prognosis among all subtypes [2]. European guidelines define the clinicopathological surrogate of luminal A-like subtypes as those tumors with high estrogen receptor expression; low proliferation index; high progesterone receptor expression (with a suggested cutoff value of 20%); negative HER2 and a low tumor burden, meaning a lower or absent nodal involvement (N 0–3); and smaller T size (T1 or T2) [9, 12].

All luminal cancers should be treated with endocrine therapy (ET). ET is indicated in all patients with detectable ER expression (defined as ≥1% of invasive cancer cells) independently of the use of chemotherapy and/or targeted therapy. Hormonal therapies include selective estrogen receptor modulators (SERMs), such as tamoxifen, and aromatase inhibitors. The choice of agent is primarily determined by the patient's menopausal status (see Chap. 4). Other factors include side effect profiles.

It is among those luminal breast cancer patients that clinicians express highest uncertainty about optimal treatment and chemotherapy indications, as clinicians seek to avoid overtreatment and undertreatment. Results from two randomized trials of adjuvant chemoendocrine therapy for node-negative breast cancer patients showed no benefit of chemotherapy in the subgroup with high ER receptor, negative HER2, and low proliferation [14].

Moreover, the first retrospective studies with generation multigene signatures, as Oncotype DX, also showed that among patients with ER-positive breast cancer, there is no benefit of chemotherapy treatment for the low proliferative tumors. The 21-gene recurrence score (RS) assay (Oncotype DX; Genomic Health Inc., Redwood City, CA) quantifies risk of distant recurrence in patients with node-negative, estrogen receptor (ER)-positive breast cancers and has been validated retrospectively in two independent datasets. In the NSABP-B20 trial, patients with ER-positive, node-negative breast cancer were randomized to receive tamoxifen or tamoxifen plus a first-generation chemotherapy regimen (cyclophosphamide, methotrexate, and 5-fluorouracil). Chemotherapy showed a clinical benefit only in patients with high recurrence score (RS > 31) [15].

Albain et al. investigated whether the RS was prognostic in patients enrolled into the phase III SWOG-8814 trial, in which postmenopausal women with node-positive, ER-positive breast cancers were randomized to receive tamoxifen alone or tamoxifen plus a second-generation chemotherapy regimen (cyclophosphamide, adriamycin, and fluorouracil [CAF]). The study showed no benefit of CAF in patients with a low RS (score < 18; log-rank $p = 0.97$; HR 1.02, 0.54–1.93), while an improvement in DFS was seen for those with a high RS (log-rank $p = 0.033$), after adjustment for number of positive nodes [16]. This trial demonstrated that patients with high RS will benefit from chemotherapy, whereas those with low RS did not, irrespective of nodal burden.

Pending results from ongoing trials, the TAILORx trial (Trial Assigning IndividuaLized Options for Treatment) and the MINDACT trial (Microarray In Node-negative and 1–3 positive lymph node Disease may Avoid ChemoTherapy), no prospective data are available about the use of biological subtypes as eligibility criteria to adjuvant study treatment.

Recently partial results from TAILORx trial have been published with an analysis of the women in the lowest-risk group [17]. The findings showed that for the cohort of patients who had a recurrence score of 0–10 and were assigned to receive endocrine therapy alone without chemotherapy, at 5 years, in this patient population, the rate of distant relapse-free survival was 99.3%, of invasive disease-free survival was 93.8%, and of overall survival was 98.0%. These results provide prospective evidence that the gene expression test can identify women with a low risk of recurrence who can be spared chemotherapy.

On the other hand, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis from analysis of 123 randomized trials showed that taxane-plus-anthracycline-based regimens improve substantially the long-term, relapse-free, and overall survival independently by age, nodal status, tumor diameter, differentiation, and subgroup [18].

According to the available evidence, the National Comprehensive Cancer Network (NCCN) guidelines indicate to add chemotherapy to endocrine therapy for ER-positive HER2-negative node-positive disease (one or more ipsilateral lymph nodes) and for node-negative disease both for intermediate and higher recurrence score risk subgroups of patient tested by Oncotype DX test [11]. The 2015 St. Gallen Consensus report and European Society for Medical Oncology (ESMO) guidelines recommend to consider chemotherapy other than endocrine therapy not only in patients with multiparameter molecular marker at

"unfavorable prognosis" if available but also looking at clinicopathological surrogate classification for luminal-like A disease if four or more nodes are involved or if there are characteristics of luminal-like B disease, such as lower ER/PgR with clearly high Ki-67, more extensive nodal involvement, histological grade 3, extensive lymphovascular invasion, and larger T size (T3) [9, 12].

42.3 Luminal B-Like HER2-Positive Subtypes and HER2-Enriched Subtypes

The human epidermal growth factor receptor 2 (*HER2*) gene (also referred to as *ERBB2*) is amplified and/or overexpressed in approximately 15–20% of primary breast cancers.

Gene expression studies revealed that HER2-positive subtypes were characterized by an expression of several genes in HER2 amplicon and a significant frequency of TP53 mutation (71% of cases). More extensive studies with 50-gene test "PAM50" [7, 19] depicted HER2-enriched subtype as clinically HER2 positive, with high proliferation index, low expression of luminal genes, and lack of expression of basal cluster. The surrogate immunohistochemical markers to distinguish this subtype are hormone receptor-negative (ER and PgR) and HER2-positive breast cancer.

HER2-positive breast cancer could also express hormone receptors. This histopathological subtype is similar to the genome intrinsic subtype known as luminal B HER2-positive (hormone receptor positive and HER2 positive).

Overexpression of the ERBB2 oncoprotein is a well-known poor prognostic factor, and studies on clinical outcome of different subtypes revealed also that the basal-like and the HER2-positive subgroups were those with the shortest survival and relapse-free survival [2].

Trastuzumab is a recombinant humanized monoclonal antibody. The addition of trastuzumab to conventional chemotherapy in breast cancer patients overexpressing HER2 dramatically improves disease-free and overall survival in the adjuvant setting, with a 10% absolute improvement in disease-free survival (DFS) and 9% increase in 10-year overall survival (OS) [20–22].

Adjuvant treatment guidelines are unanimous to indicate chemotherapy with anthracyclines followed by a taxane-containing regimen concurrent to trastuzumab for patients with stages 2 and 3. Some specific considerations among guidelines were developed for stage 1 disease. For pT1b (tumor diameter, 0.6–1 cm) and pT1c (tumor diameter, 1.1–2 cm) tumor, chemotherapy associated to trastuzumab is also recommended [23]. The preferred chemotherapy regimen remains anthracyclines and taxane based specially for pT1c tumors, but also regimen avoiding anthracycline (paclitaxel combined to 1 year of trastuzumab) is a considerable option for pT1b tumors, based on the excellent outcome recently showed [24]. In selected cases with stage 1 disease and a very low risk, as pT1a tumor (tumor diameter 1.1–5 mm), chemotherapy and trastuzumab can be omitted.

Luminal B HER2-positive disease, differently from HER2-enriched subtype (non-luminal), requires endocrine therapy in addition to chemotherapy plus trastuzumab. Endocrine therapy should be given sequentially to chemotherapy, concomitantly to trastuzumab, and the choice of endocrine therapy should be always suggested by patient's menopausal status. No randomized trials exist to support endocrine therapy plus trastuzumab avoiding chemotherapy in this tumor subtype.

Only in selected cases of contraindications to chemotherapy or patient refusal might the combination of targeted agents (endocrine therapy and trastuzumab) be offered [12].

Based on adjuvant trials, the administration of trastuzumab should be avoided concomitantly to anthracyclines due to its cardiotoxicity (not routinely recommended outside of clinical trials) [20–22, 25], but it may be safely used concomitantly to taxane and also during radiotherapy, when indicated. It has been in fact demonstrated that trastuzumab concomitantly to taxane regimen is more effective than sequential use [21].

Standard duration of trastuzumab is 1 year according to literature data [20–22, 26, 27, 28].

No statistically significant evidence of superiority in terms of disease-free survival was observed combining dual anti-HER2 therapy including trastuzumab and lapatinib, an oral dual inhibitor of epidermal growth factor receptor (EGFR) and HER2 tyrosine kinases [29].

42.4 Triple-Negative Subtype

Among breast cancer subtypes, gene expression array study identified the basal epithelial cells that expressed a characteristic gene cluster including keratin 5, keratin 17, integrin beta 4, and laminin. These tumors also showed a lack of ER and most of the other genes that were usually co-expressed with estrogen receptors [1].

Basal phenotype is defined as negative for hormone receptors and HER2 and positive for cytokeratin 5/6 or epidermal growth factor receptor; it represents a different clinical entity associated to highest TP53 mutations and shorter survival times with a 5-year survival rate of 79.0% (70.8–85.3) and a 73.5% disease-free survival at 5 years (65.0–80.5) [2, 30].

Randomized controlled trials and retrospective studies evaluating the correlation between chemotherapy benefit and ER status suggest that the magnitude of the benefit of chemotherapy is large in patients with ER-negative subtypes

[18, 31]. Due to the absence of known specific therapeutic target, chemotherapy is the standard indication of the international guidelines favoring anthracyclines and taxane-based regimens [9, 11, 13].

Classical cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) is reported as effective for the treatment of TNBC and may still be used in selected cases [14, 32].

Controversies exist about the use of anthracycline and taxane dose-dense schedules (with granulocyte colony-stimulating factor support) [33, 9, 11, 13] although this treatment can be regarded as a reasonable option, particularly in highly proliferative tumors.

Primary Systemic Therapies: Guidelines

43

Jenny Furlanetto and Gunter von Minckwitz

43.1 General Principles

The idea of prioritizing the systemic treatment before surgery was first developed based on the hypothesis to reduce the risk of progress to metastatic disease if the disseminated tumor cells are rapidly killed. However, further studies did not confirm this assumption. A meta-analysis of nine randomized trials found no differences between neoadjuvant and adjuvant treatments according to death, disease progression, and distant disease recurrence [1]. Two big randomized phase III trials, the NSABP B-18 and the NSABP B-27 study, did not show any difference in disease-free survival (DFS) and overall survival (OS) between preoperative and postoperative chemotherapy. Only a trend in favor of preoperative chemotherapy for DFS and OS in women younger than 50 years was observed in the NSABP B-18 study [2].

Three main reasons for choosing neoadjuvant therapy can be identified: to improve the surgical outcome, to determine the response to preoperative treatment, and to obtain long-term disease-free survival. In locally advanced breast cancer, the major goal is to facilitate surgical options and in patients with operable breast cancer candidate for adjuvant chemotherapy, to obtain freedom from disease [3].

Recommendations

1. The neoadjuvant chemotherapy (NACT) should be applied only if invasive breast cancer is diagnosed.
2. Preoperative treatment should be considered in women with locally advanced breast cancer or large operable tumors.
3. The same regimen recommended in the adjuvant setting could be used in the neoadjuvant setting [4] (Table 43.1).
4. The addition of taxanes to anthracycline-based NACT should be used to improve the pathologic complete response (pCR) and DFS and decreases the incidence of local recurrence [4].
5. Dose-dense NACT has been shown to improve pCR, disease-free survival, and overall survival compared to standard dose chemotherapy [11]; notably, pCR has a potential surrogate value for survival in trials comparing dose-dense regimens versus standard regimens [17]. As it is less tolerated compared to standard treatment, dose-dense chemotherapy should only be considered as investigational.
6. The full planned treatment should be completed before surgery to increase the chance of pCR [18] (Table 43.2).
7. At least six cycles equivalent to at least 18 weeks of NACT should be administered [7, 23].
8. Following a full course of NACT, no additional postoperative adjuvant chemotherapy is recommended, whether pCR was achieved or not [24]. However, preliminary data suggest an improvement in DFS for patients without pCR receiving six cycles of capecitabine [25].
9. If no response is observed in an inoperable tumor or the disease progressed under treatment, alternative chemotherapy regimens should be carefully considered. Available results deriving from clinical trials failed to show additional benefit especially among patients with hormone receptor-positive tumors who did not respond to standard initial NACT, switching to a non-cross-resistant regimen [26, 27]. In this scenario, preoperative radiotherapy should also be taken into account [4] (Table 43.2).

43.2 HER2-Positive Breast Cancer

Trastuzumab is a monoclonal antibody directed against the sub-domain IV, a juxta-membrane region of HER2's extracellular domain. It exerts its effect by inhibiting the ligand-independent signaling and by blocking HER2 cleavage. Buzdar et al. firstly demonstrated that the addition of trastuzumab to anthracyclines-taxane-based chemotherapy significantly increased the pCR rate. Patients were treated

Progressive disease	
Stop of NACT and immediate surgery or radiotherapy	Kaufmann et al. [5]
Additional adjuvant chemotherapy with non-cross-resistant regimen	Mittendorf et al. [22]

DAC docetaxel, doxorubicin, cyclophosphamide

with 4 cycles of paclitaxel followed by 4 cycles of FEC-75 (5-fluorouracile, epirubicin, cyclophosphamide); trastuzumab was given simultaneously with a weekly schedule. The pCR rate was more than double in the trastuzumab arm (65.2% vs. 26.0%; $p = 0.016$) [28], with long-term follow-up not showing new safety concerns [29]. The HER2-positive cohort of the GeparQuattro trial showed a pCR in 31.7% of tumors [30]. Moreover, the NOAH trial showed a higher DFS when trastuzumab was added to a neoadjuvant regimen consisting of doxorubicin and paclitaxel followed by paclitaxel or CMF (cyclophosphamide, methotrexate, and 5-fluorouracile) (5-year DFS 58% vs. 43%; HR = 0.64; $p = 0.016$) [31, 32]. The following studies investigated the effect of different anti-HER2 treatments on pCR as well as the combination of targeted agents. Lapatinib is an inhibitor of the intracellular tyrosine kinase domains of both EGFR and of HER2 receptors. In the GeparQuinto trial, patients receiving trastuzumab as part of standard anthracycline-taxane-based chemotherapy experienced higher pCR compared to patients receiving only lapatinib (30.3% vs. 22.7%; $p = 0.04$) [33]. Similar results emerged from the NeoALTTO trial [34]. Moreover, patients receiving both anti-HER2 agents experienced a significantly higher pCR rate compared to trastuzumab alone (51.3% vs. 29.5%; $p < 0.01$). In the NSABP B-41 study, patients were randomized to receive 4 cycles of doxorubicin and cyclophosphamide followed by 4 cycles of weekly paclitaxel. Concurrently with weekly paclitaxel, patients received either trastuzumab weekly, lapatinib daily, or trastuzumab plus lapatinib until surgery. Substitution of lapatinib for trastuzumab in combination with chemotherapy resulted in similarly high percentages of pCR (53.2% vs. 52.5%; $p = 0.985$). Combined HER2-targeted therapy did not increase the pCR rate compared to the single-agents alone [35]. Several other studies showed a lower pCR rate when lapatinib was used as single agent as part of NACT [36–38].

Pertuzumab is a monoclonal antibody directed at the dimerization domain of HER2 that exerts its effect by inhibiting the ligand-dependent signaling, particularly between HER2 and HER3. The NeoSphere trial firstly demonstrated the achievement of a higher pCR rate with the dual anti-HER2 blockade pertuzumab and trastuzumab added to docetaxel compared to trastuzumab or pertuzumab alone. Only marginal benefit was seen when the two agents were administered alone without the chemotherapy backbone [39]. In the pertuzumab/trastuzumab and pertuzumab/docetaxel arms, respectively, 3-year survival rates were 88% vs. 84% for DFS and 81% vs. 82% for PFS. Across all four treatment arms, for all patients who achieved pCR (ypT0/is ypN0) versus all patients who did not achieve pCR, the HR for DFS was 0.68 (95% CI, 0.36–1.26) and the HR for PFS was 0.54 (95% CI, 0.29–1.00). The TRYPHAENA trial confirmed the efficacy of the double anti-HER2 blockade in particular when given together with docetaxel and carboplatin. Importantly, a lower rate of symptomatic left ventricular systolic dysfunction was reported [40].

Given these data and in conjunction with the high efficacy of pertuzumab in the metastatic breast cancer setting, pertuzumab in combination with trastuzumab and docetaxel gained accelerated approval from the Food and Drug Administration (FDA) in 2012 for the use in the neoadjuvant setting, as well as European Medicines Agency (EMA) authorization in 2015.

Recommendations

1. Women with HER2-positive breast cancer should receive trastuzumab as part of neoadjuvant chemotherapy in order to increase the chance of achieving a pCR.
2. Pertuzumab in combination with trastuzumab and docetaxel is a valid option. Due to the limited information on its effect on survival, the use might be restricted to more advanced tumors (e.g., tumors greater than 5 cm or nodal involvement).
3. The use of lapatinib as a single agent is not approved. Given the conflicting results available and its more unfavorable toxicity profile, the use of lapatinib in combination with trastuzumab in the neoadjuvant setting is not recommended.

43.3 Triple-Negative Breast Cancer

Given the significant prognostic impact of pCR on outcome [41], several agents have been under investigation in triple-negative breast cancer (TNBC), in order to increase the pCR rate. Whether or not carboplatin should routinely be administered as part of standard NACT in patients with TNBC is still a matter of debate. In the GeparSixto study, the addition of neoadjuvant carboplatin to a regimen of a taxane and anthracycline significantly increased the proportion of TNBC patients achieving a pCR (with carboplatin, 53.2%, 95% CI 54.4–60.9; without carboplatin, 36.9%, 95% CI 29.4–44.5; p = 0.005) [13]. Moreover, patients with TNBC were found to have homologous recombination-deficient tumors in 70.5%, which has been shown to be independently predictive of high pCR rates following neoadjuvant treatment with paclitaxel and liposomal doxorubicin with or without carboplatin [42]. Interestingly carboplatin induces a significantly improved disease-free survival in patients with TNBC (with vs. without carboplatin, 85.8% vs. 76.1%; HR = 0.56 [95% CI 0.33–0.96]; p = 0.035) but not in patients with HER2-positive disease (with vs. without carboplatin, 86.7% vs. 83.4%; HR = 1.33 [95% CI 0.71–2.48]; p = 0.372) (interaction test p = 0.046) [43].

The CALGB 40603 evaluated the impact of adding carboplatin and/or bevacizumab to standard anthracycline-taxane-based chemotherapy. The addition of either carboplatin (60% vs. 44%; $p < 0.001$) or bevacizumab (59% vs. 48%; $p < 0.001$) significantly increased pCR defined as ypT0/is, whereas carboplatin only (54% vs. 41%; p = 0.003) significantly increased pCR in breast and nodes (ypT0/is ypN0) [14]. Despite significantly higher pCR rates, neither carboplatin nor bevacizumab has yet been shown to improve relapse-free survival or OS when administered as part of neoadjuvant therapy in TNBC [44].

Further trials investigated the role of bevacizumab in TNBC. In all of them, the anti-VEGF therapy was able to increase the pCR rate compared to anthracycline-taxane-based chemotherapy alone [45–47]. The GeparQuinto study as well as two big adjuvant trials did not show an improvement in survival with bevacizumab [48–50]. In contrast, the NSABP B-40 trial reported a significant increase in survival with the addition of neoadjuvant plus adjuvant bevacizumab [51]. In the GeparSepto study, nab-paclitaxel increased significantly the pCR rate compared to paclitaxel (38.0% vs. 29.0%; $p < 0.001$), especially in patients with triple-negative tumors (48.2% vs. 25.7%; $p < 0.001$) [52]. The ADAPT TN trial suggested high efficacy and favorable toxicity of 12 weeks therapy with nab-paclitaxel and carboplatin compared to nab-paclitaxel and gemcitabine in TNBC (49.2% vs. 25%; p = 0.006) [53].

Recommendations

1. A sequential regimen of anthracycline-taxane-based chemotherapy should be applied to the majority of patients.
2. Carboplatin and nab-paclitaxel seem to increase responses in patients with TNBC, the former at the cost of major hematological toxicities and discontinuations and the latter of a higher rate of sensory neuropathies. Ambiguous results have been reported for the effect of carboplatin on survival. Therefore, the decision of adding these agents to standard NACT should be based on the individual basis weighing risks and benefits for the patient.
3. So far, there is no role for bevacizumab in the neoadjuvant setting in patients with HER2-negative disease.

43.4 Neoadjuvant Chemotherapy in Luminal B-Like Tumors

Hormone receptor (HR)-positive/HER2-negative breast cancer even with a higher proliferation rate (luminal B-like) has a lower chemosensitivity compared to the HER2-positive or triple-negative subtype and needs longer treatment in order to increase the probability to achieve a pCR [54]. For luminal B-like high-risk breast cancer, chemotherapy followed by hormone therapy is recommended for the majority of cases (conventionally dosed AT-based chemotherapy; dose-dense chemotherapy in case of high tumor burden). All patients with luminal B-like HER2-positive breast cancer should receive chemotherapy, anti-HER2 treatment, and hormone therapy [24].

43.5 Neoadjuvant Endocrine Therapy

The neoadjuvant endocrine therapy is an alternative approach in women with luminal A-like breast cancer, in particular when high levels of estrogen receptor are present. Invasive

lobular carcinomas show significantly lower pCR rates after NACT compared to the other histological tumor types, mainly due to their HR positivity [55]. Several trials show the superiority of the aromatase inhibitors anastrozole and letrozole over tamoxifen in terms of objective response and breast conserving surgery [56–58]. In premenopausal patients, the use of goserelin together with anastrozole leads to a higher rate of partial or complete response compared to goserelin plus tamoxifen (70.4% vs. 50.5%; estimated difference between groups 19.9% [95% CI 6.5–33.3]; $p = 0.004$) [59].

Compared to neoadjuvant chemotherapy, endocrine treatment needs more time to show a response and to achieve a pCR. Therefore, treatment should continue for at least 4–8 months or until maximum response [60]. Moreover, considering the time needed to observe a decrease in tumor size and the lower pCR rate, a careful patient selection is mandatory. Given the antiproliferative effect of hormone therapy, Ki67 has been widely evaluated as an early predictor of response. It has been demonstrated that levels of Ki67 during treatment are more related to long-term prognosis compared to pretreatment levels and change in Ki67 is accepted as a validated end point for comparing endocrine agents in the neoadjuvant scenario. Patients who failed to obtain an early reduction in Ki67 levels need to be considered for an alternative approach [61, 62].

Recommendations

1. In patients with luminal A-like breast cancer, neoadjuvant endocrine therapy should be considered if a rapid onset of response is not necessary.
2. Aromatase inhibitors are the agents of choice in postmenopausal patients, and in premenopausal patients, GnRH analogues might be added.
3. Treatment should be prolonged until achievement of maximum response.
4. Ki67 should be used to identify early responders. If no Ki67 reduction is observed, other agents should be considered.

43.6 pCR and Outcome

The relationship between pCR and outcome has been widely investigated. Two large meta-analyses tried to define if pCR could be used as surrogate end point for survival. The German Breast Group investigated the association between pCR and outcome in 6377 patients with primary breast cancer receiving neoadjuvant anthracycline-taxane-based chemotherapy in seven randomized trials. Overall, patients with no residual disease in breast and nodes (ypT0 ypN0) experienced a better DFS and OS, but the impact of pCR on outcome broadly varies among subgroups. In patients with less aggressive tumors (low proliferation, lobular, grade 1, hormone receptor positive), pCR was not predictive for OS and DFS, whereas in patients with grade 2–3 tumors, HR negative, and ductal histology, the achievement of a pCR was associated with a better outcome. When considering the different breast cancer subgroups, no impact of pCR on prognosis was seen in luminal A-like and in luminal B/HER2-positive tumors, whereas a great impact was seen for HER2-positive, TNBC, and luminal B/HER2-negative tumors [41]. In the CTNeoBC meta-analysis, a total of 12 trials including 11,955 patients and including almost all studies of the German meta-analysis were analyzed. The study confirmed that pCR (ypT0 ypN0) was associated with a better outcome with a greater effect observed in aggressive subtypes (TNBC, HER2 positive HR negative) [63]. The magnitude of pCR improvement needed to predict long-term clinical benefit is still a matter of debate. Based on the results of the CTNeoBC trial, the FDA recognized ypT0/is ypN0 as the preferred definition for pCR as a regulatory end point, mainly because the use of the more stringent definition could result in a lower rate of pCR, affecting the real benefit of the drug. In contrast to the previous data, a meta-regression analysis of 29 studies based on data extracted from the literature failed to support the use of pCR as surrogate end point for DFS and OS. However, an increased level of surrogacy of pCR was found in trials comparing intensified/dose-dense regimens vs. standard regimens [17]. Even if an association between pCR and outcome has not yet been proven for all patients affected by breast cancer, several studies support this association for HER2-positive tumors [30, 63]. Further doubts about the value of pCR as a surrogate end point have been underlined by the results of the ALTTO trial that investigated the use of trastuzumab and/or lapatinib in the adjuvant setting. In contrast to the NeoALTTO trial, the ALTTO study did show only a marginal but nonsignificant reduction in disease recurrence after a median follow-up of 4.5 years [64]. This result goes in line with the other neoadjuvant trials that did not show a significant improvement of pCR by lapatinib [35, 38]. Moreover, the analysis of Korn and colleagues fails to provide sufficient evidence to the use of pCR to recommend a treatment based solely on a positive trial result or eliminate a new agent from further development based on a negative trial results [65].

Recommendations

1. pCR surrogacy has still to be proven. Given the available data, every effort should be taken to achieve a pCR at least in aggressive phenotypes, especially in HER2-positive tumors.

43.7 Residual Disease After Neoadjuvant Chemotherapy

In order to define the prognosis of patients with residual disease after NACT, several classifications could be applied. The German Breast Group previously described the correlation between outcome and the TNM staging system [41]

that remains a valid tool also in the post-NACT setting. Currently, other widely used classification systems are the clinicopathological stage and biological markers (CPS-EG) score, the residual cancer burden (RCB) score, and the integrated score of RCB and Ki67 (RPCB) score. The integration of estrogen receptor status and tumor grading in the CPS score allowed the identification of seven distinct patients groups having different metastasis-free survival and disease-specific survival. In particular, HR-negative disease and G3 tumors were additional independent risk factors [22, 66, 67]. The RCB score is calculated as a continuous index combining pathological measurements of primary tumor and nodal metastases to predict distant relapse-free survival. In particular the presence of an extensive residual disease is associated with poor prognosis, irrespective of the type of neoadjuvant chemotherapy administered, adjuvant hormone therapy, or the pathological stage of the residual disease [68]. Given that high posttreatment Ki67 values measured on the surgical excision specimen are independently associated with poorer DFS and OS, the integration of posttreatment Ki67 with RCB provides more prognostic information than the two variables alone [69].

No agent is currently approved for patients with residual disease after NACT. The NaTaN study failed to demonstrate an improvement in terms of DFS in patients treated with zoledronate as post-neoadjuvant therapy after standard anthracycline-taxane-based NACT [70]. In contrast the CREATE-X trial demonstrates a 2-year DFS benefit of adding capecitabine to standard adjuvant treatment in patients with HER2-negative residual disease after anthracycline-taxane-containing NACT (2-year DFS with/without capecitabine, 87.3% vs. 80.5%; $p = 0.001$) [25]. Given the high risk of these patients and the lack of data deriving from the post-neoadjuvant setting, they should be referred for participation in clinical trials. Several studies are ongoing to define if new agents could improve the prognosis of patients with residual disease after a preoperative chemotherapy. The PenelopeB study (NCT01864746) investigates the role of palbociclib in addition to standard endocrine therapy in patients with a CPS-EG score ≥3 or 2 but with metastatic lymph nodes after NACT. The Katherine study (NCT01772472) compares the use of trastuzumab vs. TDM-1 as adjuvant therapy in patients with HER2-positive breast cancer who have residual tumor in the breast, whereas the Olympia trial (NCT02032823) investigates the role of olaparib as adjuvant therapy in TNBC patients harboring germline *BRCA*1/2 mutations.

Recommendations

1. Patients with HER2-negative residual disease after anthracycline-taxane NACT could derive further benefit from the addition of capecitabine as part of standard adjuvant chemotherapy [25]. Given the few data available on post-neoadjuvant chemotherapy for patients who failed to achieve a pCR, the participation in clinical trial is still a recommended option.
2. Patients with HR-positive disease should start endocrine treatment. Patients becoming HR positive after NACT should also be considered for antihormonal therapy.
3. Patients with HER2-positive disease should complete trastuzumab therapy for up to 1 year.

Conclusion

The neoadjuvant setting provides the unique opportunity to directly observe the effect of treatment on the tumor and to apply new strategies to nonresponding patients to increase their outcome. Further research is needed in order to better select the right patients for the right therapy in order to maximize the benefit and minimize toxicities.

Treatment of Advanced Disease: Guidelines

44

Rosario Andre, Simona Ruxandra Volovat, and Fatima Cardoso

44.1 Introduction

Breast cancer (BC) is the most prevalent malignancy in women and the second leading cause of cancer-related death in developed countries. In 2015, in the United States, about 231,840 new cases of invasive BC will be diagnosed in women, and 40,290 women will die from this disease [1]. In Europe, there were an estimated 464,000 new BC cases and 131,000 BC-related deaths in 2012 [2]. The majority of breast cancer-related deaths are associated with metastatic disease. Over the past decades, we have observed a stage migration, with a greater proportion of patients being diagnosed with early breast cancer. Nonetheless, 6–10% of women diagnosed with BC present with metastatic disease ab initio in developed countries. The percentage reaches 50–60% in developing countries [3]. Additionally, 20–50% of patients first diagnosed with early BC will eventually develop metastatic disease [4].

Nomenclature wise, the words advanced, metastatic, and secondary are all used to define stage IV breast cancer. Following the ABC guidelines [5], we will consider in this chapter that advanced breast cancer (ABC) includes metastatic and inoperable locally advanced disease. For consistency, we will mostly use advanced breast cancer (ABC) throughout the text.

Significant advances in the treatment of patients with ABC have been observed in the last 30 years. More therapeutic options are available nowadays, contributing to an improvement in the overall outcome of this disease and in the quality of life of patients with ABC. Nevertheless, very few of these treatments have provided a survival benefit, and the prognosis remains poor with a median overall survival (OS) of only 2–3 years [6, 7]. ABC continues to be generally incurable, but it is a treatable disease, and some patients can live with it for extended periods of time. The main treatment goals in this setting are to control symptoms and to extend survival, without compromising quality of life. These treatment goals should be discussed with the patient, in an accessible and comprehensive way, always respecting individual characteristics, beliefs, and cultural differences. Although less common, a very important subset of patients with ABC, for example, those with oligometastatic disease (defined as low-volume metastatic disease with limited number and size of metastatic lesions—up to 5 and not necessarily in the same organ [8]—or low-volume metastatic disease that is highly sensitive to systemic therapy), can achieve complete remission and a long survival. A multimodal approach, including local-regional treatments with curative intent, should be considered for these selected patients.

BC is a heterogenous goup of diseases which results from various molecular alterations; activation/inhibition of different cellular pathways separates it into different subtypes, characterized by different clinical behavior and response to various treatment options. As more information regarding the biology of BC has emerged, various tailored treatments are currently available according to specific BC subtype, resulting in improved outcomes, specifically in the HER-2-positive ABC and, more recently, in luminal ABC.

According to the German Tumor Registry Breast Cancer study [9] that included 1409 ABC patients, the proportional distribution of the BC subtypes in the advanced setting does not differ much from the distribution in the early setting. These researchers have found that 58% of cases were hormonal receptor (HR) positive/HER-2 negative, 19% were triple positive, 13% had triple-negative disease, and 10% of the patients had HR-negative/HER-2-positive breast cancer. This study also confirmed that ABC patients usually receive a substantial number of lines of therapy, with 60% of HR-positive population and 40% of the HR negative receiving at least three lines of treatment.

The management of ABC not only depends on various tumor-related factors but also on patient characteristics and previous drug exposure. As a general idea, patient's age should not be the only factor when deciding to withhold

treatment (in elderly patients) or to overtreat (in young patients) [10–12]. Taking into account the complexity of the disease and also the management, ABC patients should be treated in a specialized breast unit, where all appropriate specialties (including, but not restricted to, medical, radiation, surgical oncologists, imaging experts, pathologists, gynecologists, nurses, psycho-oncologists) forming a multidisciplinary team could be involved. Although routinely applied in the early breast cancer setting, a multidisciplinary expert approach is not always offered to ABC patients. The development of the international advanced breast cancer (ABC) consensus guidelines has reinforced this need and contributed to the development of international standards and to the improvement in advanced breast cancer care.

There are few proven standards of care with high level of evidence in ABC management. Clinical trials addressing important unanswered clinical questions in this setting are urgently needed. Whenever clinical trials are available, patients should be offered inclusion in well-designed, prospective, independent trials [10].

44.2 Diagnosis and Staging Recommendations

The staging evaluation of women who present with metastatic or recurrent breast cancer should always include a history and physical examination, complete hematology, and biochemistry tests including liver function tests, renal function, electrolytes, calcium, total proteins and albumin, and imaging of the chest, abdomen, and bone [13]. Although patients with HER-2-positive or triple-negative MBC have a higher probability of CNS metastatic disease, current recommendations do not support routine brain imaging in asymptomatic patients [5]. Positron emission tomography scan (PET scan) should not be routinely part of the staging workup but should be used selectively, namely, following equivocal findings on conventional imaging techniques when a relapse is suspected [14] or to confirm the diagnosis of oligometastatic disease. The usefulness of serum tumor markers in BC is not well established for diagnosis or follow-up after adjuvant therapy. However, if initially elevated, tumor markers such as CA15-3, CEA, or CA-27.29 may aid in evaluating response to therapy, particularly in patients with nonmeasurable metastatic disease [5]. Tumor markers should not be used alone for treatment change decisions, in particular in the beginning of treatment. An early rise in tumor marker levels during the first 4–6 weeks of a new therapy can be a result of a tumor flare [15].

Biopsy of metastatic disease at presentation or at first recurrence of disease should be performed, if easily accessible, in order to confirm the diagnosis of metastatic disease and to test for hormone receptors (estrogen receptor and progesterone receptor) and HER-2 expression [5, 16]. Depending on the metastatic site (e.g., bone tissue), technical considerations need to be discussed with the pathologist. Adequate characterization of the BC phenotype will allow better definition and selection of treatment strategy. Several reports have demonstrated discordance between ER/PR and HER-2 status of primary tumor and corresponding metastases [17–19]. The reasons for this discordance may be related to clonal selection during tumor progression, intratumoral heterogeneity, selective pressure from therapy, independent evolution of a clone in both sites, or false shifts related to evaluation including tissue processing and scoring interpretation [17]. If the results of tumor biology in the metastatic lesion differ from the primary tumor, it is currently unknown which result should be used for treatment decision making. Following ABC recommendations, targeted therapy (ET and/or anti-HER-2 therapy) should be considered when receptors are positive in at least one biopsy, regardless of timing [5].

44.3 Treatment Recommendations

BC is a heterogeneous disease with diverse clinicopathological features, deregulation of distinct signaling pathways, and different drug sensitivity. Selecting therapies in ABC must therefore take into account both the biology and disease extent and patient characteristics. Many factors must be considered for tailoring the decision in this setting, always giving priority to the patient's preferences; these factors are described in Table 44.1.

Table 44.1 Factors to consider in treatment decision making for ABC patients

Disease-related factors	Hormonal receptor status HER-2 status BRCA 1/2 mutation Disease-free interval Tumor burden (defined as number and site of metastases) Need for a rapid disease/symptom control
Patient-related factors	Patient's choice Biological age Performance status Comorbidities Liver, renal, heart function Menopausal status Socioeconomic and psychological factors
Treatment-related factors	Previous therapies received Response to previous therapies Toxicity of previous therapies Availability of therapies

Note: Adapted from ABC 2 [10]

44.3.1 Hormone Receptor-Positive/HER-2-Negative Advanced Breast Cancer

HR-positive BC is the most common subtype among ABC patients, representing approximately 75% of cases [20]. In these patients, endocrine therapy is an effective treatment [21] and should be used as first option, even in the presence of visceral metastasis, unless there is immediate life-threatening disease or visceral crisis, in which case chemotherapy should be considered [22]. According to the ABC 2 consensus guidelines, "visceral crisis" is defined as "severe organ dysfunction as assessed by signs and symptoms, laboratory studies and rapid progression of disease, implying important visceral compromise, not only the presence of visceral disease" [8]. The use of endocrine therapy in HR-positive ABC is supported by its mechanism of action, low toxicity profile, and lower response of this type of tumors to chemotherapy [20].

All international guidelines [8, 10, 16, 23] recommend ovarian suppression/ablation combined with additional endocrine therapy as the first choice for premenopausal women. The additional endocrine agent can be an aromatase inhibitor or tamoxifen, according to the type and duration of prior adjuvant endocrine therapy. Fulvestrant is also a valuable option, but fewer data exists regarding its use in premenopausal patients, and for the moment it requires concomitant ovarian suppression/ablation [5, 10].

For postmenopausal women, the preferred first-line endocrine therapy depends on the type and duration of adjuvant endocrine therapy, as well as the time elapsed from the end of adjuvant endocrine therapy. An aromatase inhibitor, tamoxifen, and fulvestrant are all acceptable options [5, 10, 16].

The addition of everolimus to an aromatase inhibitor is an option for some postmenopausal patients with disease progression after a nonsteroidal aromatase inhibitor, since it significantly prolongs PFS albeit not OS [5, 24]. Due to its toxicity profile and lack of overall survival benefit, the decision must be taken on a case-by-case basis, after careful discussion with the patient and with adequate education of a preventive measure for the most common toxicities.

In the phase 2 trial PALOMA-1/TRIO-18 [25], the addition of palbociclib (a CDK4/6 inhibitor) to an aromatase inhibitor yielded a substantial PFS benefit, as first-line therapy for postmenopausal women. However, these results must be confirmed in the phase 3 trial, PALOMA-2, which has already finalized accrual, before becoming a recommended option.

The addition of palbociclib to fulvestrant, mostly in second-line therapy for post-, peri-, and premenopausal patients, has provided a PFS benefit in the PALOMA-3 trial [26]; due to its favorable toxicity profile and improvement of quality of life, despite not yet providing OS benefit, it can be considered as a treatment option in this setting. For pre-/perimenopausal patients, the addition of an LHRH agonist is needed [27].

Concomitant chemotherapy and endocrine therapy have not shown a survival benefit and should not be performed outside a clinical trial [10].

44.3.2 Triple-Negative Breast Cancer

Triple-negative breast cancer (TNBC) identifies invasive BCs that lack the expression of ER, PR, and HER-2 and accounts for 15% of all BC [28]. Generally, patients with metastatic TNBC have a poorer prognosis compared with women with other ABC subtypes, with a median survival of only 13 months [29, 30]. There is no specific systemic regimen for sporadic (non-BRCA associated) TNBC and little data to support treatment selection [31, 32]. Platinum agents, including carboplatin and cisplatin, may be of special interest in cells that are deficient in homologous recombination repair mechanisms such as BRCA-mutated cells. Evidence from preclinical and some clinical studies seem to confirm the efficacy of this strategy [33–35]. In particular, recent phase 2 randomized trials demonstrated improved pCR rates in patients treated with neoadjuvant treatment that included a platinum compound [36, 37]. In metastatic TNBC patients previously treated with anthracyclines with or without taxanes in the (neo)adjuvant setting, carboplatin demonstrated comparable efficacy and a more favorable toxicity profile, compared to docetaxel, in the TNT UK trial, and is therefore considered an important treatment option [10, 38, 39].

44.3.3 HER-2-Positive Breast Cancer

The amplification of HER-2 occurs in approximately 20% of all BC and was associated with a more aggressive disease phenotype, with a poorer prognosis and shorter overall survival [40]. The development and approval of trastuzumab, the first HER-2-targeted therapy, has changed significantly the natural history of HER-2-positive ABC patients. Since then, several other HER-2-targeted therapies have been approved for the treatment of this BC subtype. In fact, HER-2-positive ABC is probably the subtype for which highest level of evidence exists for the largest number of management strategies. Level 1 evidence supports the recommendations for early (as first line) administration of anti-HER-2 therapy to all patients with HER-2-positive ABC, except in the presence of contraindications, and for continuing anti-HER-2 therapy with subsequent treatment in patients progressing on an anti-HER-2 agent combined with chemotherapy or endocrine therapy [5, 8, 10, 16].

For patients with ER+/HER-2-positive ABC for whom endocrine therapy was chosen over chemotherapy, the use of anti-HER-2 therapy (either trastuzumab or lapatinib) in combination with endocrine therapy for highly selected patients can be considered [8]. Moreover, if chemotherapy plus anti-HER-2 therapy was chosen as first-line therapy and provided a benefit, it is reasonable to use endocrine therapy plus anti-HER-2 therapy as maintenance therapy, after stopping chemotherapy, although this strategy has not been studied in clinical trials [8].

It has become a not-so-uncommon situation to have ABC patients with HER-2-positive tumors in complete remission for long periods of time. An important clinical question is when to stop the anti-HER-2 therapy in these cases. The ABC consensus [10] suggests that stopping the anti-HER-2 therapy, after several years of sustained complete remission, may be considered in some patients, particularly if treatment rechallenge is available in case of progression [8].

The current preferred first-line therapy, for patients previously untreated with anti-HER-2 therapy, is the triplet trastuzumab + pertuzumab + chemotherapy, which has been shown to improve PFS and OS in the CLEOPATRA trial [41]. For patients previously treated in the (neo)adjuvant setting with anti-HER-2 therapy, the combination of chemotherapy + trastuzumab + pertuzumab is an important option for first-line therapy, but not the only standard of care since very few (88) of these patients were treated in the CLEOPATRA trial and all with trastuzumab-free interval >12 months. In addition, in the MARIANNE trial [42], dual blockade with T-DM1 and pertuzumab was not superior to T-DM1 alone nor to trastuzumab plus chemotherapy (taxanes) in the first-line setting.

For patients who relapse either on or within 12 months of adjuvant trastuzumab, there are currently no data regarding the best treatment strategy, since these patients were excluded from the CLEOPATRA [41] and MARIANNE trials [42]. This is therefore a research priority, in view also of their bad prognosis.

Results from the EMILIA [43] and TH3RESA [44] trials support the use of T-DM1 as the standard of care for patients with disease progression after treatment with at least one line of trastuzumab-based therapy. However, there are no data on the use of T-DM1 after dual blockade with trastuzumab and pertuzumab.

In case of progression on trastuzumab-based therapy, the combination of trastuzumab and lapatinib is a reasonable treatment option for some patients and may actually be one of the few indications of this agent in ABC, since phase 3 randomized trials [45–47] have proven that combinations of chemotherapy and trastuzumab are superior to combinations of chemotherapy and lapatinib.

In view of these new compounds recently approved in HER-2-positive ABC, optimization of sequencing and combining strategies and better predictive markers of response are of paramount importance.

44.3.4 Cytotoxic Therapy

Classic chemotherapy still plays an important role in the treatment of ABC. Unlike the adjuvant setting, in which the goal of therapy is cure, the aim of therapy in the setting of ABC is essentially palliation. Therefore, besides efficacy, tolerability and quality of life are major factors that need to be taken into account when evaluating potential gains in disease response and survival.

In recent years, the patterns of the use of chemotherapy in ABC patients have changed, and in the majority of patients, sequential single-agent therapies are preferred over aggressive multidrug regimens. Several randomized trials and a Cochrane meta-analysis provide level 1 evidence for the recommendation to preferably use sequential monotherapy, since the overall efficacy is similar to combinations and the toxicity and quality of life are better [47–56]. Therefore, all international guidelines recommend that sequential single-agent therapy should be the preferred choice for most ABC patients, except in cases of rapid progression, visceral crisis, or highly symptomatic disease [10, 16]. This strategy will allow in patients not requiring rapid tumor shrinkage, significantly lower toxicity without compromising efficacy, and disease control.

Metronomic chemotherapy is also a good treatment option for patients not requiring rapid tumor response and has a very favorable toxicity profile. The better-studied regimen is CM (low-dose oral cyclophosphamide and methotrexate), but others, such as capecitabine and oral vinorelbine, are being evaluated [57, 58].

44.3.5 Specific Sites of Metastases

In recent years, the role of local treatment of metastatic lesions in patients with ABC has been growing. Besides surgery, alternative modalities such as stereotactic radiotherapy or tumor embolization with isotope-loaded microspheres may be considered for the local treatment of metastatic lesions.

According to some retrospective data, oligometastatic disease in the liver or lung can be treated with "curative-intent" surgery, providing long-term complete remissions [59]. However, the reported outcomes were in a highly selected patient population, and, although encouraging, this approach can only be considered in selected cases with good performance status, limited liver/lung involvement, and no extrahepatic or extrapulmonary lesions and after adequate disease control by systemic treatment [10]. Moreover, further

prospective studies evaluating the impact of local treatment on survival are needed. Furthermore, a multidisciplinary team involving medical oncologists, surgeons, radiation oncologists, and radiologists is crucial to define the best therapeutic strategy for each individual patient.

In patients with bone metastasis, further radiological assessments that could indicate signs of pathological fractures are recommended in case of persistent and localized pain. In case of fracture of a long bone, an orthopedic evaluation is required in order to establish the indication for surgery, which is generally followed by radiotherapy. In the absence of a clear fracture risk, radiotherapy is recommended [10]. In cases of neurological symptoms and signs suggestive of spinal cord compression, further investigations should be urgently recommended in order to identify one or multiple concomitant lesions. Due to increased sensitivity, MRI is preferred over CT scans. If immediate decompressive surgery is not optional, emergency radiation therapy should be performed. The early use of a bone-modifying agent (bisphosphonate or denosumab) in combination with other systemic therapy is supported by different international recommendations [5, 60, 61]. In cases of oligometastatic disease, with an isolated bone lesion, it is not clear to date which is the optimal regimen and duration of the bone-modifying treatment, but there is no strong reason to stop after 2 years as it was initially recommended. Radiotherapy should be offered to patients with painful bone metastasis and for the management of spinal cord compression [62]. In cases of isolated bone lesions, stereotactic body radiotherapy or vertebroplasty should be considered, with the goal of delaying morbidity associated with the lesion and maintaining/improving quality of life.

Brain metastases are relatively frequent in patients with HER-2-positive and triple-negative ABC. In HER-2-positive ABC, brain involvement occurs later, and the outcome is dependent on the response to anti-HER-2 therapy and control of extracranial disease. In patients with triple-negative ABC, brain metastases appear earlier in the course of the disease and are associated with a poorer outcome. In recent years, the role of local management has increased for brain metastases. Neurosurgery development has been associated with a decrease in perioperative mortality, and the introduction of noninvasive techniques such as stereotactic radiosurgery has allowed for the use of less toxic approaches in selected patients. In patients with a single or a small number of brain lesions, surgery or radiosurgery should be used [63, 64]. If surgery or radiosurgery is performed, it may be followed by whole-brain radiotherapy, but this should be discussed in detail with the patient, balancing the longer duration of intracranial disease control and the risk of neurocognitive effects [10]. In fact, whole brain radiotherapy is now delayed as much as possible, especially in HER-2-positive ABC since these patients can now live several years. For other cases, where these less toxic options are not feasible, whole-brain radiotherapy is the treatment of choice [5]. In patients with HER-2-positive ABC with brain metastases and stable extracranial disease, systemic therapy should not be changed [8]. For patients with HER-2-positive cancers where brain metastases are the only site of recurrence, the addition of chemotherapy to local therapy is not known to alter the course of the disease. It is recommended to restart the anti-HER-2 therapy (trastuzumab) if this had been stopped [8].

44.3.6 Locoregional Treatment of the Primary Tumor in De Novo Stage IV Patients

Several retrospective series and a meta-analysis [65] of these retrospective data have suggested a survival benefit associated with the removal of the primary tumor in patients with de novo stage IV breast cancer. To achieve that survival benefit, the surgery must be performed with the same quality as in early breast cancer, i.e., complete removal of the tumor and management of the axilla. There is no evidence to perform the so-called palliative mastectomy except in cases of need to control local symptoms such as bleeding or ulceration and where the surgical approach could improve the quality of life. Even in those cases, palliative radiotherapy must also be discussed as an alternative option.

More recently, two small but prospective randomized studies were [66, 67] presented and did not confirm the survival benefit. These were small studies, with different timing and patient selection for surgery, and do not yet provide a definite answer to this important question.

However, it is now recommended to consider this surgery only in highly selected patients, for example, those with bone-only disease, after careful discussion with the patient [8].

Further clinical trials evaluating this approach concerning the timing, patient population, and methods are currently ongoing [8].

44.4 Follow-Up of Patients with Advanced Breast Cancer

In order to effectively manage patients with advanced/metastatic disease, serial evaluation is a key component of the care that clinical oncologists must provide. There is currently a lack of evidence from prospective randomized clinical trials comparing surveillance strategies in patients with ABC. Thus, information must be drawn from current available guidelines (ABC, AGO, ASCO, ESMO, NCCN) and from common clinical practice.

The goals for evaluation and follow-up of patients with ABC are to manage symptoms associated with the disease and treatment and to direct therapy, in an effort to maximize both length and quality of life [13]. Therefore, assessment should include review of toxicities, symptoms and quality of life evaluation, physical examination, imaging, and blood tests. Strong consideration should be given to the use of validated patient-reported outcome measures (PROMs) for patients to record the symptoms of disease and side effects of treatment experienced as a regular part of clinical care. These PROMs should be simple and user-friendly to facilitate their use in clinical practice. Systematic monitoring would facilitate communication between patients and their treatment teams by better characterizing the toxicities of all anticancer therapies. This would permit early intervention of supportive care services enhancing QoL [8]. As an important prognostic factor, performance status should be assessed at each visit, as it may have a major impact on treatment decisions and overall goals of care. In cases where patients are being treated with oral regimens, adherence to treatment should also be assessed. Initial radiological evaluation of response to treatment should be performed 2–4 months after beginning each line of treatment for endocrine treatment or after 2–4 cycles for chemotherapy, depending on the dynamics of the disease and type of treatment [13]. The timing and interval between subsequent evaluations should be adapted to the clinical situation and disease aggressiveness. Most commonly, imaging studies will include CT scans of the chest/abdomen and bone scans. Routine pelvis CT, although performed in some countries, has a very low yield, adds cost, and appears unnecessary in most cases. 18F-Fluorodeoxyglucose (FDG)-PET and PET-CT can define extent of disease and demonstrate alterations in tumor size and metabolic activity over time; however, robust data demonstrating cost-effectiveness relative to CT/bone scan-based approaches are lacking. In this context, PET-CT is not recommended for routine staging of ABC patients, but it can be used to confirm oligometastatic disease and relapse or progression in case of doubt [8]. In patients where cord compression is suspected, MRI is the modality of choice.

In patients with bone metastases, bone scans remain the mainstay of evaluation, since data from a meta-analysis has failed to demonstrate significant benefits of PET over bone scan in this context. Interpretation of bone scans must be cautious during the first months of treatment, since a possible "flare" may be observed.

If progression of disease is suspected, additional testing should be performed irrespective of the interval from the last set of staging evaluations.

Therapy for ABC should be continued as long as the therapeutic index remains positive. There is no evidence that changing to an alternative therapy (endocrine or chemotherapeutic) regimen before progression is beneficial.

Although currently not in clinical practice, detection of circulating tumor cells (CTCs) might be useful for the follow-up of ABC patients. Several studies have shown that the dynamics of CTCs after treatment initiation are a useful predictor of treatment efficacy in ABC, being associated with progression-free survival [26, 68, 69]. In the SWOG 0500 study, patients with metastatic disease and elevated CTCs under systemic treatment are randomly assigned either to continue current therapy (until evidence of disease progression, evaluated by traditional evaluation) or to make an early switch to an alternative treatment [13]. CTCs also reflect tumor biology. Their unique phenotypic characteristics and the possibility of collecting sequential blood samples may potentially allow for real-time monitoring of treatment efficacy and for better defining the adequate treatment strategy. For example, in the NCT01185509 trial, trastuzumab-based chemotherapy will be offered to patients with HER-2-negative BC according to biopsy and with HER-2-positive CTCs. In the EORTC Treat CTC trial, patients with HER-2-positive CTCs are also randomized to receive trastuzumab.

Conclusion

In the management of ABC patients, one of the most important elements is symptom control, as sooner or later all patients with metastases will have symptoms related to organ involvement, treatment, or both. This aim is frequently challenging, as the strategy involves frequent and close communication with the patient, family, and other caregivers. However, along with disease control, ensuring and maintaining quality of life for ABC patients is crucial and mandatory and must be sought.

Endocrine Therapies in the Adjuvant and Advanced Disease Settings

45

Olivia Pagani

45.1 Introduction and Background

Hormone receptor-positive (HR+) breast cancer (BC) is the most common histological subtype across all age groups, but the proportion of HR+ BC is inversely correlated with age [1–4]. The therapeutic manipulation of endogenous estrogen levels and/or the estrogen receptor interaction is the milestone of adjuvant and palliative therapy in female patients with HR+ BC, i.e., estrogen receptor positive (ER+) and/or progesterone receptor positive (PR+). As a consequence, the accurate assessment of HR status is critical for the optimal use of endocrine therapy (ET). Over the years, HR determination has often been inaccurate and irreproducible, with variable thresholds for positivity (e.g., ≥1%, ≥10%, any) [5], significantly impacting interpretation of trial results. The 2010 joint American Society of Clinical Oncology/College of American Pathologists guideline recommendations for immunohistochemical testing of ER and PR established a cutoff of at least 1% of positive tumor cells for a specimen to be considered positive [6]. The degree of positivity provides valuable predictive and prognostic information to plan treatment strategies: several studies showed patients with higher HR levels have a higher probability of positive outcomes when treated with ET [7–11]. For the few patients reported as ER−/PR+, repeating testing on another tissue sample is recommended to rule out a false-negative or false-positive result which could influence treatment efficacy. Retesting is also recommended in case of ER- and PR-negative results in tumor subtypes (i.e., tubular, lobular, and mucinous) almost always associated with HR positivity [6]. The absence of benefit from ET for women with ER− BC has been confirmed in large overviews of randomized clinical trials.

45.2 Early Breast Cancer

45.2.1 Indications

Precise assessment of menopausal status is important when deciding the optimal ET in the individual patient. The available biomarkers to determine the postmenopausal status [follicle-stimulating hormone (FSH), estradiol, inhibin B, and anti-Müllerian hormone (AMH)] are of limited availability, reliability, or reproducibility. Practical guidelines to properly discriminate pre- and postmenopausal patients have been developed [12]: in general, women >60 years, after bilateral oophorectomy, and <60 years not using oral contraceptives or hormone replacement therapy (HRT) with an intact uterus and amenorrhea for at least 1 year can be considered postmenopausal. On the contrary, women having regular periods without using oral contraceptives or HRT can be classified as premenopausal. The most difficult clinical situation is defining and managing the perimenopausal transition period [13]: cautious decisions and careful monitoring should be made in these patients.

45.2.2 Tamoxifen

Tamoxifen is a selective ER modulator (SERM) used for over 40 years to treat HR+ BC.

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analyses repeatedly reported the benefits of adjuvant tamoxifen in pre- and postmenopausal women with HR+ BC regardless of age, the use of chemotherapy, and nodal status. In the 2011 overview [8], 5 years of tamoxifen compared to no ET were associated with a 15-year risk reduction of 39% in BC recurrence and of 30% in BC mortality. Efficacy is evident even at relatively low levels of ER positivity and independent of PR status: in ER+ disease, the absolute recurrence reduction at 15 years seems somewhat greater in ER+/PR poor disease than in ER+/PR+ disease,

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_45

possibly because of the somewhat higher risk of recurrence without treatment in this tumor subtype [14]. The potential antagonism between tamoxifen and chemotherapy suggested by preclinical data [15] has not been definitively proven [16, 17]. The ongoing OPTIMA studies evaluate whether chemotherapy plus ET is better than ET alone in patients with positive nodes [18]: while waiting for new data, tamoxifen should be initiated at the end of chemotherapy, when given.

45.2.3 Premenopausal Women

The optimal adjuvant ET for premenopausal women is still a matter of debate. For over 30 years, tamoxifen for 5 years has been the gold standard in this setting. The sustained reduction in BC mortality well beyond year 10 is of particular interest in younger women. Several currently available additional therapeutic options [i.e., the combination of ovarian function suppression (OFS) to oral ET (either tamoxifen or aromatase inhibitors (AIs)] will be illustrated in the following paragraphs. The individual choice should consider the risk of recurrence, the latest scientific evidence, as well as toxicity profile, patient's comorbidities, and her personal preference.

45.3 Ovarian Function Suppression

OFS by surgical castration or ovarian irradiation was the first ET used in premenopausal patients [19]. In developed countries, this approach has been progressively replaced by gonadotropin-releasing hormone analogues (GnRHa) with comparable results [20]. Surgical castration remains a low-cost choice in developing countries. Bilateral salpingo-oophorectomy is also a valid alternative in BRCA1/2 mutation carriers who completed family planning.

The 2007 EBCTCG meta-analysis [21] looked at 11,906 HR+ premenopausal women (from 16 trials) who received GnRHa as OFS. As compared to the previous 2005 analysis [20], showing a benefit for OFS in terms of BC-related mortality and relapse rate in the absence of other systemic treatments, the updated results proved OFS to be beneficial whether used alone (recurrence risk reduction of 28%, $p = 0.08$), in addition to tamoxifen or chemotherapy (recurrence risk reduction of 13%, $p = 0.02$), or as an alternative to chemotherapy. The benefit was especially evident in young women (≤40 years of age) after adjuvant chemotherapy, either alone or in addition to tamoxifen. The latter effect is probably explained by the lack of permanent amenorrhea with chemotherapy alone in this subgroup of patients, treated with new chemotherapy regimens associated with less ovarian toxicity compared to CMF [22]. Few trials tested the addition of GnRHa to tamoxifen (±chemotherapy), and no trials compared a GnRHa against chemotherapy with tamoxifen in both arms.

The long-term results of the ZIPP trial [23] (median follow-up 12 years) were not included in the 2007 EBCTCG overview. The trial randomized 2710 patients into four arms: 476 patients (17.5%) did not receive any adjuvant ET, 469 (17.3%) received single-agent goserelin, 879 (32.4%) received tamoxifen alone, and 882 (32.5%) received the combination of goserelin + tamoxifen. ET was administered for 2 years. In all the three treatment arms, the disease-free survival (DFS) was higher than in the control arm, with no significant differences between treatments, in particular with no added benefit by the addition of GnRHa to tamoxifen. The 2009 Cochrane review [24], run in over 13,000 premenopausal women randomized in 14 trials, concluded that (1) there is no enough data to determine whether GnRHa alone is comparable to tamoxifen alone, (2) there is a trend of reduction in BC recurrence in favor of the combination of GnRHa + tamoxifen versus GnRHa alone, and (3) the association of GnRHa and chemotherapy shows no differences in recurrence or overall survival (OS) compared to GnRHa alone. The authors highlighted the need to assess the role for GnRHa when added to modern chemotherapy regimens and tamoxifen, to continue the follow-up in order to provide long-term outcomes, to compare different durations of GnRHa and the addition of aromatase inhibitors (AIs). The 2015 meta-analysis by Yan and colleagues [25] examined only trials comparing tamoxifen alone with tamoxifen plus OFS (6279 patients) and concluded that the addition of OFS to tamoxifen does not provide additional benefits in patients who did not received chemotherapy. Instead, in the subgroup with chemotherapy, the addition of OFS significantly improved OS with a mortality reduction of 24% ($p = 0.03$), possibly because these patients were considered at sufficient risk of relapse to candidate for adjuvant chemotherapy. This meta-analysis has some limitations, as stated by its authors: the results of the subgroup analyses were based on relatively small numbers of patients; the chemotherapy regimens varied across trials according to the period of enrollment as did the criteria for definition of menopausal status.

Since the abovementioned publications, the results of the International Breast Cancer Study Group (IBCSG)-led Suppression of Ovarian Function Trial (SOFT) became available [26]: 3066 premenopausal women were randomized to 5 years of tamoxifen, tamoxifen + OFS, or exemestane + OFS. Overall, at median follow-up of 5.6 years, adding OFS to tamoxifen did not provide a significant benefit in terms of DFS (84.7% in the tamoxifen group, 86.6% in the tamoxifen + OFS group; hazard ratio (HR) 0.83; 95% confidence interval [CI], 0.66–1.04; $p = 0.10$). The preplanned analysis according to the administration of chemotherapy allowed discriminating two different groups of patients and outcomes. In the low-risk patient subgroup

(mostly >40 years, with small, node-negative tumors of low-intermediate grade) who did not receive chemotherapy, >95% of patients remained free from BC at 5 years irrespective of treatment assignation. In contrast, in the cohort of patients at higher risk of relapse, who deserved chemotherapy according to the treating physician and remained premenopausal afterward, the rate of freedom from BC at 5 years was significantly higher among patients receiving tamoxifen + OFS than tamoxifen alone (82.5% and 78.0%, respectively, HR 0.78; 95% CI, 0.60–1.02). Of note, in the subset of very young patients (<35 years), BC recurred in approximately one third of the patients receiving tamoxifen alone and in one sixth of those treated with exemestane + OFS (67.7% and 83.4%, respectively), suggesting OFS plays a major role in younger premenopausal patients. SOFT data allow to better select premenopausal patients for whom tamoxifen alone is not indicated, as acknowledged in all the most recent consensus guidelines [27–30].

Data on the efficacy and safety of 3-monthly versus monthly GnRHa are scarce. In 170 Japanese women, 3-monthly goserelin was not inferior to monthly administration in terms of estradiol suppression, safety, and tolerability [31]. In clinical practice, the 3-monthly administration can be considered in older premenopausal women (>40 years): despite technical challenges, estradiol, LH, and FSH levels should be regularly checked and suppressed, as amenorrhea is not the only reliable indicator of OFS [27, 30].

45.3.1 Aromatase Inhibitors

Third-generation AIs (the nonsteroidal letrozole and anastrozole, the steroidal exemestane) efficiently block the enzyme aromatase which synthesizes estrogens from androgens and achieve a nearly complete suppression of total-body aromatization and plasma estrogen levels in postmenopausal women [32]. Conflicting evidence has questioned the benefit of AIs in overweight/obese patients: the increased body aromatization in the fat tissue may in fact induce incomplete suppression of estrogen production by AIs. In overweight (BMI ≥25 kg/m^2) premenopausal patients treated with anastrozole in the ABCSG-12 trial, the risks of recurrence and death were significantly higher (HR, 1.49; 95% CI, 0.93–2.38; $p = 0.08$ and HR, 3.03; 95% CI, 1.35–6.82; $p = 0.004$, respectively) than in patients treated with tamoxifen [33]. In the ATAC study, menopausal women with a BMI >35 had a poor prognosis compared to lean women independent of treatment (tamoxifen or anastrozole) with a nonsignificant reduced benefit for anastrozole among obese individuals [34]. In contrast, in the BIG 1-98 study, the added benefit of letrozole over tamoxifen was irrespective of BMI [35]. No correlation was found between on-treatment aromatization levels or aromatase inhibition and BMI in 64 patients treated within six different clinical trials with a panel of aromatase inhibitors [36]. While waiting for the BMI data from TEXT-SOFT in premenopausal women, there is no sound data suggesting not prescribing AIs in overweight patients, if indicated [37].

45.3.2 Postmenopausal Women

Different AI treatment algorithms have been studied: (1) head-to-head comparison versus tamoxifen for a total of 5 years, (2) following 2–3 years of tamoxifen for a total of 5 years versus AI or tamoxifen for 5 years, and (3) following 5 years of tamoxifen for a total of 10 years of ET. In comparison 1 (9885 patients from the ATAC [38] and BIG 1-98 trials) [39], the 2015 EBCTCG overview [40] showed recurrence (local-contralateral-distant) was significantly reduced (by about 30%) by AIs as compared to tamoxifen during the treatment period but not afterward, suggesting that 5 years of an AI reduces recurrence by about one third during years 5–9, as does 5 years of tamoxifen. Little follow-up data are available beyond year 10. The 10-year BC mortality is also significantly but slightly reduced (by about 15%) by AI over tamoxifen even though about half the deaths were not due to BC. In the switching comparison (12,779 patients), recurrence was significantly reduced only during the first years when the treatments differed (RR 0.74; 95% CI, 0.62–0.89; $2p = 0.002$) and not afterward (RR 0.99), if both groups received an AI: no significant further effect was evident after year 5, but little follow-up data were available beyond year 7. These smaller reductions in recurrence, as compared to the head-to-head comparison, can possibly be attributed to the shorter duration in which treatment differed. BC mortality was not significantly reduced (RR 0.89; 95% CI, 0.78–1.03; $2p = 0.11$). The highest reduction in the recurrence rate during the treatment period was observed when the switching strategy was compared to tamoxifen for 5 years (11,798 patients) (RR 0.56; 95% CI, 0.46–0.67; $p < 0.0001$) with no significant further effect afterward but lack of sufficient follow-up beyond year 10. To accommodate for different randomization criteria in the different trials, only patients who completed 2 years of tamoxifen without recurrence were included. BC mortality was not statistically reduced (RR 0.84; 95% CI, 0.72–0.96; $2p = 0.015$). The BIG 1-98 trial [39] was the only study also to explore the reverse sequencing (tamoxifen following 2–3 years of letrozole for a total of 5 years versus AI for 5 years). Letrozole followed by tamoxifen provided similar DFS and OS to letrozole monotherapy in all patient groups: despite the study was not powered to test equivalence and these results are based on few patients and events they are of interest for women who do not tolerate AI. On the contrary, letrozole monotherapy tended to be better than tamoxifen followed by letrozole, especially for

control of distant recurrence in patients at higher risk of early relapse (e.g., patients with positive axillary nodes).

No apparent differences in efficacy emerge between different aromatase inhibitors: indirect and randomized comparisons [41] show little difference between AIs.

Overall, the reduction in 10-year BC mortality with AIs compared with tamoxifen is only slight but significant. As a consequence, as stated in the last San Gallen Consensus [28], tamoxifen alone may be suitable for patients at low risk of disease recurrence, while for patients at higher risk (i.e., ≥4 positive nodes, grade 3, high proliferation index), an AI should be considered and given up front. This attitude is supported by the STEPP analysis, performed in BIG 1-98 patients, of a composite measure of prognostic risk factors (i.e., number of involved lymph nodes, grade, tumor size, presence of peritumoral vascular invasion, age, and biological characteristics) which are commonly considered in clinical practice when deciding the best adjuvant ET for the individual patient. This analysis revealed patients at lowest risk did similarly well with letrozole monotherapy, a sequence of letrozole and tamoxifen, or tamoxifen monotherapy [42].

In a retrospective analysis of the BIG 1-98 trial, the magnitude of benefit of adjuvant letrozole seems greater for patients with lobular carcinoma ($n = 324$) versus ductal carcinoma ($n = 2599$) [43]. The small number of lobular cancers in the analysis and the unclear underlying biological mechanisms require further validation before AIs can be routinely recommended in this subset of patients. In the same analysis, no difference between letrozole and tamoxifen was reported in women with ductal carcinomas and luminal A-like subtype, defined as ER and/or PR+, HER2 negative, and with Ki-67 <14%. On the contrary, women with ductal carcinomas and luminal B-like subtype (i.e., Ki-67 ≥14%) experienced a significant reduction in the hazard of a DFS event with letrozole. This observation reinforces the role of tamoxifen in patients with favorable biological characteristics.

45.3.3 Premenopausal Women

The combined analysis of SOFT and TEXT (Tamoxifen and Exemestane Trial), comparing 5 years of exemestane + OFS with tamoxifen + OFS (4690 patients), after a median follow-up of 68 months, showed an absolute 3.8% gain in the 5-year DFS in patients treated with exemestane + OFS compared to those receiving tamoxifen + OFS (91.1% versus 87.3%, HR 0.72; 95% CI, 0.60–0.85; $p < 0.001$) [44], comparable with the benefit of AIs in postmenopausal women. Overall, 57.4% of the patients did receive adjuvant chemotherapy. Timing of chemotherapy and ET initiation was different in SOFT and TEXT: in TEXT, patients received OFS at randomization concurrently with chemotherapy, at an average of 1.2 months after surgery; in SOFT, patients completed all chemotherapy before randomization and started OFS at an average of 8 months after surgery but were allowed to receive oral ET (typically tamoxifen) while waiting for menses to resume. In women who had received chemotherapy, the rate of freedom from BC at 5 years was higher with exemestane + OFS than with tamoxifen + OFS (5.5% in TEXT and 3.9% in SOFT): the shorter time before starting OFS might explain the different treatment benefits in TEXT compared with SOFT. Among patients who did not receive chemotherapy (20.7% and 8.3% node positive in TEXT and SOFT, respectively), >97% of those who received exemestane + OFS and approximately 95% of those receiving tamoxifen + OFS remained free from BC at 5 years: these data show effective combined ET alone is associated with excellent outcomes also in node-positive patients, arguing the routine administration of chemotherapy to all premenopausal patients with HR+ disease. Overall, the 5-year OS did not significantly differ between exemestane + OFS (95.9%; 95% CI, 94.9–96.7) and tamoxifen + OFS-treated patients (96.9%; 95% CI, 96.0–97.6): longer follow-up is however needed as HR+ patients can develop late relapses.

The Austrian Breast and Colorectal Cancer Study Group (ABCSG) 12 trial randomized 1803 premenopausal patients to 3 years of goserelin + tamoxifen or anastrozole [45]. After 94.4 months of median follow-up, no DFS difference between treatments was reported, but a higher risk of death for anastrozole-treated patients was observed (HR = 1.63; 95% CI, 1.05–1.45; $p = 0.03$). Overall, after disease recurrence, 61% of patients in the tamoxifen group received AIs as opposed to only 41% of patients in the anastrozole group. ABCSG-12 and SOFT-TEXT have several differences which can potentially explain the divergent results: in particular, in the Austrian trial, the statistical power was lower (half the number of events), and treatment duration was only 3 years, which is not the current standard of care for oral ET.

These data help clinicians in selecting premenopausal women with HR+ early BC who could benefit from the addition of AIs to OFS, according to their individual risk and the toxicity profile, as recommended in all the most recent consensus guidelines [27–30].

45.4 Treatment Duration

Women with HR+ tumors show no plateau for both recurrence and OS, with a low but continuous risk of relapse and death even after 10 years [46]: the annual rate for late recurrences exceeds 2% for at least 15 years, even after 5 years of tamoxifen therapy. The analysis of 111,993 patients, diagnosed between 1990 and 2003 and included in the SEER database, showed age differences in late relapses, younger age (<40 years) being associated with the higher hazard of BC-specific mortality throughout the period of 5–10 years, irrespective of nodal status [47]. Several clinicopathological parameters (e.g., nodal status and tumor size) are also associated with an increased risk

of late recurrence. Altogether, these results may help clinicians determine which patients are the best candidates for extended ET. Further research is therefore needed to detect individual biomarkers or multigene signatures for the identification of women at high risk of late recurrence, particularly in node-negative disease.

In contrast with earlier, smaller studies [48, 49], the ATLAS [50] and aTTom [51] trials show, in almost 20,000 pre- and postmenopausal women, that continuing tamoxifen to 10 years provides a further reduction in both disease recurrence and mortality. In the ATLAS trial, at median follow-up of 7.6 years, BC recurrence was reduced by 3% (RR 0.84; CI 95%, 0.76–0.94; $p = 0.002$), breast cancer mortality by 2% ($p = 0.01$), and overall mortality by 2.48% ($p = 0.01$). The protective effect extends well over the 10 years' treatment period (RR 0.90; 95% CI, 0.79–1.02 during years 5–9 and 0.70, 95% CI, 0.62–0.90 during subsequent years), regardless of age and nodal status. Premenopausal patients constituted only approximately 9% of the study population, and statistical significance was not reached in this subgroup, likely because of the much smaller number of events: nevertheless, these results provide the only available evidence of a beneficial effect of extended ET in premenopausal patients and should be discussed on an individual basis, especially for patients at high risk of recurrence. In the aTTom trial, despite HR status was not available in a consistent proportion of patients, the longer-treatment group had fewer BC recurrences (28% versus 32%; $p = 0.003$), and BC mortality was reduced (21% versus 24%; $p = 0.06$). Overall, these results can be considered practice changing, especially in case of a significant risk of recurrence.

In the NCIC-CTG MA.17/BIG 1-97 study, patients receiving 5 years of letrozole after 5 years of tamoxifen experienced overall an improved DFS, but a significant OS benefit was evident only in patients with node-positive disease [52]. The best DFS benefit (HR 0.25; 95% CI, 0.12–0.51) was reported in premenopausal women at diagnosis who became definitively postmenopausal at the time of randomization, providing a new treatment option in this subgroup of patients, if clinically indicated.

Other two smaller trials (ABCSG 6a and NSABP-B33) confirmed the efficacy of 3-5 additional years of an AI beyond 5 years of standard tamoxifen.

Based on the available evidence, both extended adjuvant ETs with an AI after 5 years of tamoxifen in menopausal women and tamoxifen for 10 years in pre- and postmenopausal women reduce the risk of cancer recurrence. Tamoxifen for 2–3 years followed by an AI for additional 5 years, for a total duration of up to 7–8 years of therapy, is also a valuable treatment option [53]. It is not known which strategy is preferred; tamoxifen and AIs have different adverse effects which may influence treatment decisions.

In postmenopausal women who received adjuvant AIs in the first 5 years, several trials addressed different strategies of AI extension. Patients' populations are not homogeneous across trials (e.g. upfront therapy and total duration of AI), making the results difficult to interpret and translate into clinical practice. In the recently reported studies (MA.17R, NSABP-B42, DATA), a DFS benefit was shown only in the MA.17R trial, mainly driven by reduction in the incidence of contralateral disease. No survival benefit was reported so far [54]. Consequently, extended AIs should not be routinely proposed but possibly discussed in women at higher risk of relapse who did not experience significant toxicity under previous AIs.

Molecular signatures able to predict distant recurrence rates (BCI, EndoPredict, PAM50) need to be prospectively tested to define the cost-benefit ratio of extended ET.

The optimal duration of adjuvant GnRHa has not been established. In different trials, GnRHa were given for 2, 3, or 5 years, with no direct comparisons. The latest ESMO guidelines suggest at least 2 years of treatment [55]: the excellent outcome of patients treated for 3 years in the ABCSG-12 trial suggests this can be reasonable, especially in women reporting severe side effects. In the TEXT and SOFT trials, duration of both oral ET and OFS was 5 years: to date, there are no data on their extension beyond 5 years. A phase II single-arm trial evaluated, after at least 4.5 years of adjuvant tamoxifen, 2 years of OFS in combination with the AI letrozole [56]. The study was closed after only 16 patients enrolled over 3.5 years, suggesting young women may not be highly motivated to extended ET and challenging the feasibility of future studies.

45.5 Advanced Breast Cancer (ABC)

45.5.1 Indications

For patients with HR+ ABC, ET is the recommended initial treatment even in the presence of visceral metastases: chemotherapy should be reserved in case of rapidly progressive disease or proven endocrine resistance [57]. Confirmatory biopsy of metastases, where feasible, should be considered as it may confirm concordance (or discordance) of endocrine sensitivity allowing better identification of patients likely to benefit from ET [58]. Different sequential ETs can be given until disease progression, unacceptable toxicity, or development of symptomatic visceral disease. The sequential use of ETs with different mechanisms of action may prolong the duration of response, reduce the risk of resistance, and delay the need for chemotherapy [59]. Most studies addressing the combination of ET and chemotherapy showed an increased overall response rate (ORR) or an increased time to progression (TTP) but no improvement in OS with no age-related differences [60]. Trials examining concurrent versus sequential ET and chemotherapy need therefore to be conducted. The specific scenario of patients with both HR- and HER2-positive disease will be addressed in a separate chapter.

45.5.2 Available Options

The third ESO-ESMO ABC consensus conference confirmed the statement that for postmenopausal patients, the choice of first-line ET depends both on type and duration of adjuvant ET and disease-free interval (DFI) from the end of adjuvant ET. AIs, tamoxifen, or high-dose (HD) fulvestrant (i.e., 500 mg monthly) are acceptable alternatives. In the FIRST phase II study [61], HD fulvestrant proved to be superior to anastrozole in terms of OS (median OS 54.1 months versus 48.4 months; HR 0.70; 95% CI, 0.50–0.98; $p = 0.04$). These data need to be interpreted cautiously as the OS analysis was not originally planned and not all patients had OS follow-up: the preliminary results of the larger phase III FALCON trial (450 patients) showed a PFS benefit (16.6. vs 13.8 months, HR 0.797) with immature OS data. The combination of a nonsteroidal AI and LD fulvestrant (250 mg monthly) showed discordant results in two phase III trials with similar designs [62, 63]. Subset analysis in the successful SWOG study suggests a benefit in the PFS and OS for the combination therapy only in patients without prior adjuvant tamoxifen [63] to whom this strategy can be offered. In this study, the addition of fulvestrant to anastrozole significantly decreased anastrozole concentrations in a subset of patients treated with the combination, potentially affecting treatment efficacy [64].

The optimal sequence of endocrine agents after first-line ET is uncertain and depends on which drugs were used in the neoadjuvant/adjuvant and first-line ABC settings. Reasonable options include AIs, tamoxifen, fulvestrant, progestins, high-dose estrogens, and androgens [57].

For premenopausal women, ovarian suppression/ablation combined with additional ET is the treatment of choice [65]. A meta-analysis of four studies ($n = 506$) comparing GnRHa ± tamoxifen showed the outcomes were significantly improved in patients who received the combination [66]. The limited evidence available [67] and indirect comparison of data from the adjuvant setting [44] and menopausal patients [68] suggest AIs can be a valuable alternative to tamoxifen: decisions should be made according to type and duration of prior adjuvant ET, DFI, toxicity profile, and patients' preferences. Fulvestrant is also a valuable option which mandates OFS [67]. Ovarian ablation (OA) by laparoscopic bilateral oophorectomy ensures definitive estrogen suppression and contraception, avoids potential initial tumor flare with GnRHa, and represents a cost-effective alternative particularly in middle-low-income countries. Patients should be informed on the options of OFS/OA, and decision should be made on a case-by-case basis.

45.5.3 Targeting Endocrine Resistance

Several potentially targetable mechanisms of intrinsic and acquired endocrine resistance have been identified, such as ER alterations (mutations, amplifications, or translocations) and upregulation of alternative growth pathways (i.e., the HER, the PI3K/Akt/mTOR, and the CDK4/CDK6 pathways). Tumors that are both ER and HER2+ are less responsive to tamoxifen treatment [69, 70]. At central review, 7% and 10.5% of patients in the BIG 1-98 and ATAC trials overexpressed HER2, respectively: in both trials, the benefit of AIs over tamoxifen was independent of HER2 status of the primary tumor. In SOFT and TEXT, 12% of premenopausal patients had HER2+ tumors and ~60% received HER2-targeted therapy, reflecting the accrual time period. In SOFT, the addition of OFS to tamoxifen appeared to be beneficial over tamoxifen alone (HR, 0.78; 95% CI, 0.62–0.98; $p = 0.03$) [26] as previously reported by others [71]. On the other hand, in the combined TEXT-SOFT analysis, in the presence of OFS, exemestane did not confer any advantage over tamoxifen (DFS HR = 1.25; 95% CI, 0.80–1.94) [44]. HER2 central assessment and further analysis are however needed before HER2 status is used for oral ET selection in premenopausal women.

45.5.4 mTOR Inhibitors

The mTOR inhibitor everolimus has proven to be effective in postmenopausal women relapsing/progressing under AIs both in combination with exemestane in the BOLERO-2 phase III trial [72] and with tamoxifen in the phase II TAMRAD study [73]. In the BOLERO-2 trial, a significantly longer median progression-free survival (PFS) with the combination versus exemestane alone was reported (central review: 11.0 months versus 4.1 months, respectively; HR 0.38; 95% CI, 0.31–0.48; log-rank $p < 0.0001$) [74]. Several predefined or exploratory subgroup analyses [75] demonstrated the PFS benefit was irrespective of age (i.e., <65, ≥65, and ≥70 years), the administration of prior chemotherapy for ABC (6.1 months versus 2.7 months; HR 0.38; 95% CI, 0.27–0.53), and the presence of visceral disease (6.8 months versus 2.8 months; HR 0.47; 95% CI, 0.37–0.60; $p < 0.05$). In addition, everolimus increased the median PFS in patients recurring after adjuvant therapy (11.5 months versus 4.1 months; HR 0.39; 95% CI, 0.25–0.62), suggesting to be potentially effective as first-line therapy. The overall PFS advantage did not translate into a survival benefit: the median OS in patients receiving the combination was 31.0 months compared with 26.6 months in patients receiving exemestane alone (HR 0.89; 95% CI, 0.73–1.10; log-rank $p = 0.14$) [76]; one possible explanation is that the trial was not powered to detect an OS advantage as the sample size was based on the primary end point of PFS. A network meta-analysis compared the PFS of everolimus + exemestane, as reported by the BOLERO-2 trial, with that of LD/HD fulvestrant after adjuvant or first-line ET from six studies [77]. Everolimus + exemestane was more efficacious than both

LD and HD fulvestrant (HR 0.47 and 0.59, respectively). Overall, these results contrast with those of the first-line HORIZON study, wherein adding the mTOR inhibitor temsirolimus to letrozole did not improve PFS in 1112 patients with AI-naïve ABC [78]. The single-arm BOLERO-4 phase II trial, assessing the safety and effectiveness of first-line therapy with everolimus + letrozole, has completed accrual and will also provide information on the efficacy of continuing everolimus after initial disease progression (PD); patients progressing under treatment will be allowed to maintain everolimus and add exemestane until further PD or unacceptable toxicity [79]. Everolimus is being studied also in the adjuvant setting [80, 81]. The decision to give everolimus must take into account the potential relevant toxicities associated with this combination and should be made on a case-by-case basis.

45.5.5 CDK4/CDK6 Inhibitors

The randomized phase I/II PALOMA-1 study showed an impressive PFS improvement in patients treated with the combination of the CDK4/CDK6 inhibitor palbociclib and letrozole compared to letrozole alone as first-line treatment (20.2 months versus 10.2 months; HR 0.488; $p = 0.0004$). The presence of CCND1 amplification and/or p16 loss was not predictive for efficacy. No significant difference in OS has been shown so far: a preliminary analysis suggested a trend toward increased OS (37.5 months versus 33.3 months; HR 0.813; $p = 0.2105$) in the combination arm [82]. Combination therapy was very well tolerated, and common grade 3/4 toxicities seen in the palbociclib-containing arm versus the letrozole alone arm were neutropenia (54% versus 1%), leucopenia (19% versus 0%), fatigue (4% versus 1%), and anemia (6% versus 1%). On the basis of these favorable results, the FDA granted palbociclib accelerated approval as first-line treatment for postmenopausal women with HR+ and HER2− ABC pending confirmatory results from the phase III PALOMA-2 trial (NCT01740427). The double-blind phase III PALOMA-3 trial evaluated the efficacy of palbociclib + HD fulvestrant versus HD fulvestrant alone in pre- and postmenopausal women with HR+/HER2− ABC who had relapsed/progressed on prior ET [83]. Pre and perimenopausal women received also the GnRHa goserelin. At the first interim analysis, the primary end point was reached; the median PFS was 9.2 months in the combination arm and 3.8 months in the fulvestrant arm (HR 0.422; 95% CI, 0.318–0.560; $p < 0.000001$). Of note, the relative difference in PFS was independent of menopausal status, providing a new treatment option also for young patients with HR+ ABC. At the time of the interim analysis, data on OS were immature, with a total of only 28 deaths. Several trials evaluating palbociclib plus ET are in progress in the adjuvant and neoadjuvant settings, as well as in combination with chemotherapy and HER2-targeted agents. A significant PFS improvement was also reported with Ribociclib, another selective CDK4/6 inhibitor, in combination with letrozole as first-line treatment in menopausal women, myelosuppression being the only relevant associated toxicity of the compound [84]. A third agent (LY2835219, abemaciclib) is under evaluation in different disease settings.

45.5.6 Other Compounds

The encouraging results in terms of efficacy and tolerability of a small phase II placebo-controlled trial ($n = 43$) of anastrozole combined with gefitinib, an orally active EGFR tyrosine kinase inhibitor, compared to anastrozole alone [85] were not replicated in a larger phase II study ($n = 71$) with similar design [86]. Overall, both the RR, not clearly superior to ET alone, and the toxicity profile do not support further evaluation of this combination. Efficacy of VEGF inhibitors has been disappointing to date: the pan-VEGF inhibitor pazopanib is being evaluated as an add-on therapy in a phase II trial of patients with HR+, locally advanced or metastatic BC progressing on nonsteroidal AIs in the adjuvant or metastatic setting (NCT01466972). Several additional targeted agents are under evaluation in combination with ET, e.g., PI3K, SRC, FGFR, and histone deacetylase inhibitors [87].

It is currently unknown how the different combinations of ET + biological agents compare with each other and with single-agent chemotherapy and whether a targeted agent should only be combined with ET to restore endocrine sensitivity or whether it may also prevent or delay the development of resistance [88]. Appropriate patient selection based on prior treatment history and disease characteristics will become increasingly important in maximizing the potential incremental benefit from these new agents combined with standard ET.

45.5.7 Side Effects and Adherence

ET is associated with potential physical and psychosocial long-term and late effects, specific of the drugs used and their duration. Accurate evaluation of potential contraindications to specific compounds and strategies to manage the most common toxicities [29, 54, 89, 90] should be part of routine clinical care.

ET adherence and persistence are relevant and may affect disease outcomes [91, 92]. A systematic review of 29 studies in the adjuvant setting showed that at the end of 5 years of treatment, adherence ranged from 41% to 72% (59% nonadherence for tamoxifen and 50% for AIs) and nonpersistence from 31% to 73%. Age (older or younger), increasing out-of-pocket costs, follow-up care with a general practitioner instead of an oncologist, and treatment side effects were all

negatively associated with adherence and/or persistence [93]. Health professionals should routinely assess and encourage adherence to ET [54, 94] and specifically address side effects to reduce symptom burden and potentially improve adherence [90].

The most commonly reported side effects of tamoxifen mimic menopausal symptoms including hot flashes, weight gain, sleep disturbance, sexual dysfunction, and gynecologic complications which may negatively impact QoL: rare but serious toxicities include increased risks of endometrial cancer and thromboembolism. In premenopausal women, there is little uterine cancer risk or excess risk of fatal pulmonary embolism [8]. The incidence of endometrial cancer and thromboembolism is very low even with longer therapy duration (3.1% versus 1.6% endometrial cancers for tamoxifen-treated versus placebo-treated women and relative risk of pulmonary embolism of 1.87 in the ATLAS trial) [51]. As opposed to menopausal women, tamoxifen may decrease bone mineral density (BMD) in premenopausal women, although the exact mechanism remains unclear [95].

Bothersome toxicities of AIs include musculoskeletal symptoms (i.e., arthralgias, myalgias, tendonitis, and carpal tunnel syndrome), menopausal symptoms, decreased BMD and consequent increased risk of fracture, and dyslipidemia [40]. Interestingly, although all AIs have the same mechanism of action and side effect profile, some patients who are treated with more than one of the individual AIs experience a different constellation of side effects from the different drugs. A meta-analysis of seven randomized controlled trials that compared AIs and tamoxifen as adjuvant ET in postmenopausal women (30,023 patients) showed AIs were associated with increased cardiovascular disease (OR = 1.26; 95% CI = 1.10–1.43; $p < 0.001$) and bone fractures (OR = 1.47; 95% CI = 1.34–1.61; $p < 0.001$) but a decreased odds of venous thrombosis (OR = 0.55; 95% CI = 0.46–0.64; $p < 0.001$) and endometrial cancer (OR = 0.34; 95% CI = 0.22–0.53; $p < 0.001$) [96]. Switching from one class of drug to the other can be a valuable strategy for balancing serious adverse events of individual drugs. ET may also adversely affect cognition [97]: objective but not subjective cognitive function improved approximately 1 year after cessation of either adjuvant letrozole, tamoxifen, or their sequence in a subset of patients treated within the BIG 1-89 study [98].

The addition of OFS to oral ET is associated with greater menopausal symptoms, anxiety, and depression [27]: in women who develop severe side effects, the risk-benefit ratio should be discussed according to the individual risk of relapse and OFS interruption proposed. Side effects and quality of life (QoL) have been extensively analyzed in SOFT and TEXT. Overall, 16.1% of the patients in the exemestane + OFS group and 11.2% of those in the tamoxifen + OFS group completely stopped ET. Global QoL and symptom indicators were assessed every 6 months for 24 months and then every year between years 3 and 6 in 4096 patients of both trials. Patients under tamoxifen + OFS reported more hot flushes, vaginal discharge, and sweats than those under exemestane + OFS, whereas patients who received exemestane + OFS had more bone/joint pain, vaginal dryness, and greater loss of sexual interest compared with patients on tamoxifen + OFS. Nonetheless, during the treatment period, changes in global QoL from baseline were similar between the two treatment groups [99].

Genetic polymorphisms may classify low or extensive drug metabolizers of either tamoxifen, via CYP2D6, or AIS, via CYP19A1. Many attempts have been undertaken to explore the impact of ET metabolism on toxicity and outcome with discordant results, preventing the utilization of pharmacogenomic data to select the best oral ET in the individual patient [100–102].

As ET side effects are related to suppression of estrogen production or ER blockade, it has been questioned whether the development of side effects is related to ET benefit. A number of unplanned retrospective analyses evaluated the association between symptoms of ET in general, rather than specifically for tamoxifen or AIs, and BC outcome. Most but not all analyses identified a positive association between musculoskeletal toxicity and improved DFS and OS. A subset also identified associations between vasomotor symptoms and improved outcomes. Major limitations of these data include: physician-graded adverse events instead of patient-reported outcomes, with the related underreporting of symptoms and no consistent definition for musculoskeletal symptoms across studies; exclusion of symptomatic patients at baseline, not capturing baseline symptoms and global severity, which makes it difficult to interpret these findings and to possibly apply this information to drive treatment decisions in individual patients [89].

45.6 Fertility Considerations and Pregnancy

Fertility and safety of pregnancy after the disease are major concerns for many young women with early BC [103, 104]. Fertility preservation should be addressed early after diagnosis according to all the most recent guidelines [30, 105, 106]: ideally patients should be referred to a fertility specialist before starting therapy to discuss all the available options [107]. Pregnancy following BC does not seem to negatively influence DFS or OS in HR+ premenopausal patients [108, 109]. A global IBCSG-led trial (POSITIVE-IBCSG 48-14 NCT02308085) is assessing patients' safety and pregnancy outcomes of interrupting ET after at least 18 months but no longer than 30 months to attempt conception.

45.7 Future Directions and Conclusions

The current therapeutic armamentarium in early BC requires a careful evaluation of both tumor's and patient's characteristics to select the optimal class of drugs, their sequence, and duration, carefully monitoring side effects and adherence. Patient's preference, requiring adequate and complete information, is therefore a key point to ensure the excellent outcomes reported by clinical trials translate in the overall population.

Cross talks between ER and growth factor pathways and discovery of new molecular aberrations in breast tumors will allow to develop new strategies for the cure of HR+ BC, moving from the advanced disease setting to earlier disease stages. Future treatments will likely include combination of several targeted therapies with cumulative side effects and extra personal and social costs which need to be anticipated and managed. A marker-driven selection of targeted agents for each patient and the reproducible and biologically significant detection of key molecular alterations responsible for both intrinsic and acquired resistance are therefore mandatory if we want to move to precision medicine and optimal resource allocation. As a consequence, sensitive, early, and reproducible predictors and markers of response/resistance are urgently needed in ABC to avoid unnecessary and toxic therapies. This is particularly relevant as improvements in PFS not always translate into OS benefit. Different disease end points, e.g., the post-progression survival (SPP) and/or composite end points including measurements of efficacy and toxicity and patients reported outcomes, such as the ESMO Magnitude of Clinical Benefit Scale [110], need therefore to be systematically implemented and tested.

Chemotherapy Regimens in the Adjuvant and Advanced Disease Settings

46

Christopher D. Hart, Laura Biganzoli, and Angelo Di Leo

Abbreviations

AC	Doxorubicin plus cyclophosphamide, 4 cycles given 3 weekly (2 weekly for dose-dense) (×4, q21 or q14)
CMF	Cyclophosphamide, methotrexate, fluorouracil, ×6 q28 (d1+d8)
FEC	Fluorouracil, epirubicin, cyclophosphamide, ×6 q21
EC	Epirubicin cyclophosphamide
(F)EC-D	Epirubicin plus cyclophosphamide (with or without fluorouracil) ×3 followed by docetaxel ×3, q21 (or q14 for dose-dense)
TC	Docetaxel cyclophosphamide ×4 q21
TCH	Docetaxel cyclophosphamide trastuzumab ×4 q21, trastuzumab continued for total 1 year
TCarboH	Docetaxel carboplatin trastuzumab ×6 q21, trastuzumab continued for total 1 year

46.1 Adjuvant Chemotherapy Regimens

The administration of chemotherapy after primary breast cancer surgery revolutionised early breast cancer management. The groundbreaking trials by Bonadonna established CMF as a benchmark adjuvant regimen that led to reduced recurrence rates and long-term survival in all postoperative EBC patients, both node-positive and node-negative [1]. Subsequently, anthracycline regimens were found to be at least equivalent or superior to CMF, followed by third-generation taxane-containing regimes that proved superior again [2]. Chemotherapy is of clear benefit in node-positive disease but also has evidence of reducing recurrence and mortality in node-negative disease.

The emergence of the importance of HER2 status and molecular subtypes changed the paradigm for treatment. It became recognised that cancers with the same clinicopathological features (size, grade, nodal status) can have vastly different prognoses and responses to treatment, depending on subtype. This in turn impacts on the decision to give chemotherapy and what sort to give. The principles for deciding whether or not to use chemotherapy are covered in another chapter; here we focus on the choice of chemotherapy regimen.

Many adjuvant regimens exist with proven efficacy, yet there is no single combination that is considered best, due to the multitude of concurrent yet uncoordinated adjuvant trials using various combinations of agents. Chemotherapy choices may be broken down into first (CMF)-, second (anthracycline)- and third (taxane combinations with or without anthracycline)-generation regimens; however, within generations, few head-to-head trials have been performed to demonstrate an optimal regimen. Increasing dose and intensity beyond certain limits was proven counterproductive in the trials of very high-dose regimens that required autologous stem cell support, which resulted in worse survival and greater long-term morbidity, and is not recommended today [3].

Selecting an optimal regimen for an individual patient requires consideration of a number of prognostic factors, possible predictive factors and careful discussion of relative risks and benefits with the patient to allow an informed decision, in much the same way as the decision whether or not to give chemotherapy in the first place. Typical factors include age and comorbidities, tumour size, grade and extent of neurovascular invasion, nodal status and hormone receptor and HER2 status. Whether intrinsic molecular subtype, surrogate definitions of subtype or prognostic genomic panels can help in this regard is the subject of debate and remains under investigation.

While the arrival of anthracycline- and taxane-anthracycline-based regimens has improved disease-free and overall survival [2], these newer combinations come at the

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_46

price of increased toxicity, which must be weighed against the expected absolute benefit of the chemotherapy regimen. This is particularly relevant in the better prognosis cancers, e.g. luminal A with no nodal metastases. Here, the absolute survival benefit from adjuvant chemotherapy may be in the order of <5%, and, consequently, absolute differences between newer and older regimens in terms of overall survival may be negligible. Given that the long-term risk of leukaemia and congestive heart failure following anthracycline therapy is 1%, it would seem reasonable to avoid anthracycline-containing regimens in these scenarios.

Taxane-only regimens have also been compared to anthracycline combinations in an effort to find equivalent regimens that are better tolerated and reduce the risk of long-term anthracycline-related toxicity. AC has been a standard short course treatment after proving equivalent or superior to CMF in node-positive and node-negative populations [4–5]. Subsequently, a single study demonstrated superiority of TC compared to AC in node-negative and node-positive patients, suggesting a general superiority of taxanes [6]. However in another study comparing AC to single-agent paclitaxel in women with 0–3 positive nodes, AC proved to have the higher 5-year overall survival at 95% compared to 94%, despite a treatment-related death rate of 0.5% (mainly AML) vs 0% [7]. Thus, while weekly paclitaxel is a simpler, more tolerable regimen, it is not considered equivalent to polychemotherapy. Nevertheless, the degree of inferiority may be acceptable to some patients, and it remains a reasonable regimen for intermediate-risk patients unfit for stronger combinations.

Results from two trials suggest that the fluorouracil component of FEC chemotherapy does not improve survival but does contribute to toxicity. In an Italian study using a 2 × 2 design, investigators compared FEC-paclitaxel three-weekly and two-weekly and EC-paclitaxel three-weekly and two-weekly (dose-dense) [8] and showed that omission of fluorouracil had no impact on survival but did lead to a reduction in cytopenias and gastrointestinal adverse events, suggesting that the FEC-D regimen from the PACS-01 study [9] may not suffer from dropping the fluorouracil component. Similarly, the NSABP-B36 study compared six doses of FEC100 to four doses of AC, each given at 3-week intervals, and found them to be equivalent in terms of outcome, but with greater toxicity in the FEC arm [10]. It would seem reasonable then to prefer non-fluorouracil anthracycline combinations, and our practice is to use EC-D or EC-weekly paclitaxel.

46.1.1 Dose-Dense Regimens

Regimens that reduce the time interval between doses are associated with improved relapse-free and overall survival in meta-analysis [11], although the survival benefit was not entirely seen in hormone receptor-positive patients, being statistically non-significant. Dose-dense administration comes with the advantage of reducing the total length of time a patient is undergoing treatment but may be associated with increased rates of some toxicities. Granulocyte colony-stimulating factor support is mandatory to reduce the rate of myelosuppression compared to standard dosing, which adds to cost. As the improved outcome is only incremental, the use of a dose-dense regimen may be warranted mainly in the highest-risk categories where chemotherapy is expected to offer reasonable absolute benefit—triple negative or luminal B with other high-risk features. As always, patient wishes are crucial—some may be keen to try a tougher regimen in order to complete it sooner. Having commenced a dose-dense regimen, it is entirely reasonable to switch to standard dosing if it is proving intolerable.

A widely used dose-dense regimen, particularly in North America, is AC-paclitaxel, given two-weekly. This is based on the results of the CALGB 9741 trial, which demonstrated superiority of the schedule over three-weekly AC-paclitaxel [12]. Similarly, FEC-paclitaxel and EC-paclitaxel given at two-week dose intervals resulted in statistically significant improvement in relapse-free and overall survival after 7-year follow-up, compared to standard three-week dosing [8]. Of note is the fact that three-weekly dosing of paclitaxel is now recognised as inferior to the weekly dosing schedule [13], making the comparator arm in both trials a non-standard of care and limiting conclusions. Nevertheless, when a dose-dense regimen is preferred, AC or EC, followed by either two-weekly paclitaxel ×4 or weekly paclitaxel ×12, would be appropriate.

46.1.2 Bevacizumab

The use of bevacizumab in early breast cancer has been controversial and is not currently recommended in adjuvant treatment. Neoadjuvant bevacizumab has been shown to improve pCR rates, but has not led to improved long-term outcomes, although recent data from the NSABP B40 study suggests otherwise [14]. In this study of 1186 women with HER2-negative EBC, after a median follow-up for·7 years, the addition of bevacizumab led to significantly increased overall survival (hazard ratio 0·65 [95% CI 0·49–0·88]; $p = 0·004$) and non-significantly increased disease-free survival (HR 0·80 [0·63–1·01]; $p = 0·06$) [14]. This study employed a 3 × 2 factorial design to compare additional chemotherapy agents on top of the neoadjuvant AC-docetaxel backbone, which may complicate conclusions. Further studies are required, but the increased response rate, pCR rate and different toxicity profile associated with bevacizumab mean that its use as a neoadjuvant agent is not unreasonable, preferably in a trial setting.

46.2 Recommendations

46.2.1 ER-Positive, HER2-Negative EBC

In the luminal cancers, effective adjuvant endocrine therapy is considered to be of primary importance, with chemotherapy contributing less to improved outcomes. Nevertheless, there may be important differences between luminal A and B that could impact on chemotherapy choice.

Longer-term follow-up of BIG 2-98 and a pooled analysis of four trials revealed that the benefit from the addition of taxanes to anthracycline-based therapy in terms of relapse-free or overall survival is limited to ER+ patients with high Ki67 (≥14%), a marker that can separate luminal A and B [15]. We have also shown preliminary evidence that clinicopathological markers of luminal A disease (ER- and PR-positive, HER2-negative, Ki67 low) may be sufficient to identify a group of patients where the benefit of anthracycline regimens over CMF, and of taxane regimens over anthracyclines, is small or negligible [16]. This may in part be by virtue of the fact that this is a subgroup with better prognosis, and thus a significant benefit is harder to discern. There is also evidence that luminal A disease is inherently less chemosensitive, which may also lead to irrelevant differences between newer and older regimens [17]. But whether predictive or only prognostic, consideration of tumour biology is relevant.

Thus, when it has been decided that adjuvant chemotherapy is warranted, in luminal A disease, the choice of regimen may be made with greater emphasis on acceptable toxicity and dosing schedule. The shorter course TC regimen would be acceptable or even classical CMF to avoid the risk of taxane neurotoxicity, both of which avoid risk of long-term anthracycline complications. CMF however is a long six-month course CMF therefore is to be considered mainly when alopecia is an issue for the patient.

It must be noted that surrogate definitions of luminal subtype using IHC remain controversial, particularly in regard to the use of Ki67, and have not been prospectively validated. While their use cannot be formally recommended at this stage, expert review panels have condoned it in principle [18].

Bearing in mind that there is no strong evidence for selecting a single regimen over another, and that each case must be assessed on its merits, we offer the following suggestions:

46.2.2 Luminal A

For 1–3 positive nodes and large tumours (i.e. intermediate risk): TC or EC (TC preferred), CMF, weekly paclitaxel × 12 (if unfit for polychemotherapy).

For >3 positive nodes, (F)EC-D, EC-paclitaxel.

46.2.3 Luminal B

As for node-positive luminal A, except with a lower threshold for prescribing taxane-containing regimens:

Node-negative: TC (or EC, but not recommended), CMF, weekly paclitaxel (if unfit for polychemotherapy).

Node-positive: (F)EC-D or EC- paclitaxel, consider dose-dense regimen for multiple high-risk features.

46.2.4 After Genomic Assay Recurrence Risk Stratification

In the case of receiving prognostic information from gene signature models such as the 21-gene recurrence score (RS) that suggest when to use of adjuvant chemotherapy, there is still little guidance on the most appropriate regimen. Furthermore, it is unknown if one can apply other prognostic factors after RS stratification—for example, in RS high patients with luminal A-like disease (unlikely but possible), is there a degree of chemotherapy insensitivity that limits the incremental difference of taxanes over anthracyclines?

Given that a high score correlates with an aggressive phenotype and high risk of relapse, it would seem reasonable to use combined anthracycline taxane regimes in these situations. For an intermediate score, we would rely on more classical markers such as nodal status—in node-positive disease, an anthracycline-taxane-containing regimen is an option; in node-negative, if it is to be given at all, short course TC, or alternatively, if a less toxic regimen is required, weekly paclitaxel or CMF. In all cases, a discussion of the risks and benefits of newer versus older generation regimens is vital to gauge the patient's priorities and wishes.

There is now evidence that cancers with very low scores in node-negative disease have such a low likelihood of relapse that there is no benefit to be gained from adjuvant chemotherapy [19]. Ongoing trials are assessing the benefit of chemotherapy in intermediate- and high-risk scores, in both node-positive and node-negative disease. Whether this helps with chemotherapy selection is yet to be seen.

46.2.5 HER2-Positive Disease

Trastuzumab revolutionised outcomes for women with HER2-positive early breast cancer and is a vital component of their adjuvant therapy. Lapatinib, conversely, has not proven to be beneficial [20–21]. More recently developed HER2-targeting agents are under investigation in this setting—pertuzumab, an inhibitor of dimerization of HER2 and HER3, and trastuzumab emtansine (T-DM1), an antibody-drug conjugate. The addition of pertuzumab to trastuzumab neoadjuvant therapy resulted in higher pCR rates in a phase

II trial (NeoSphere) [22], and phase III trials are ongoing (Aphinity).

Recommended duration of trastuzumab treatment is 12 months, based on trials that demonstrated inferiority of six months (PHARE) [23], and non-superiority for 24 months (HERA) [24]. The main toxicity associated with trastuzumab is cardiomyopathy, which usually resolves on treatment withdrawal [25]. However, this is increased when combined with anthracyclines, even if given sequentially [26]. Trastuzumab is commenced with the adjuvant chemotherapy regimens, and taxane-anthracycline combinations are generally recommended, with trastuzumab administered with the taxane after completion of the anthracycline component.

The BCIRG006 trial investigated the potential for omitting doxorubicin from the adjuvant regimen, comparing docetaxel and carboplatin plus 52 weeks of trastuzumab (TCarboH) to doxorubicin and cyclophosphamide followed by docetaxel every 3 weeks plus 52 weeks of trastuzumab (AC-TH), as well as a non-trastuzumab arm, AC-T. They enrolled 3222 women with HER2-positive early-stage breast cancer, and results were recently reported for long-term follow-up of median 10.3 years [27]. Compared to AC-T, AC-TH and TCarboH reduced the risk of disease recurrence by 30% and 24%, respectively, and the risk of death by 36% and 24%, respectively. The difference between the trastuzumab-containing regimens was not statistically significant, although the study was not powered to compare the two directly. However, there were five times as many cases of congestive heart failure cases in the AC-TH regimen compared to TCarboH (21 cases vs. 4), a rate of 2.0% in AC-TH versus 0.4% in TCarboH and 0.8% in AC-T. Furthermore, patients treated with TCarboH had lower rates of sensory neuropathy and severe neutropenia but higher rates of anaemia and thrombocytopenia.

Unfortunately, there were no results reported for subgroups by ER status. Late relapse tends to occur more frequently in ER-positive patients compared to ER-negative and are considered a failure of endocrine therapy, while relapses due to failure of chemotherapy are usually in the first 3–5 years. Thus, with longer follow-up, a survival benefit from chemotherapy in ER-positive disease will become less apparent and may dilute or mask the benefit seen in ER-negative patients when the two groups are combined. Therefore, the AC-TH may yet be shown to be clinically and perhaps statistically superior to TCarboH in ER-negative patients.

Tumour size is an important consideration. T1a (≤5 mm) and T1b (5–10 mm) tumours were poorly represented in initial trials of adjuvant trastuzumab, making it difficult to know whether such cancers require adjuvant therapy or what combination to use. A single-arm study of tumours up to 3 cm treated with adjuvant weekly paclitaxel × 12, plus trastuzumab for 1 year, showed extremely low 3-year recurrence of 98.7%, lower still in the ER-positive or <1 cm subgroups [25]. Although this was only after median 4-year follow-up, the results are encouraging for those early-stage patients who would prefer a less toxic regimen.

For the most part, we would recommend a taxane-anthracycline regimen, in combination with 12 months of trastuzumab, in all HER2-positive disease. In the case of anthracycline contraindication, or lower-risk node-negative disease, TCarboH or other non-anthracycline-based regimens would be appropriate, such as TCH. For node-negative disease <2 cm, particularly if ER-positive and employing endocrine therapy, the weekly paclitaxel-trastuzumab regimen is suggested.

In the neoadjuvant setting, the addition of pertuzumab to trastuzumab would be reasonable, given current evidence, although it comes at significantly greater financial cost with no current evidence of survival benefit.

46.2.6 Triple Negative

Breast cancers lacking expression of both hormone receptors and HER2 are not eligible for targeted therapy, making chemotherapy the only adjuvant therapy available. Furthermore, despite being relatively chemosensitive, these cancers have a generally worse prognosis. Therefore, adjuvant chemotherapy is recommended in most cases, and the threshold for prescribing a taxane-anthracycline regimen is low. For small node-negative tumours, TC or CMF may be an acceptable, less toxic regimen.

There is considerable focus on the potential of platinum agents in cancers that have altered DNA repair mechanisms, particularly deficient homologous recombination repair mechanisms such as are seen in BRCA1-/BRCA2-mutated breast cancers [28], and high rates of pathological complete response have been seen in BRCA patients in early neoadjuvant studies [29]. However, these data were not confirmed in the GeparSixto trial, where the benefit of neoadjuvant carboplatin was seen in all triple negative patients, regardless of BRCA status [30]. At present, the use of platinum salts in early breast cancer remains investigational.

46.3 Metastatic Chemotherapy Regimens

Unlike early breast cancer in which the aim of adjuvant treatment is increased cure rate, in advanced disease, the aims of chemotherapy are increased survival, palliation of cancer-related symptoms and maintenance of quality of life. Thus, a greater importance is placed on balancing toxicity with meaningful outcomes. There is no single agent or sequence of agents that is considered optimal, allowing choices of the many chemotherapeutic options to be based on tolerability and patient-specific factors. In this vein, standard recommendations are for

the use of single-agent over combination chemotherapy, as it results in reduced adverse events with no significant negative impact on survival [31–32].

While not prolonging life, combination regimens are associated with increased response rate and progression-free survival [32–33]. Thus, they may be preferred in situations where rapid disease control is required, such as visceral crisis, multiple uncontrolled painful metastases or rapidly deteriorating performance status. Bevacizumab plus chemotherapy has similar activity with a different toxicity profile and is an alternative to doublet cytotoxic regimes. Several trials have documented significantly prolonged PFS with bevacizumab plus chemotherapy compared to chemotherapy alone, particularly in combination with paclitaxel, although none demonstrate overall survival benefit [34–35]. However, it is an expensive option, and no predictive biomarkers exist yet to help tailor its use.

Duration of treatment with each regimen is not set and is usually dictated by development of adverse effects. Current evidence suggests that continuation of treatment after achieving best response, either until progression or intolerable toxicity, is associated with longer survival [36].

In HER2-negative disease, it is recommended to start with weekly paclitaxel or doxorubicin, unless these agents were used in the adjuvant setting within the previous two years. Prior adjuvant anthracycline use per se is not an absolute contraindication to palliative use—monitoring of cardiac function can be performed before and during treatment, and while the cumulative risk of delayed cardiotoxicity must be considered, the timeframe until it appears clinically may exceed life expectancy. An alternative taxane is nab-paclitaxel, which may be attractive as it does not require steroid premedication and has similar efficacy. However, at the full 150 mg/m2 weekly dose, it is associated with increased haematological and neurological toxicity.

An alternative choice, particularly for ER-positive disease, is oral capecitabine, as it is generally very well tolerated, has reduced rates of alopecia and does not require hospital admission for intravenous administration, making it a somewhat gentler transition to cytotoxic treatment after failure of endocrine therapy. In a phase II study, capecitabine led to increased median overall survival compared to CMF, with a response rate of 30% [37].

Beyond these options, a number of other single agents have shown activity.

Vinorelbine is effective in first and subsequent line, may be given in oral form and is generally well tolerated with no alopecia [38]. Intravenous form may be less convenient for the patient but is associated with less gastrointestinal symptoms and similar efficacy [39].

Eribulin has shown significant activity in heavily pretreated advanced breast cancer—in the EMBRACE trial, eribulin improved overall survival compared to treatment of physician's choice (13.1 vs 10.6 months) [40]. In a separate trial of eribulin vs capecitabine as first-third line chemotherapy in advanced disease, there was no significant difference in survival [41], but in pooled analysis of the two trials, eribulin was associated with improved overall survival in all subgroups [42]. Neutropenia and alopecia are common, and although neuropathy may be less frequent than with taxanes, it remains a risk.

Platinum salts, gemcitabine and cyclophosphamide all have modest activity but are commonly used in combination with other agents. Platinum agents also may be of particular use in patient with evidence of homologous recombination deficiency (HRD), such as BRCA1/BRCA2 carriers. The phase III TNT trial compared single-agent docetaxel to carboplatin in women with advanced triple negative breast cancer [43], and in the BRCA-mutated subgroup, response rates were considerably higher with carboplatin than with docetaxel, at 68 and 33%, respectively. Progression-free survival was 6.8 months and 3.1 months, respectively, yet in the overall population, docetaxel had slightly greater efficacy. A genomic pattern, based on its similarity to the patterns in BRCA-mutant breast cancer, has been identified that appears to predict strongly for platinum sensitivity, even in ER-positive tumours [44]. This has the potential to become a useful biomarker for the use of platinum agents but required further validation.

46.3.1 Combination Treatments

A variety of multichemotherapy regimens have been trialled in advanced breast cancer, and the choice of regimen should be guided by careful consideration of toxicity profile, as well as prior therapies and responses. Similar combinations to those used in adjuvant treatment can be employed, although dose reduction may be appropriate to improve tolerability.

Other combinations include gemcitabine plus taxane and capecitabine plus docetaxel with overall response rates over 40%. CMF has activity and may be preferred for its low alopecia rate but has been shown to be inferior to capecitabine [45].

Capecitabine and vinorelbine have been shown to be an effective combination that is particularly well tolerated, with similar disease control rate (71%) and overall survival compared to capecitabine plus docetaxel [46–47]. The two agents have distinct mechanisms of action and, given together, appear to reduce the rate of capecitabine-related hand-foot syndrome. The combination may be preferable to patients due to the oral administration and low rates of alopecia and cytopenias.

In triple negative cancers, which can be aggressive and may have fewer opportunities to try new options, combination regimens may be more appropriate. An ongoing phase

II/III trial is assessing the combinations nab-paclitaxel plus gemcitabine, nab-paclitaxel plus carboplatin or gemcitabine plus carboplatin in first-line treatment, which may shed light on optimal doublet regimens and use of platinum agents [48].

Metronomic oral chemotherapy, where doses are administered less frequently, can be an effective way to reduce toxicity and improve compliance while still improving disease control [49–52]. Data is limited to phase II trials, but where tolerability is a major concern, this may be a preferred strategy, particularly in frail patients.

46.3.2 HER2-Positive

In HER2-postive advanced breast cancer, the general consensus is to maintain HER2-directed therapy throughout treatment, with or without concomitant chemotherapy. This consists of four agents: trastuzumab with or without pertuzumab, trastuzumab-emtansine (T-DM1) and lapatinib. All except T-DM1 may be given concomitantly with non-anthracycline chemotherapy. In ER-positive disease, once a maximal response is achieved, chemotherapy may be switched to 'maintenance' endocrine therapy while continuing HER2 blockade to improve tolerability, although there are no proven strategies for this approach. In ER-negative disease, chemotherapy should generally be continued for as long as it is tolerated and there is clinical benefit but can also be ceased once maximum clinical response is seen.

The triplet combination of trastuzumab plus pertuzumab plus taxane chemotherapy is considered standard first-line therapy in HER2-positive disease, based on the substantial overall survival benefit from the addition of pertuzumab demonstrated in the Cleopatra trial [53]. In this trial, patients receiving all three agents gained an extra 15.7 months overall survival compared to trastuzumab and docetaxel plus placebo (56.5 months versus 40.8 months, respectively), although this came at the expense of higher rates of diarrhoea, rash and febrile neutropenia.

For patients relapsing during, or within 12 months of, adjuvant trastuzumab, T-DM1 is an alternative to the Cleopatra regimen, based on the results of the EMILIA trial [54]. In this study, women who had progressed on prior trastuzumab therapy were randomised to T-DM1 or lapatinib plus capecitabine. T-DM1 resulted in a longer median overall survival of 31 months compared to 25 months, and had lower rates of grade 3 or 4 toxicity, particularly diarrhoea and hand-foot syndrome, although thrombocytopenia and elevated liver enzymes were more common.

If not used in first line, T-DM1 should be considered standard second-line therapy [54]. Alternatively, it may also be employed in third or subsequent lines, as there is evidence of benefit in this setting from the TH3RESA trial. Compared to treatment of physicians' choice, T-DM1 led to a significant improvement in median progression-free and overall survival (6.2 versus 3.3 months and 22.7 versus 15.8 months, respectively) [55].

For subsequent lines of therapy, or as alternatives to the above regimens, a number of options exist. Trastuzumab is active in combination with a variety of single-agent chemotherapy, such as vinorelbine, taxane and capecitabine. Vinorelbine plus trastuzumab was compared to docetaxel plus trastuzumab in first line and showed equivalent progression-free and overall survival but significantly less treatment discontinuation due to toxicity [56]. Thus, its use in later lines of therapy should be similarly well tolerated. Furthermore, it represents a reasonable first-line therapy if pertuzumab is unavailable or taxanes are contraindicated. Given the lack of evidence supporting one combination over another, the choice should be made based on expected tolerability and patient preference.

Lapatinib plus capecitabine is another HER2-targeting combination, having been shown to be superior to capecitabine alone, modestly prolonging progression-free survival, with a trend to improving overall survival [57–58]. As a general alternative to trastuzumab, lapatinib is not preferred. When compared to trastuzumab plus paclitaxel in first line, lapatinib plus paclitaxel had a shorter time to progression and higher rates of toxicity [59]. Combining lapatinib and trastuzumab without chemotherapy improves overall survival compared to lapatinib alone in patients who have progressed on prior trastuzumab [60], and thus may be considered an alternative to trastuzumab plus chemotherapy, particularly in heavily pretreated patients with good performance status.

Anti-HER2 Therapies in the Adjuvant and Advanced Disease Settings

47

Elisabetta Munzone

47.1 HER2-Positive Disease

Overexpression of human epidermal growth factor receptor type 2 (HER2, also referred to as HER2/neu or ErbB-2), a 185-kD receptor, was first described more than two decades ago [1]. Approximately 15–20% of breast cancers show amplification of the HER2 gene on chromosome 17 [2]. In the past, patients with HER2-positive breast cancer reported worse outcomes than did other patients with different subtypes of the disease [3]. Approval in 1998 of the first anti-HER2 agent (trastuzumab) led in a new era of molecularly targeted therapies for HER2-positive breast cancer and significantly improved outcomes in these patients [4].

Overexpression of HER2 in breast cancer is usually assessed by immunohistochemistry (IHC) or fluorescent in situ hybridization (FISH) on histopathological samples of primary cancer or metastatic tissue (Fig. 47.1). According to the American Society of Clinical Oncology (ASCO)/College of American Pathologists (CAP), HER2 positivity is defined by an IHC score of 3+, with strong staining of more than

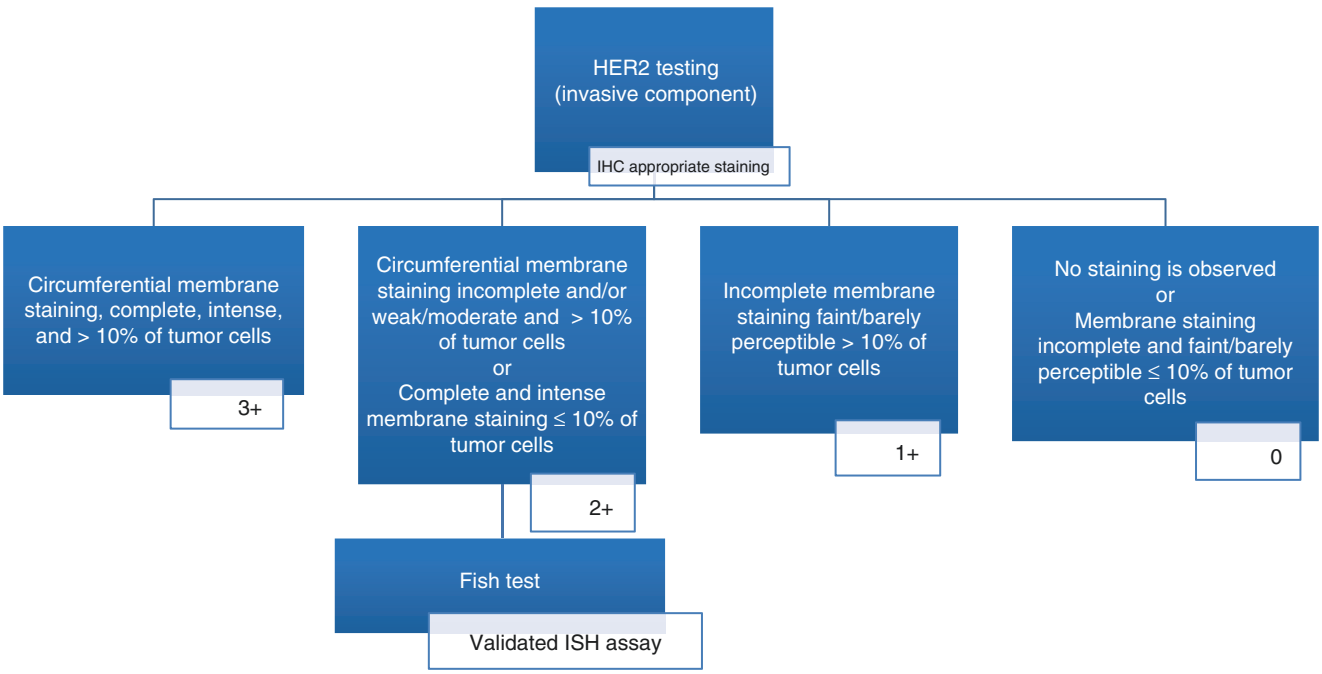

Fig. 47.1 Assessment of HER2 overexpression according to ASCO/CAP guidelines

10% of all invasive tumor cells. An IHC score of 2+ needs further investigation, whereas IHC scores of 0 and 1+ are representative of HER2 negativity. FISH analysis can be performed as an additional determination after an IHC score of 2+ and also as a stand-alone test. FISH is based on the HER2 gene copy number, i.e., the ratio between the HER2 gene copy number and the number of chromosome 17 centromeres (CEP17). The ASCO/CAP define the presence of a HER2 amplification in FISH analysis as a dual-probe HER2/CEP17 ratio of ≥2.0 or a single-probe average HER2 copy number of ≥6.0 signals/cell [5].

47.2 HER2 Signaling and Overexpression

HER2 signaling promotes cell proliferation through the RAS–MAPK pathway and inhibits cell death through the phosphatidylinositol 3′-kinase (PI3K)–AKT–mTOR (mammalian target of rapamycin) pathway [6]. AKT includes three distinct enzymes, each of them is a member of the protein kinase family that is specific for serine–threonine and that inhibits apoptosis (programmed cell death); mTOR regulates the cellular functions that integrate upstream signaling inputs. Although HER2 overexpression has been described in a variety of human malignant conditions, gene amplification is usually rare except in breast cancer [7–12].

47.3 Currently Used HER2-Targeted Drugs

47.3.1 Trastuzumab

Trastuzumab is a humanized monoclonal antibody against the extracellular domain of the HER2 receptor [13].

The mechanism of action of trastuzumab may occur through both innate and adaptive immunities. Innate mechanisms lead to cell cycle arrest, with an increase in p27 levels, and decrease in cyclin D1 and cyclin-dependent kinase 2 activity [14]. Trastuzumab alone does not seem to promote a significant level of apoptosis, but it is synergistic with most chemotherapeutics in preclinical models. This synergism is felt in part to be explained by inhibition of the PI3K/AKT signaling pathway, which normally promotes cell survival [15]. Nevertheless, the innate mechanism alone does not fully explain the effect of trastuzumab on tumor regression. Adaptive mechanisms are also present, and preclinical models suggested that trastuzumab recruits immune effector cells that are responsible for antibody-dependent cell-mediated cytotoxicity (ADCC) [16]. This is likely to be T-cell mediated, through activation of the FC receptor, leading to increased cell death [17].

Several possible mechanisms by which trastuzumab might decrease signaling may include also prevention of HER2-receptor dimerization, increased endocytotic destruction of the receptor, inhibition of shedding of the extracellular domain, and immune activation [18].

Trastuzumab is approved for the treatment of early breast cancer overexpressing HER2 as part of a regimen consisting of anthracycline and sequential combination with either paclitaxel or docetaxel, or with carboplatin and docetaxel, or as a single agent following anthracycline-based therapy. Trastuzumab is approved for an overall duration of 12 months in the adjuvant setting (HERA trial). Trastuzumab is also approved for the treatment of metastatic breast cancer in combination with pertuzumab and taxanes for first-line treatment of HER2-overexpressing disease or in combination with other chemotherapeutic or endocrine agents for subsequent lines.

47.3.1.1 Subcutaneous Trastuzumab

The subcutaneous (SC) formulation of trastuzumab has been developed to provide an alternative to standard 3-weekly intravenous (IV) administration. The ready-to-use liquid SC formulation is injected as a fixed 600 mg dose in approximately 5 min [19].

The trastuzumab SC dose was selected based on nonclinical xenograft, pharmacology, and pharmacokinetics mouse and minipig studies. Initially a two-part phase I/Ib dose-finding/dose-confirmation study assessed trastuzumab SC dose according to body weight [20]; subsequently, pharmacokinetic modeling and simulation were used to determine a fixed (non-body-weight-adjusted) dose of trastuzumab SC that could be given without a loading dose. These analyses predicted that a fixed 600-mg dose of trastuzumab SC, administered every 3 weeks without a loading dose, would provide trastuzumab serum trough concentrations and exposure at least as high as those seen with the standard 3-weekly IV regimen. This fixed-dose trastuzumab SC regimen was then confirmed as appropriate in a phase III (neo)adjuvant randomized trial, the HannaH trial [21], which included 596 HER2-positive breast cancer patients. Trastuzumab SC was shown to be non-inferior to IV counterpart with regard to the co-primary end points. The SC and IV safety profiles were, in general, similar, with comparable distributions and types of adverse events (AEs), although a numerically higher proportion of serious AEs (SAEs) were reported with SC formulation. Updated safety data, along with efficacy data (EFS) from HannaH after a median follow-up of ~20 months, were subsequently reported and were consistent with the previously published data and the known safety profile of IV trastuzumab. EFS rates were comparable between the IV and SC groups [22].

SC and IV trastuzumab were also compared in the international, multicenter, open-label, randomized PrefHer study (n = 245 patients). PrefHer demonstrated that patients with HER2-positive early breast cancer (EBC) preferred SC over

IV administration, because it saved time and caused less pain, discomfort, and side effects [23]. PrefHer and HannaH confirmed SC trastuzumab as a validated and mostly preferred option for HER2-positive breast cancer patients.

47.3.2 T-DM1 (Ado-trastuzumab Emtansine)

Trastuzumab emtansine (T-DM1) is an antibody–drug conjugate that is effective and generally well tolerated when administered as a single agent in advanced HER2-positive breast cancer patients. Efficacy has now been demonstrated in randomized trials as first-line, second-line, and later than the second-line treatment of advanced breast cancer.

T-DM1 is also an excellent example of a principle suggested almost 40 years ago to use antibodies as carriers of drugs to highly specific targets [24]. Antibody–drug conjugates (ADCs) are a means to deliver cytotoxic drugs specifically to cancer cells. The first ADC targeting the HER2 receptor is T-DM1 (ado-trastuzumab emtansine; T-MCC-DM1), which is a conjugate of trastuzumab and a cytotoxic moiety (DM1, derivative of maytansine).

T-DM1 has several mechanisms of action consisting of the antitumor effects of trastuzumab and those of DM1, a cytotoxic anti-microtubule agent released within the target cells upon degradation of the human epidermal growth factor receptor-2 (HER2)-T-DM1 complex in lysosomes [25, 26].

A key clinical trial to investigate the efficacy and safety of T-DM1 in the treatment of breast cancer was the EMILIA trial [27]. As patients assigned to T-DM1 lived longer (30.9 versus 25.1 months, respectively) and had fewer serious adverse events, T-DM1 was approved by the US Food and Drug Administration (FDA) in February 2013 for the treatment of patients with HER2-positive metastatic breast cancer who had previously received trastuzumab and a taxane. In the subsequent TH3RESA study, patients treated with T-DM1 achieved longer PFS (6.2 versus 3.3 months, respectively, hazard ratio 0.53, 95% CI 0.42–0.66) and longer survival (not reached versus 14.9 months) and had fewer severe adverse effects compared with a regimen chosen by the physician [28]. T-DM1 is currently being evaluated as adjuvant treatment for early breast cancer (NCT01853748, ATEMPT trial).

47.3.3 Pertuzumab

Pertuzumab is a recombinant humanized monoclonal antibody different from trastuzumab, because it is directed against the extracellular dimerization domain (subdomain II) of HER2, preventing dimerization of HER2 with other members of the HER family, such as HER3, HER1, and HER4 [29]. This results in inhibited downstream signaling of two key pathways that regulate cell survival and growth (the mitogen-activated protein kinase [MAPK] pathway and the phosphoinositide 3-kinase [PI3K] pathway), in addition to mediating antibody-dependent cell-mediated cytotoxicity. Pertuzumab is the first drug of a novel class of therapeutic antibodies known as HER dimerization inhibitors, which represent a complementary mechanism of action to trastuzumab. The addition of pertuzumab after progression to ongoing trastuzumab in xenografts was shown to synergistically increase tumor inhibition compared to trastuzumab treatment alone [30].

In combination with trastuzumab and docetaxel, pertuzumab was demonstrated to improve PFS and OS versus trastuzumab and docetaxel in the phase III CLEOPATRA trial in first-line HER2-positive metastatic breast cancer patients [31]. In a substudy of CLEOPATRA evaluating potential pharmacokinetic drug–drug interaction, pertuzumab showed no impact on the pharmacokinetics of trastuzumab or docetaxel [32].

Pertuzumab is the first drug to receive a fast-track approval from the US FDA, based on the pathologic complete response—as the primary end point—achieved in patients treated with neoadjuvant chemotherapy for breast cancer. Pertuzumab is also approved as first-line treatment in metastatic setting both by FDA and EMA in combination with trastuzumab and docetaxel.

47.3.4 Lapatinib

Lapatinib is a dual EGFR/HER2 tyrosine kinase inhibitor that binds to the intracellular ATP-binding pocket of the protein kinase domain of HER2. By binding, lapatinib prevents autophosphorylation of the cytoplasmic domain and thereby downstream signaling and tumor cell growth [33]. Lapatinib reduces EGFR and HER2 signaling and induces apoptosis in multiple models of HER2-overexpressing breast cancer [34].

In 2007, the US Food and Drug Administration approved lapatinib for use in combination with capecitabine for the treatment of women with HER2-overexpressing, advanced, or metastatic breast cancer after cytotoxic drugs or trastuzumab. In 2010, the EMEA approved lapatinib with letrozole in postmenopausal HER2-positive, hormone receptor-positive breast cancer for the first-line treatment of postmenopausal women [35].

The registration of lapatinib was approved primarily based on a phase III, randomized, open-label study comparing lapatinib plus capecitabine with capecitabine alone in 324 patients with HER2-positive advanced breast cancer or metastatic breast cancer that had progressed during prior treatment with anthracyclines, taxanes, and trastuzumab [36].

47.4 Adjuvant Anti-HER2 Treatments

Current clinical guidelines clearly state that standard of care in 2015 recommends the use of the monoclonal anti-HER2 antibody trastuzumab in combination with or after adjuvant chemotherapy in medically fit patients diagnosed with stage I–III HER2-positive breast cancer [37, 38].

Guidelines are based on the results of six phase III randomized trials published or reported so far, exploring the benefit of adding trastuzumab to adjuvant chemotherapy for early HER2-positive breast cancer patients (Table 47.1).

The herceptin adjuvant trial (HERA trial) enrolled 5090 women with HER2-positive early breast cancer after completion of locoregional therapy (surgery ± radiotherapy) and at least four courses of chemotherapy. Patients were randomized to either a control group or 1 or 2 years of treatment with trastuzumab. A first analysis—after 1 year of median follow-up—indicated the benefit of trastuzumab in adjuvant systemic therapy with an unadjusted hazard ratio (HR) of 0.54 for an event in the trastuzumab group (1 year) compared to the observation group [39]. A final comparison of the interventional arms showed no evidence of better outcome with 2 years versus 1 year of trastuzumab. Nevertheless, the number of adverse cardiac events slightly rose through 2 years of drug administration compared to 1 year. The HR for disease-free survival (DFS) and also for overall survival (OS) was 0.76 each, for 1 year of trastuzumab treatment versus observation, which confirms the efficacy of trastuzumab therapy [40].

The results of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31 trial and the North Central Cancer Treatment Group (NCCTG) N9831 trial were presented together in one analysis. In both trials, 4046 women with HER2-positive early-stage breast cancer were treated with chemotherapy consisting of four cycles of doxorubicin and cyclophosphamide (AC) followed by paclitaxel for 3 months (weekly or q21d). The NSABP B-31 study randomized patients to chemotherapy with or without 52 weeks of trastuzumab administration afterward. The NCCTG N9831 study had three arms: chemotherapy only, chemotherapy plus concurrent trastuzumab, and paclitaxel or plus sequential trastuzumab after paclitaxel. The interim and final analyses of the trials demonstrated the benefit of adding trastuzumab for DFS and OS, by increasing the 10-year OS rate from 75.2% to 84%, thus leading to a 37% relative improvement in OS (HR 0.63, $P < 0.001$). The DFS benefits from trastuzumab showed an increase of the 10-year DFS rate from 62.2% to 73.7%. Thus, HER2 blockade resulted in a 40% (HR 0.60, $P < 0.001$) improvement of the DFS [41, 42]. Further analysis in the NCCTG N9831 study was done regarding the efficacy of concurrent versus sequential administration of trastuzumab. Although the analysis results were not statistically significant, they showed a trend of a prolonged DFS in the concurrent treatment arm (concurrent/sequential HR 0.77; 99.9% confidence interval (CI), 0.53–1.11, $P = 0.02$) and supported the recommendation of a concurrent regimen of trastuzumab with taxane [43].

Another adjuvant trial was the Breast Cancer International Research Group (BCIRG)-006 study (NCT00021255), which investigated the efficacy of trastuzumab as well as the effectiveness and safety of an anthracycline-free chemotherapy regimen in order to reduce cardiac toxicity. After randomization, 3222 women with HER2-positive early-stage high-risk breast cancer were treated with doxorubicin, cyclophosphamide, docetaxel (ACT), ACT plus trastuzumab for 1 year (AC-TH), or with the non-anthracycline regimen consisting of docetaxel, carboplatin, and 52 weeks of trastuzumab (TCH). The final analysis confirmed the importance of trastuzumab treatment, with superiority of both the trastuzumab-containing regimes compared to ACT (OS 87%, DFS 75%). No significant difference was observed in

Table 47.1 Adjuvant trastuzumab trials

Trial	Median FU (years)	*N* Patients	Treatament	DFS: HR (95% CI)	DFS	OS:HR (95% CI)	OS
HERA	8	5099	CT vs. CT ➔ T	0.76 (0.67–0.86)	70% vs. 76%	0.76 (0.65–0.88)	84.5% vs. 87%
NSABP B-31	8.4[a]	4046[a]	AC ➔ P vs. AC ➔ PT ➔ T	0.60 (0.53–0.68)	62.2% vs. 73.7%	0.63 (0.54–0.73)	75.2% vs. 84%

CT chemotherapy, *T* trastuzumab, *AC* doxorubicin Cyclophosphamide, *P* paclitaxel, *D* docetaxel, *Carbo* carboplatin, *FEC* fluorouracil epirubicin cyclophosphamide, *ED* epirubicin docetaxel

OS and DFS for AC-TH (OS 92%, DFS 84%) and TCH (OS 91%, DFS 81%). A trend for better outcome occurred in the AC-TH arm compared to TCH (124 vs. 144 distant relapse events). Cardiotoxicity was lower in the TCH arm. Especially for patients with high risk of cardiac toxicity, the TCH regimen may be considered as an appropriate alternative [44].

The FinHER study analyzed 1010 patients randomized to receive adjuvant docetaxel or vinorelbine followed by FEC regimen. Patients with an amplified HER2/neu gene ($n = 232$) were further randomized to receive weekly trastuzumab for 9 weeks, concurrently to docetaxel/vinorelbine or not. At a median follow-up of 36 months, the inclusion of trastuzumab in the adjuvant chemotherapeutic regimen resulted in a significantly better DFS (HR 0.42 95% CI, 0.21–0.83; $p = 0.01$); also, OS tended to be better, although not significant ($p = 0.07$) [45]. The last update of the study, at a median follow-up of 5 years, confirmed the benefits of adding a short course of concurrent trastuzumab to docetaxel followed by FEC versus chemotherapy alone (HR for distant disease recurrence 0.32, $p = 0.029$) [46]. However, due to the limited sample size, these results need to be confirmed in larger series.

Recently, the PHARE trial further explored the question of the optimum duration of adjuvant trastuzumab treatment. In total, 3381 patients with HER2-positive early breast cancer who had received at least four cycles of chemotherapy and up to 6 months of trastuzumab prior to randomization were randomized to continue trastuzumab for a total of 12 or 6 months [47]. This was a non-inferiority study, aiming to prove that the shorter course of trastuzumab is not inferior to standard 1 year of treatment. The study did not meet its primary end point; after a median follow-up of 42.5 months, 175 and 219 DFS events were observed in the 12-month and in the 6-month group, respectively, with the 2-year DFS rates being 93.8% (95% CI 92.6–94.9) and 91.1% (89.7–92.4), respectively (HR 1.28, 95% CI 1.05–1.56; $p = 0.29$). The 6-month trastuzumab duration was associated with fewer cardiac events as compared to the 12-month group (32 of 1690 patients vs. 96 of 1690 patients, respectively, $p < 0.0001$).

In the PACS-04 study, after a first randomization between epirubicin docetaxel and FEC, HER2-positive patients ($n = 528$) were randomly assigned to receive sequential trastuzumab or to observation. At a median follow-up of 4 years, the addition of sequential trastuzumab failed to detect a significant reduction in the risk of recurrence or death [48].

The Adjuvant Lapatinib and/or Trastuzumab Treatment Optimisation (ALTTO) trial started with the aim to analyze the efficacy of the combination therapy in adjuvant treatment. The trial was the largest study on adjuvant therapy in HER2-positive breast cancer enrolling more than 8000 participants. Women were treated with surgery and chemotherapy (anthracycline based vs. anthracycline-free), followed by randomization to trastuzumab alone, lapatinib alone, trastuzumab followed by lapatinib, or concurrent therapy with lapatinib and trastuzumab. Anti-HER2 therapy was given for 52 weeks and was combined with paclitaxel/docetaxel in women with prior anthracycline-based chemotherapy for the first 12 weeks. The lapatinib arm was prematurely closed since an interim analysis in 2011 suggested inferiority of this arm. First results were presented at the ASCO Annual Meeting in 2014 [49]. After 4 years of follow-up, the DFS rate for trastuzumab plus lapatinib was 88% compared to 86% for trastuzumab monotherapy (HR 0.84, 97.5% CI 0.7–1.02, $p = 0.048$) and 87% for trastuzumab followed by lapatinib versus 86% for trastuzumab monotherapy (HR 0.96, 97.5% CI 0.8–1.25, $p = 0.610$). In addition, the combination of trastuzumab and lapatinib showed no benefit regarding OS compared to trastuzumab. Adverse events were more likely in patients within the lapatinib arm; the overall cardiac toxicity was tolerable.

47.4.1 Small HER2-Positive Tumors

Retrospective evidence from institutional series of reference cancer centers or country databases [50, 51] and also subgroup analysis of one of the major pivotal trials [44] (e.g., BCIRG 006) suggest a benefit for the administration of trastuzumab compared to the nonuse of trastuzumab that may still warrant the risks for "small" T1a,bN0M0 tumors.

In a retrospective series on 16,975 consecutive patients with T1a/b HER2-positive disease, 5-year invasive distant recurrence-free interval was 99.0% for T1a patients and 97.0% for T1b patients [52].

These small tumors indeed have an adverse prognosis when untreated and remain at significant risk of relapse when treated with chemotherapy only. The NCCN Guidelines Version 1.2016 Breast Cancer available at http://www.nccn.org/professionals/ physician_gls/pdf/breast.pdf and the St. Gallen Guidelines [37] do recommend administering adjuvant trastuzumab for early breast cancer patients with T1b tumors (>0.5 and 1.0 cm) and lymph node negative.

For an evaluation of single standard treatment in patients with small ($T < 3$ cm), node-negative HER2-positive breast cancer, Tolaney et al. [53] recruited 406 patients in a single-group study. Women were treated with paclitaxel and trastuzumab for 12 weeks, followed by trastuzumab monotherapy for 40 weeks. The 3-year rate of survival free from invasive disease was 98.7% (95% CI 97.6–99.8), and the 3-year rate of recurrence-free survival was 99.2% (95% CI 98.4–100). With a risk of early recurrence of about 2% and a low rate of serious toxic effects (symptomatic congestive heart failure 0.5%), treatment with adjuvant paclitaxel and trastuzumab could be considered as an option for node-negative, small HER2-postive breast cancer.

The excellent disease-free survival observed with adjuvant paclitaxel and trastuzumab without anthracyclines highlighted the possibility to de-escalate treatment for low-risk, early-stage, HER2-positive disease.

47.5 Neoadjuvant Anti-HER2 Trials

The main candidates for neoadjuvant treatment in the HER2-positive setting are patients with a high likelihood of achieving a pCR. A recent meta-analysis, from the Collaborative Trials in Neoadjuvant Breast Cancer (CTNeoBC), included 11,955 patients treated in 12 randomized neoadjuvant trials [54]. Results indicated that patients who obtain a pCR, defined as either the absence of invasive and in situ carcinoma in breast and axilla or only invasive carcinoma in both breast and axilla, have a more favorable long-term outcome than those without a pCR (HR for OS = 0.36 with both definitions, HR for event-free survival [EFS] = 0.44 with ypT0 ypN0, and HR = 0.48 with ypT0/Tis ypN0) [54].

The Early Breast Cancer Trialists' Collaborative Group overview of neoadjuvant trials demonstrated that standard chemotherapy regimens (anthracyclines/taxanes) whether given preoperatively or postoperatively provided the same long-term clinical outcomes. Therefore, one can now potentially deliver standard systemic treatment in either the neoadjuvant or adjuvant setting with similar confidence [55]. The same is true, if not even more so, for HER2-positive breast cancers. The additional advantages of delivery in the neoadjuvant setting include the ability to study new agents with the utility of a surrogate end point for outcome; the ability to obtain tumor tissue for pharmacodynamic assessment, understanding of biology, and discovery of predictive biomarkers; earlier initiation of systemic therapies; and the ability to monitor response (which is clearly not possible in the adjuvant setting).

In an early MD Anderson trial comparing trastuzumab-containing therapy versus chemotherapy alone, the pCR rate was doubled (67% versus 25%) with trastuzumab, leading to early termination of the trial (Table 47.2) [56].

One of the first trials underlining the concept of dual blockade was the phase III GeparQuinto trial (NCT00567554), in which the addition of trastuzumab versus lapatinib to anthracycline–taxane-based neoadjuvant chemotherapy was tested in 620 women with operable or locally advanced HER2-positive breast cancer. Patients were treated either with epirubicin, cyclophosphamide and docetaxel plus trastuzumab, or the same chemotherapy regimen plus lapatinib for a total of 6 months and underwent surgery afterward. The trastuzumab arm showed a significantly better pathologic complete response (pCR) rate, with 30.3% versus 22.7% in the lapatinib group [57]. Consequently, the authors

[a]5-years EFS

concluded that outside clinical trials, lapatinib should not be used as single anti-HER2 treatment in combination with neoadjuvant chemotherapy.

The randomized phase III NOAH trial conducted by Gianni and colleagues confirmed the significant pCR and EFS benefit of combining trastuzumab with neoadjuvant chemotherapy and continuing adjuvant trastuzumab after surgery in HER2-positive disease [58]. Furthermore, it showed that combining trastuzumab with anthracycline-based chemotherapy is tolerable and is not associated with an increase in cardiac toxicity. Updated NOAH results were presented at the 2013 American Society of Clinical Oncology (ASCO) Annual Meeting. After a median follow-up of 5.4 years, the EFS benefit with trastuzumab was confirmed, and a strong trend toward improved OS was observed. Cardiac tolerability was good despite concurrent administration of trastuzumab with doxorubicin [59]. Accordingly, a more recent small study including only 80 patients showed a 92.9% 4-year RFS in patients who achieved pCR after trastuzumab-based neoadjuvant treatment versus 72.4% without pCR. All cases of symptomatic cardiotoxicity were resolved during follow-up [60]. On the basis of the NOAH results, the European Medicines Agency (EMA) extended the approved indication for trastuzumab to include its use in combination with neoadjuvant chemotherapy followed by adjuvant trastuzumab monotherapy for locally advanced and inflammatory HER2-positive disease or for tumors >2 cm in diameter. The impressive results observed with trastuzumab in the neoadjuvant setting led to the initiation of several trials evaluating new HER2-targeted agents with or without trastuzumab.

Subsequently, the NSABP B-41 and the NeoALTTO trials compared trastuzumab single agent, lapatinib single agent, and the dual HER2 blockade by combination of trastuzumab plus lapatinib. In these studies, the substitution of lapatinib for trastuzumab in combination with chemotherapy resulted in similarly high pCR rates (52.5% with trastuzumab versus 53.2% with lapatinib, $p = 0.985$) [61, 62]. Furthermore, in the long follow-up of the NeoALTTO trial, neither EFS nor OS did differ between the lapatinib and trastuzumab groups (EFS, HR 1.06, $p = 0.81$; OS, HR 0.86, $p = 0.65$) [63].

However, although the combination of trastuzumab and lapatinib plus chemotherapy led to a higher pCR rate compared to anti-HER2 single-agent treatment in the NeoALTTO trial (51.3% with combination versus 29.5% with single agent; $p = 0.0001$), it did not reach statistical significance in the NSABP B-41 (pCR 52.5% with trastuzumab versus 62.0% with combination, $p = 0.095$). The same approach with double HER2 inhibition has been explored in the randomized phase II CHER-LOB trial [64], confirming the potential role of lapatinib associated with trastuzumab.

The Cancer and Leukemia Group B 40601, a neoadjuvant phase III trial of weekly paclitaxel (T) and trastuzumab (H) with and without lapatinib (L) in HER2-positive breast cancer, was presented at the 2013 ASCO Annual Meeting [65]. This trial randomly selected 305 patients, of which two thirds had clinical stage II disease. The pCR rates in the breast alone were 51% (42–60%) in the THL arm, 40% (32–49%) in the TH arm, and 32% (22–44%) in the TL arm. The combination arm of THL was not significantly different from the standard arm of trastuzumab and paclitaxel ($p = 0.11$).

In the NeoSphere trial [66], the combination of trastuzumab, pertuzumab, and docetaxel demonstrated a significantly higher pCR rate than with trastuzumab and docetaxel alone (pCR 29.0% with docetaxel plus trastuzumab, 45.8% with docetaxel plus trastuzumab and pertuzumab, 16.8% with trastuzumab and pertuzumab alone, and 24.0% with docetaxel and pertuzumab), without substantial differences in tolerability. These findings justified the EMA approval of pertuzumab as primary systemic therapy for HER2-positive early breast cancer.

Moreover, the TRYPHAENA phase II randomized trial suggested that combining pertuzumab and trastuzumab with standard neoadjuvant chemotherapy posed no cardiac safety concerns, and it demonstrated a pCR rate higher than 66% with an anthracycline-free regimen [67].

Taking into account the results of all these clinical trials, neoadjuvant treatment with anti-HER2 targeted agents should be offered to patients with HER2-positive locally advanced or inflammatory breast cancer.

47.6 Treatment of HER2-Positive Metastatic Breast Cancer

The landscape of HER2-positive metastatic BC treatment is evolving rapidly. In the past decade, first-line trastuzumab combined with a taxane (paclitaxel or docetaxel) or vinorelbine has been considered the most active and effective treatment choice for HER2-positive metastatic breast cancer, with response rates of 50–60% and median time to progression (TTP) ranging from 7 to 15 months [68, 69]. After disease progression on first-line trastuzumab-based therapy, continued HER2 blockade with lapatinib plus capecitabine [70, 71] or trastuzumab plus capecitabine [72] was considered a standard in clinical practice.

In postmenopausal patients, chemotherapy-free therapeutic options were successfully explored in patients with highly endocrine-sensitive non-life-threatening and/or slowly progressive disease. A chemotherapy-free first-line regimen of trastuzumab plus anastrozole demonstrated a significant improvement in PFS (median 5 versus 2 months, respectively) and response rate (20% versus 7%, respectively) com-

pared with anastrozole alone [73]. Similar results were obtained with lapatinib plus letrozole (median PFS 8 versus 3 months, respectively, $p = 0.019$, clinical benefit rate 48% versus 29%, respectively, $p = 0.003$) [74].

Starting from 2012, a paradigm shift was observed in the management of HER2-positive metastatic breast cancer following the results from the CLEOPATRA [31], the EMILIA [27], and the TH3RESA trials [28]. CLEOPATRA was a double-blind placebo-controlled phase III trial comparing the combination of trastuzumab and docetaxel plus pertuzumab or placebo as first-line treatment in 808 patients with HER2-positive metastatic breast cancer [31]. At the first analysis, the addition of pertuzumab significantly improved progression-free survival (PFS 18.5 months with pertuzumab-containing therapy versus 12.4 months in the control arm, HR 0.62, 95% CI 0.51, 0.75; $p < 0.001$). The response rate was 80% versus 69%, respectively ($p = 0.001$), and a strong trend toward an OS improvement was shown with the combination of pertuzumab, trastuzumab, and docetaxel. Lately, after a median follow-up of 50 months, the final analysis showed 16 months improvement in OS (56.5 months in the pertuzumab arm versus 40.8 months in the placebo arm, HR = 0.68; $p = 0.0002$) [75]. The main criticism of the trial was that only a minority of patients had previously received trastuzumab (11% of patients) or a taxane (23% of patients) in the neo/adjuvant setting. This characteristic of the patients' population was noticed as possibly underrepresentative of everyday clinical practice. However, subgroup analyses suggested a similar benefit from pertuzumab-containing therapy irrespective of prior neo/adjuvant chemotherapy (HR 0.61 in patients who had received neo/adjuvant chemotherapy versus 0.63 in those who had not). Pertuzumab did not add to trastuzumab cardiotoxicity. The phase III EMILIA trial compared trastuzumab-emtansine (T-DM1) with lapatinib plus capecitabine in 991 patients with HER2-positive metastatic BC who were previously treated with a taxane and trastuzumab [27]. T-DM1 was associated with significantly improved PFS (9.6 months with T-DM1 versus 6.4 months with lapatinib plus capecitabine; HR 0.65, 95% CI 0.55–0.77, $p < 0.001$), OS (30.9 versus 25.1 months, respectively; HR 0.68, 95% CI 0.55–0.85, $p < 0.001$), and response rate (44% versus 31%, respectively; $p < 0.001$). Nevertheless, the benefit of T-DM1 was observed even in patients whose disease progressed less than 6 months after completing neo/adjuvant trastuzumab. Furthermore, T-DM1 was better tolerated than lapatinib and capecitabine. The phase III TH3RESA trial randomized patients with progressive disease after two or more HER2-targeted regimens for metastatic HER2-positive breast cancer. Patients received T-DM1 or physician's choice therapy [28]. Median PFS was significantly improved with T-DM1 compared with physician's choice (6.2 months versus 3.3 months, HR 0.528, $p < 0.0001$). Interim OS analysis showed a trend favoring T-DM1 (HR 0.552, 95% CI 0.369–0.826, $p = 0.0034$), but the stopping boundary was not crossed. Moreover, a lower incidence of grade 3–4 adverse events was reported with T-DM1 than with physician's choice. Following these trials, in 2013, T-DM1 was approved by EMA as a single agent for the treatment of HER2-positive, unresectable locally advanced, or metastatic breast cancer who previously received trastuzumab and a taxane, separately or in combination. As the efficacy of these first- and second-line therapies in HER2-positive metastatic breast cancer is substantial, oncologists have now an improved and challenging armamentarium for managing patients whose disease progresses after two lines of HER2-targeted therapy.

The combination of lapatinib plus trastuzumab in the EGF104900 trial [76] demonstrated improved OS compared with lapatinib alone in patients with heavily pretreated disease (median three prior lines of trastuzumab). The HR for OS was 0.74 (95% CI 0.57–0.97; $p = 0.026$), and the 1-year OS rate was 56% with the combination versus 41% with lapatinib alone. An exploratory analysis showed that combining the two anti-HER2 agents was particularly effective in subgroups of patients with ER/PgR negative tumors or treated with less than four prior lines of trastuzumab. However, in Europe, the combination of lapatinib plus trastuzumab is not approved, and the current practice in patients whose disease progresses on trastuzumab plus a taxane or on lapatinib plus capecitabine is to rechallenge with trastuzumab combined with an alternative chemotherapy, even though the evidence supporting this approach is derived only from retrospective studies [77].

Finally, the phase III study MARIANNE recently evaluated the efficacy of pertuzumab and T-DM1 compared to T-DM1 alone or trastuzumab with taxane in the frontline HER2-positive, metastatic, or locally advanced setting [78]. During the 2015 ASCO meeting, first results in 1095 patients were presented. T-DM1 treatment resulted in non-inferior, but not superior, progression-free survival (PFS) compared with trastuzumab plus a taxane (HT). Therefore, in this setting, the addition of pertuzumab to T-DM1 provided no efficacy benefit.

To summarize, following the remarkable results of recent first- and second-line trials in HER2-positive metastatic breast cancer, the optimal treatment algorithm has been revisited (Fig. 47.2). At the third disease progression in a patient still fit enough for active treatment, enrollment in a clinical trial is warranted; alternatively, rechallenge with trastuzumab combined with a non-cross-resistant chemotherapy or with single-agent anthracycline therapy may be considered.

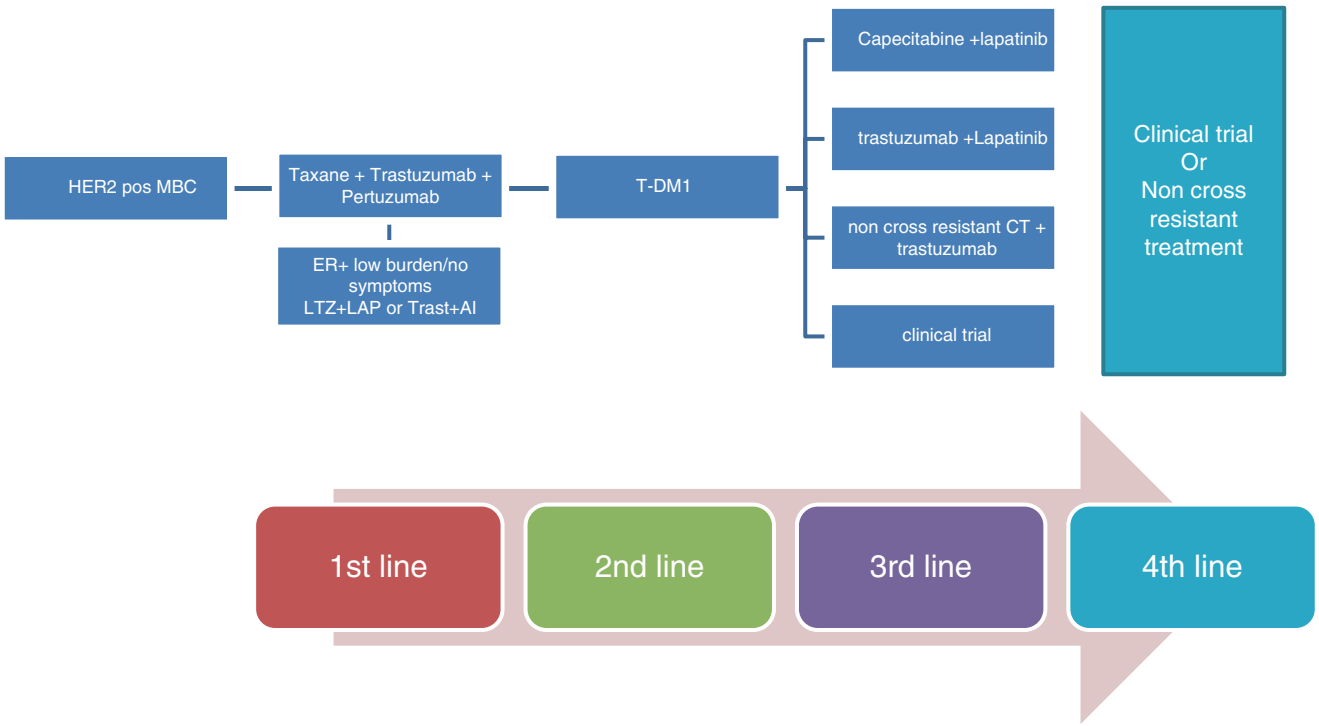

Fig. 47.2 Proposed treatment algorithm for HER2-positive MBC

47.6.1 Continuing Trastuzumab Beyond Progression

The current practice of continuing trastuzumab until progression in responding patients is based on two phase III trials, and long-term trastuzumab treatment does not appear to be associated with an excess in cardiac toxicity [79].

The German Breast Group 26 study enrolled 156 pretreated patients, the majority of whom had already received trastuzumab for metastatic disease [72]. Patients were randomized to capecitabine (1250 mg twice daily for 14 days every 3 weeks) plus trastuzumab (6 mg/kg every 3 weeks) or to capecitabine alone. With a median follow-up of 15.6 months, the addition of trastuzumab to capecitabine was associated with improvements in TTP (8.2 months vs. 5.6 months; HR, 0.69) and response rate (48% vs. 27%). Although OS was better with the combination, the effect was not statistically significant (25.5 months vs. 20.4 months, $p = 0.257$). The combination arm was not associated with increased toxicity, except for anemia (64% vs. 42%).

Several retrospective analyses of trastuzumab continuation beyond progression were published over the years [80–82]. These studies share the common limitations of a retrospective approach. However, it seems highly unlikely that there will be further prospective, randomized studies examining the specific role of trastuzumab combined with further-line chemotherapy for women who have progressed on trastuzumab. The international oncological community has already adopted the practice of continuing trastuzumab beyond progression. Nevertheless, until novel anti-HER2 therapies establish their role, continuation of trastuzumab may remain an option in the management of patients with HER2-positive advanced breast cancer.

47.7 New Anti-HER2 Drugs

47.7.1 Afatinib

Afatinib is an oral small molecule that irreversibly inhibits HER1, HER2, and HER4 [83]. A phase II study in trastuzumab-resistant metastatic patients showed initial responses [84]. Adverse events included diarrhea and rash. LUX-breast 1 is a phase III study of vinorelbine plus trastuzumab or afatinib for metastatic patients who progressed to one chemotherapy regimen containing trastuzumab (NCT01125566) [85]. As of April 2013, 508 patients were randomized. Both arms demonstrated similar PFS and ORR, but OS diverged and was shorter for the afatinib-containing arm compared to the trastuzumab arm. The safety profile of afatinib and vinorelbine was consistent with the individual monotherapies, but its tolerability compared unfavorably to trastuzumab and vinorelbine.

LUX-breast 2 is an ongoing phase II trial (NCT01271725) investigating efficacy and safety of afatinib alone (40 mg/day) followed by afatinib "beyond progression" plus chemo-

therapy. LUX-breast 3 is a randomized phase II study of afatinib alone or with vinorelbine versus investigator's choice of treatment in patients with HER2-positive breast cancer and with progressive brain metastases after trastuzumab or lapatinib-based therapy.

47.7.2 Neratinib

Neratinib is another oral, irreversible inhibitor of HER1, HER2, and HER4 [86]. A phase II trial evaluated neratinib in 136 HER2-positive patients [87] in either pretreated or trastuzumab-naïve patients. Median PFS were 22.3 and 39.6 weeks and ORR were 24% and 56%, respectively. Diarrhea was the most common grade 3/4 adverse effect. Another phase I–II trial combined neratinib plus trastuzumab in 45 metastatic and trastuzumab-resistant patients showed an encouraging 27% ORR [88]. Finally, a phase I–II trial evaluated neratinib plus vinorelbine in trastuzumab- or lapatinib-pretreated patients (n = 77) [89]. ORR was 42% in lapatinib-treated and 51% in lapatinib-naïve patients. Open-label phase II trials are currently testing neratinib monotherapy in patients with HER2-positive metastatic brain tumors (NCT01494662). Also a phase III trial (ExteNET) in the adjuvant setting is ongoing (NCT00878709). First results in 2840 women with HER2-positive breast cancer and prior adjuvant trastuzumab and chemotherapy were recently presented [90]. Patients were randomly assigned to receive either 240 mg/day of neratinib for 1 year or placebo (1420 patients in each arm). At 24 months, patients who received neratinib had an iDFS rate of 93.9% compared to 91.6% in the placebo group (hazard ratio [HR] 0.67, 95% CI [0.50, 0.91]; p = 0.009). As previously reported, diarrhea was the most common adverse event with neratinib; grade 3/4 diarrhea occurred in 39.9% of patients compared with 1.6% of patients who received placebo.

47.7.3 MM-111

MM-111 is a bi-specific monoclonal antibody that reversibly targets the HER2 and HER3 heterodimer [91]. A phase I–II study is currently evaluating its efficacy as single agent in HER2-positive advanced breast cancer patients who have received prior trastuzumab or lapatinib therapy (NCT00911898) [92]. Another phase I trial is studying MM-111 plus trastuzumab in HER2-positive, heregulin-positive, advanced, and refractory breast cancer (NCT01097460).

47.7.4 HER2-Targeted Vaccines

Cancer vaccines designed to induce specific anti-HER2 immunity are under investigation. Different strategies include protein-based vaccines, plasmid DNA-based vaccines, and vaccines that deliver HER2 in a viral vector. HER2 peptide-based vaccines were tested in patients with metastatic HER2-positive breast cancer [93, 94]. Patients immunized developed delayed-type hypersensitivity reactions and strong CD8+ cell responses specific for HER2 [95]. Among dendritic cell-based vaccine, a small group of patients with stage IV breast cancer [96] showed initial promising responses. More recently, cell-based GM-CSF-secreting vaccines are being tested in combination with trastuzumab [97, 98], and several clinical trials are underway.

The induction of a stable and strong immunity by cancer vaccines is expected to lead to establishment of immune memory, thereby preventing tumor recurrence. However, an immunological tolerance against HER2 antigen exists representing a barrier to effective vaccination against this oncoprotein. As a consequence, the current challenge for vaccines is to find the best conditions to break this immunological tolerance [99].

Several approaches have been proposed, including vaccines coupled to inhibitory molecules, monoclonal antibodies, bacteria or bacterial compounds, radiotherapy, and chemotherapy. However, the best strategy still represents a challenge.

47.7.5 PI3K/AKT/mTOR Blocking Drugs

PI3K/AKT/mTOR is an intracellular signal pathway frequently deregulated in breast cancer and involved in primary or secondary resistance to anti-HER2 agents [100]. A phase I study tested the combination of everolimus plus weekly paclitaxel and trastuzumab in 33 patients with heavily pretreated metastatic disease [101]. Encouraging activity was reported, with an overall disease control rate at 6 months of 74%. BOLERO-3 trial explored the addition of vinorelbine to everolimus plus trastuzumab in previously treated patients. With 569 patients completing the BOLERO-3 study, median PFS was 7.0 vs. 5.78 months in the placebo arm (p = 0.0067) [102].

The addition of everolimus to weekly trastuzumab plus paclitaxel in the first-line metastatic breast cancer setting did not improve outcomes in the phase III BOLERO-1 trial, but provided a hint of efficacy in the hormone receptor-negative subset [103]. The study enrolled 719 patients with locally advanced or metastatic HER2-positive breast cancer and no prior treatment in this setting. They were randomly assigned 2:1 to everolimus (10 mg/day) plus paclitaxel and trastuzumab or paclitaxel/trastuzumab alone, until disease progression or intolerable toxicity.

In the full study population, progression-free survival was comparable between the arms: 14.95 months with the addition of everolimus and 14.49 months with placebo (hazard ratio [HR] = 0.89, p = .1166). In the hormone receptor-negative subpopulation, however, everolimus-treated patients achieved a median progression-free survival of 20.27 months vs. 13.08 months with placebo (HR = 0.66, p = .0049).

47.7.6 Heat Shock Protein 90 Pathway

Heat shock protein 90 (Hsp-90) is a molecular chaperone that provides stability and supports the functionality of several proteins. Many of these proteins (i.e., Bcr-Abl, c-Kit, and PDGF-α) are pro-oncogenic. Inhibition of Hsp-90 degrades HER2 and Hsp-90 inhibitors have shown activity in HER2-driven xenograft models.

Concerning HER2-positive breast cancer, it is known that Hsp-90 is required for the stabilization of essential components of EGFR and HER2 signaling (HER2, AKT, c-SRC, RAF, and HIF-1α) [104]. Clinical data from a phase I trial with the Hsp-90 inhibitor tanespimycin used in combination with trastuzumab as second-line therapy showed evidence of antitumor activity in 63% of patients [105]. A phase II trial in 31 patients with HER2-positive metastatic breast cancer whose disease has progressed on trastuzumab further confirmed that tanespimycin plus trastuzumab has significant anticancer activity in this category of patients. The ORR was 22% and the clinical benefit reached 59% [106].

47.7.7 Other Exploratory Anti-HER2-Blocking Strategies

Trials combining anti-HER2 agents with drugs blocking different signaling pathways are ongoing trying to address further improvement. A promising approach seems to be the combination of anti-HER2 therapy with insulin growth factor receptor (IGFR-1) blocking agents. IGFR-1 inhibition has been shown to restore sensitivity to trastuzumab in animal models [107]. Another potential combination is the dual blockade of HER2 and SRC which was recently shown to work as a central node downstream of multiple trastuzumab resistance mechanisms [108]. Finally, HER3 is another strong activator of PI3K/AKT signaling pathway that has been demonstrated to be upregulated after HER2 blockade [109]. Although still in early phases of development, Rb disruption strategies and the use of promising molecules such as CDK-4/6 inhibitors may open new perspectives in the future [110].

Conclusion

Anti-HER2 treatments represent one of the most dynamic evolving fields for oncologists, as a recent great expansion in the drugs developed to target HER2-positive breast cancer raised new challenges.

Nevertheless, treatment personalization according to specific disease or patients' characteristics remains a matter of research.

Among the aspects to be improved and still under investigation, there is how to spare some side effects as cardiotoxicity. Serum cardiac biomarkers, including troponins and natriuretic peptides, represent possible tools to detect cardiotoxicity at a preclinical level and may represent an important means of selecting treatment to avoid side effects [111].

Another aspect is the possibility to de-escalate treatment for low-risk, early-stage, HER2-positive disease. The excellent disease-free survival observed with adjuvant paclitaxel and trastuzumab without anthracyclines has set a new standard of care for the adjuvant treatment of small ($T < 3$ cm), node-negative, HER2-positive breast cancer.

Recently ZEPHIR trial revealed through PET-CT assessment that almost half of the patients with advanced-stage HER2-positive breast cancer had substantial heterogeneity in HER2 expression between different metastases [112]. Pretreatment imaging of HER2 targeting, combined with early metabolic response assessment, holds great promise for improving the understanding of tumor heterogeneity in metastatic breast cancer and for selecting patients who will/will not benefit from HER2-targeted therapy.

Finally, our understanding about the mechanisms of trastuzumab resistance is still limited. The search for biomarkers to predict response and resistance is a critical part of ongoing research. Some studies suggest that the definition of HER2-driven cancers should be expanded to include both rare cases with somatic HER2-activating mutations (without gene amplification) [113] and HER2 positivity defined by gene expression.

The recognition of specific molecular predictors of response to emerging therapies will allow a more personalized approach to the treatment of HER2-amplified breast cancer. Enrolling patients into clinical trials, with the purpose to understand and target the molecular mechanisms involved in HER2 therapy resistance, is of crucial importance. As even more potential therapies appear over the horizon, advancements in biomarker discovery will be critical in optimizing treatment selection and providing personalized therapy for patients.

Adjuvant Treatment with Bone-Targeting Agents (Bisphosphonates and Anti-RANK-Ligand Antibody)

48

Michael Gnant

Bone health and breast cancer are connected subjects that make bone health a particularly important subject for breast cancer patients: First, breast cancer patients have a higher prevalence of osteopenia and reduced bone health than non-breast-cancer women of the same age [1]. While the underlying biological reasons for this finding are not well understood, patients' bone health is further impaired by most of today's state-of-the-art therapies: Most endocrine interventions reduce estrogen levels and, subsequently, lead to rapid bone loss in both premenopausal and postmenopausal women [2]. Also, cytotoxic chemotherapy may exert detrimental effects on bone health: Chemotherapy leads to ovarian dysfunction in many premenopausal women, and some cytostatic drugs have direct nonhormonal effects on the bone [3, 4].

Aromatase inhibitors (AI) have become a standard treatment for endocrine responsive breast cancer of postmenopausal patients. It has been shown in several large trials of both steroidal and nonsteroidal aromatase inhibitors that these agents lead to significant bone loss and can increase the incidence of fractures [5, 6]. Postmenopausal women receiving an aromatase inhibitor will on average lose approximately 2–3% of their bone mineral density (BMD) per year while on treatment, or more than twice the typical rate for "physiological" bone loss during menopause [5].

In premenopausal women, cancer treatment-induced bone loss may be even more dramatic because of the profound and rapid nonphysiological reduction in peripheral estradiol achieved by current anticancer therapies: Ovarian failure as a result of chemotherapy occurs in 40–90% of all premenopausal women, depending on age [7], and is accompanied by a rapid decrease in BMD (up to 7% decrease within 12 months) [2]. In premenopausal patients receiving endocrine combination therapy, bone loss is similarly dramatic [8].

Many experts believe that the prevalence of fractures caused by treatment-induced bone loss is severely underreported in pivotal AI trials, and some real-life reports of clinical practice show alarming figures [9]. In the ABCSG-18 trial [10], with its primary focus on bone health, the recorded rate of fractures in the placebo group (estimated 10% at 3 years, 16% at 5 years, and 26% at 7 years) notably exceeds previous reports from large adjuvant aromatase inhibitor trials [11].

Overall, bone health can thus be regarded as the Achilles heel of modern adjuvant anticancer treatment approaches in breast cancer. Pharmacologic interventions may help to prevent bone loss and subsequent fractures and preserve patients' quality of life. Bone-targeted agents have thus become an integral component of care for patients with postmenopausal breast cancer [12, 13]. Many guidelines and recommendations nowadays request that breast cancer patients on endocrine therapy should be monitored for bone loss and antiresorptive intervention considered when bone mineral density decreases. However, the value of routine DXA scans can be questioned since this established and rather inexpensive method may underestimate the true magnitude of the deleterious impact of endocrine therapy impairing bone health [14]. Furthermore, patient's and family history as well as lifestyle factors may likely add to an individual patient's fracture risk, as assessed by the popular FRAX score [15].

Based on the results of clinical trials, both oral bisphosphonates such as clodronate and intravenous aminobisphosphonates such as zoledronic acid are used to prevent and treat treatment-induced bone loss [16, 17]. However, recommendations vary as to which patient actually needs antiresorptive therapy from the beginning of endocrine therapy. Moreover, bisphosphonate use has been limited by side effects (compliance with oral bisphosphonates is low because of gastrointestinal sequelae), and caution is advised with intravenous bisphosphonates with respect to renal safety and dental problems. In addition, while adjuvant bisphosphonates usually stabilize bone mineral density, their effect on fracture prevention is less well defined.

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_48

This has changed with ABCSG-18 [10]: In this randomized, placebo-controlled, double-blind trial of over 3400 postmenopausal breast cancer patients, the anti-RANK-ligand antibody denosumab dramatically decreased the incidence of clinical fractures (HR = 0.5, $p < 0.0001$). These pivotal results of adjuvant denosumab (at the "bone-protecting" dose of 60 mg twice a year) follow previous demonstrations of fracture prevention by denosumab in the noncancer osteoporosis setting [18] and the demonstration of bone mineral density stabilization in a phase II trial in breast cancer patients [19]. Interestingly, ABCSG-18 showed that breast cancer patients with apparently normal bone at baseline derived similar benefit from adjuvant denosumab as those who were already osteopenic at the time of diagnosis.

Bone-targeted therapies have also been investigated in the adjuvant breast cancer setting because of their antitumor properties: After early reports that adjuvant clodronate would improve breast cancer outcomes [20, 21], there were several large studies undertaken to investigate this fascinating subject (Table 48.1). Several of them (ABCSG 12, Z/ZO-FAST, AZURE) showed improved adjuvant outcomes when zoledronic acid was added to the standard adjuvant therapy. The ABCSG-12 trial showed a 29% risk improvement for disease-free survival (DFS) in premenopausal patients [22].

From this trial, long-term follow-up results at 84 months in patients receiving 3 years of therapy with goserelin and tamoxifen or anastrozole with or without ZOL ($N = 1803$) are available [23]: Patients receiving ZOL had significant reductions in the risks of DFS events and death versus the no-ZOL group ($p \leq 0.01$ for both), supporting the potential for carryover anticancer benefit with ZOL. Adverse events that were increased in patients receiving ZOL compared to without ZOL were related to the acute-phase reaction after ZOL infusion (arthralgia, bone pain, and pyrexia). No cases of renal failure or ONJ were reported in this study. Multivariate analyses revealed a strong interaction between ZOL and patient age. Subgroup analyses by age showed that the DFS and survival benefits observed in the overall patient population were mostly derived from patients over 40 years of age (risk of DFS events =0.66, $p = 0.013$; risk of death =0.57, $p = 0.042$) rather than younger patients ($p > 0.05$ for both). Patients over 40 years of age may have achieved more complete ovarian suppression during therapy; therefore, these results are consistent with data from the postmenopausal setting. Thus, current evidence supports the addition of ZOL to standard adjuvant therapy in premenopausal patients with hormone-sensitive BC undergoing ovarian suppression. However, factors that influence hormonal suppression remain unclear.

A retrospective analysis of ABCSG-12 showed that body mass index (BMI) may influence hormonal suppression and/or aromatase availability during adjuvant therapy. Patients with a BMI ≥ 25 kg/m^2 and treated with anastrozole had an increased risk of disease recurrence (60%; $p = 0.02$) and death (twofold; $p = 0.01$) versus patients with a BMI < 25 kg/m^2 [24]. In addition, overweight patients treated with anastrozole had worse outcomes compared with tamoxifen. However, estrogen levels were not obtained in this study, so the contribution of hormonal suppression versus aromatase availability could not be exactly elucidated.

Table 48.1 Summary of large randomized bisphosphonate trials

AZURE	Placebo-controlled phase III study evaluating the benefit of ZOL in patients with early stage BC	No OS differences in overall population; however, subset analysis in patients showed that: • Among post-menopausal patients, the 5-year rate of invasive DFS was 78.2% in the ZOL group and 71.0% in the control group (HR = 0.75; $P = 0.02$) • Among patients who had undergone menopause >5 years before study entry, the 5-year OS rate was 84.6% in the ZOL group versus 78.7% in the control group (HR = 0.74; $P = 0.04$)
ABCSG-12	Placebo-controlled phase III study evaluating the benefit of ZOL in pre-menopausal patients with early stage BC	DFS benefits observed at 48-month follow-up (HR = 0.74; log-rank $P = 0.01$) were maintained at 84 months (HR = 0.71; log-rank $P = 0.011$). Subset analyses at the 84-month follow-up show that DFS benefits appear to be driven by patients >40 years of age
ZO-FAST	Immediate versus delayed ZA plus adjuvant letrozole	Reduction in DFS (HR = 0.59) at 36 and 48 months. Disease recurrence reduced at bone and at nonbone sites
Z-FAST	Immediate versus delayed ZA	Decreased recurrence at 12–48 months, not at 60 months
NSABP–B34	Placebo-controlled phase III Oral clodronate stratified by HR and nodal status, and by age <50 or ≥50 years	In patients ≥50 years of age, clodronate improved: • RFI: HR = 0.76; $P = 0.05$ • BMFI: HR = 0.61; $P = 0.024$ • nBMFI: HR = 0.63; $P = 0.015$ • OS: HR = 0.80; $P = 0.1$
GAIN	Randomized controlled, 2 × 2 factorial design trial daily ibandronate or observation	No difference in the 3-year DFS (HR = 0.945; $P = 0.59$) or the 3-year OS (HR = 1.04; $P = 0.80$) between ibandronate versus observation in the ITT population

In postmenopausal patients, recent long-term results from large phase III studies of the intravenous bisphosphonate zoledronic acid support the potential for clinical benefits from intravenous bisphosphonates in postmenopausal women. Three similarly designed studies (Zometa-Femara Adjuvant Synergy Trials: Z-FAST, ZO-FAST, and E-ZO-FAST) enrolled postmenopausal women only and examined the effects of immediate versus delayed initiation of ZOL on disease recurrence and/or DFS as secondary endpoints. The final 5-year results of Z-FAST reported a lower incidence of disease recurrence in the immediate-ZOL groups (5.3% versus 7.0% for the delayed-ZOL group), with reductions in all types of distant recurrence (not only skeletal recurrence). The safety profiles were similar between the immediate-ZOL and delayed-ZOL groups, with no confirmed cases of ONJ and any grade of renal impairment reported in 2% and 1.3% of patients, respectively.

Similar efficacy results were observed at 5 years in the immediate- versus delayed-ZOL groups of ZO-FAST (local recurrence, 5 versus 12 patients, respectively; distant recurrence, 29 versus 41 patients, respectively). Consistent with the reduced incidence of disease recurrence, there was an overall 34% relative risk reduction for DFS events at 5 years' follow-up in the immediate-ZOL group versus the delayed-ZOL group ($p = 0.0375$). Reported adverse events were consistent with the known safety profiles of letrozole and zoledronic acid, with no increases in renal adverse events in ZOL-treated patients. Three confirmed cases of ONJ were reported in patients receiving the bisphosphonate. Patients who were truly menopausal (defined as naturally occurring menopause before study entry) experienced the majority of DFS events (92 events). However, the 29% relative risk reduction in truly menopausal immediate-ZOL-treated patients did not achieve statistical significance, possibly because the analysis lacked statistical power. An analysis of postmenopausal patients in ZO-FAST using the definition from previous studies (menopause >5 years before study entry or >60 years of age) showed a 37% relative risk reduction for the immediate-ZOL-treated patients ($p = 0.052$). Similar trends were obtained for OS in the two postmenopausal groups, with a significant OS improvement with immediate ZOL in established postmenopausal women (HR = 0.50; $p = 0.02$). Notably, among the patients in the delayed-ZOL group in ZO-FAST, 27% initiated ZOL for postbaseline fractures or BMD decreases (median time, 12.8 months), further confounding accurate assessment of the DFS benefits with ZOL. Indeed, exploratory analyses revealed that initiating ZOL was the only factor to influence DFS events in the delayed-ZOL arm (HR = 0.462; $p = 0.033$) [25]. The E-ZO-FAST had shorter follow-up and very few DFS events.

In the overall "negative" AZURE study [26], the only predefined variable to affect disease recurrence, invasive DFS, and OS with ZOL versus control was menopausal status. Postmenopausal women constituted 45% of the study population, and in patients with established menopause (entering menopause ≥5 years before study entry; 31% of the overall trial population), adding ZOL to standard therapy improved invasive DFS (HR = 0.75; $p = 0.02$) and OS (HR = 0.74; $p = 0.04$). These patients are obviously expected to have the lowest hormone levels regardless of anticancer regimens used, which strongly suggests that the anticancer potential of aminobisphosphonates is influenced by the prevailing hormonal milieu rather than by the concomitant systemic therapy or age in women with breast cancer. The results of the AZURE study also support earlier evidence from ABCSG-12 and ZO-FAST suggesting a systemic anticancer effect of zoledronic acid in and outside of the bone. The incidence of serious adverse events was similar between the ZOL and placebo groups; ONJ incidence was low and as expected for these treatment regimens (1.1% versus 0%, respectively). The adverse events were not stratified by age or menopausal status, which precludes knowing if there was a bias toward postmenopausal women.

The GAIN study investigated adjuvant ibandronate, and while the study overall did not show a DFS difference (as AZURE), there was a positive trend with respect to DFS in postmenopausal trial patients [27]. Similarly, there was a significant difference in the subgroup of patients older than 50 years of age in NSABP-34, whereas the overall trial did not show an outcome benefit for 3 years of oral clodronate [28]: In the postmenopausal subgroup, which comprised 64% of the overall trial, a small, nonsignificant improvement in DFS was seen with clodronate. However, recurrence-free, bone metastasis-free, and distant metastasis-free intervals were all significantly improved by the addition of clodronate to standard care in postmenopausal women ($p < 0.05$ for all). A post hoc analysis of skeletal metastasis development showed that the benefit from clodronate was driven by patients who were 60 years of age or older at study entry. This further supports the existing evidence that patients with the lowest hormone levels derive the greatest anticancer benefits from bisphosphonate therapy in the adjuvant setting. However, in this trial 44% of patients who initially received clodronate did not complete treatment (3-year follow-up), and whether oral bisphosphonates can really provide clinical benefits to this patient population in a real-world setting remains a bit uncertain at this time.

Interestingly, all these large trials demonstrate a clear-cut pattern of dependence of a beneficial effect of bisphosphonates on breast cancer outcomes on menopausal status [29]. The "metastasis-preventing" effect of bisphosphonates was seen in

Table 48.2 DFS effects of bisphosphonates in postmenopausal trial subgroups

Study	"Postmenopausal" DFS (95% CI)	*P* Value
AZURE (n = 1041)[a]	0.75 (0.59–0.96)	0.02
ABCSG XII (n = 1390)[b]	0.66 (0.48–0.92)	0.013
ZO-FAST (n = 1065)[c]	0.66 (0.44–0.97)	0.04
NSABP-B34 (n = 2139)[d]	0.68 (0.5–0.92)	0.013
CLODROPLAC (n = 539)[e]	0.66 (0.49–0.93)	0.007
GAIN (n = 1557)[f]	0.75 (0.49–1.14)	0.17

DFS in postmenopausal subsets of large adjuvant bisphosphonate trials

postmenopausal women (and in premenopausal women who were rendered postmenopausal by receiving ovarian function suppression) (Table 48.2) but not in premenopausal patients where DFS was not improved by adjuvant bisphosphonate therapy [30]. Despite some experimental data exist that propose scientific explanations for the differential impact of silencing the microenvironment in differing menopausal states [31], this correlation is not perfectly understood.

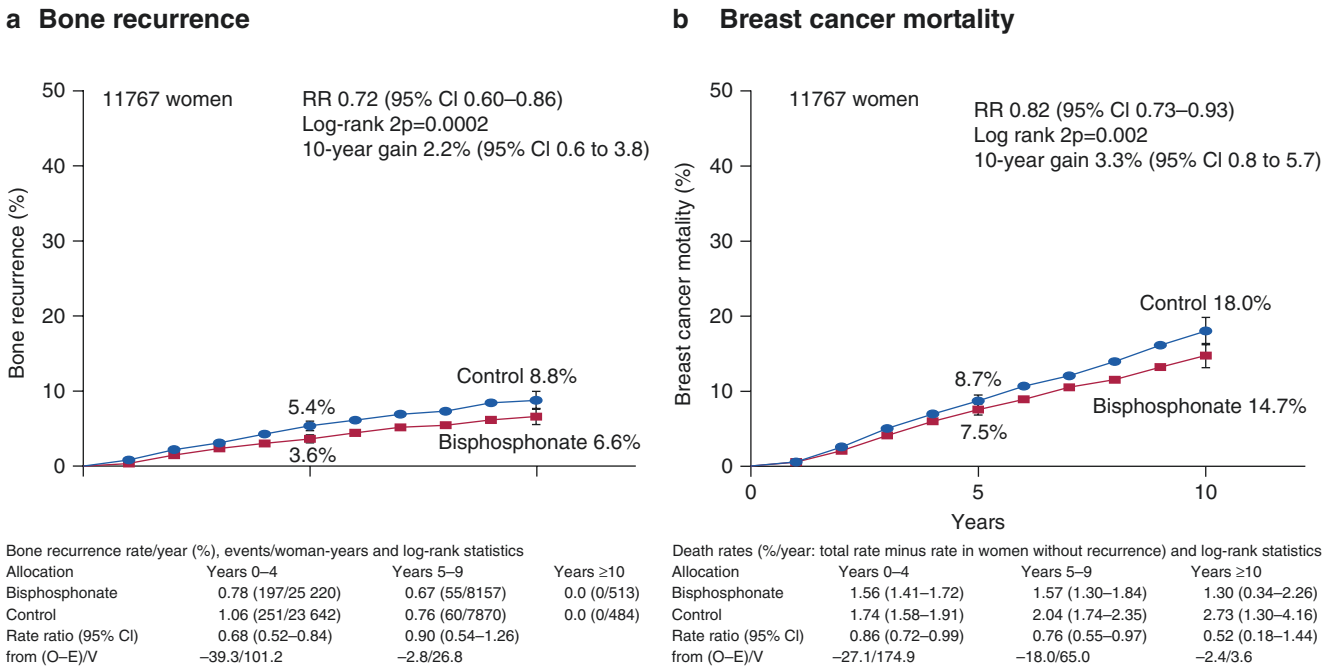
Some of these trial results were discussed in the scientific community in a truly controversial manner and sparked a discussion about the actual putative underlying mechanism of the antitumor effects of adjuvant bone-targeted therapies [32]. While "direct" anticancer properties have been well described in experimental settings (sometimes at bisphosphonate doses that cannot be achieved in the clinical setting), it appears more likely that an indirect effect on the bone marrow microenvironment is actually the foundation for the observed outcome benefits in the adjuvant setting [33, 34]. In fact, the idea that the microenvironment plays an important role in oncology has been proposed already more than a century ago by Sir Stephen Paget ("seed and soil" theory) [35]. However, this is not generally accepted, and understandably so since there are also indications for a "direct" antitumor activity, both experimentally and in the neoadjuvant clinical setting [36, 37]. Another issue that remains unclear is whether bone-targeted therapies actually can prevent metastasis outside the bone in the adjuvant setting, for which there are some indications also in the clinical setting, but most trials show primarily a "bone-only" benefit [38].

In terms of clinical consequences, the debate was eventually settled by the global meta-analysis of all adjuvant bisphosphonate trials, done by the Bisphosphonate Working Group of the Early Breast Cancer Trialists' Collaborative Group based in Oxford, UK. In this worldwide collaborative process involving over 20,000 patients from most of the randomized bisphosphonate trials ever performed, a small but significant benefit for adjuvant bisphosphonates in terms of DFS as well as overall survival was shown for postmenopausal breast cancer patients [39]. Interestingly, the meta-analysis did not indicate a difference between oral and intravenous bisphosphonates, but the overall relative reduction of breast cancer recurrences in postmenopausal patients was a relative 14% (HR = 0.86, p = 0.002), translating into absolute differences of 2.4% at 5 years and 3.0% at 10 years of follow-up (Fig. 48.1).

In summary of these results, adjuvant effects of bisphosphonates are now scientifically established not just as treatment aiming at the reduction of bone loss, but also yielding a decrease (prevention) of bone metastasis at least in postmenopausal patients [40], in some trials even a reduction of recurrences outside the bone [41]. However, lack of approved market access indications in most healthcare environments remain a major obstacle in making this treatment available for the majority of breast cancer patients.

Furthermore, ABCSG-18 fracture data—while demonstrating a dramatic reduction in fractures (HR = 0.5, $p < 0.0001$)—further added to some confusion of the clinical routine implications when they were first presented at ASCO 2015 [10]: Would the bone-health "aware" physician now have to recommend denosumab for the prevention of fractures but (and?) bisphosphonates for the prevention of recurrence [42]? Fortunately, an IDMC-recommended early DFS analysis of ABCSG-18 [43] presented at San Antonio in December 2015 indicates that adjuvant denosumab reduces recurrences in a similar manner than bisphosphonates do in postmenopausal patients (HR = 0.82, p = 0.05). This DFS benefit translates into a 1.2% absolute DFS benefit at 3 years, 2.1% at 5 years, and 3.1% at 7 years of follow-up. In higher-risk subgroups, the absolute benefit may be numerically larger, e.g., tumor size >2 cm: 3.7% at 3 years, 7% at 5 years, and 10.5% at 7 years, respectively.

In summary, there is no doubt that bone-targeted therapy plays an important role for the adjuvant therapy of postmenopausal breast cancer patients (or premenopausal patients on ovarian function suppression therapy): Adjuvant bisphosphonates both protect bone mineral density and reduce recurrences [44] and are therefore recommended for clinical practice despite regulatory and market access limitations [45]. The most recent results of ABCSG demonstrate that adjuvant denosumab similarly stabilizes bone mineral density and reduces disease recurrence, but in addition cuts treatment-induced (clinical = relevant!) fractures in half [10, 43]. With this innovative treatment addition that cuts fractures in half and improves disease-free survival similarly to what bisphosphonates do in postmenopausal women, and importantly without measurable toxicity at the low dose of 60 mg s.c. twice yearly, patients can derive considerable benefit at a burden that can be considered minimal.



Bone recurrence rate/year (%), events/woman-years and log-rank statistics

Allocation	Years 0–4	Years 5–9	Years ≥10
Bisphosphonate	0.78 (197/25 220)	0.67 (55/8157)	0.0 (0/513)
Control	1.06 (251/23 642)	0.76 (60/7870)	0.0 (0/484)
Rate ratio (95% CI)	0.68 (0.52–0.84)	0.90 (0.54–1.26)	
from (O–E)/V	–39.3/101.2	–2.8/26.8	

Death rates (%/year: total rate minus rate in women without recurrence) and log-rank statistics

Allocation	Years 0–4	Years 5–9	Years ≥10
Bisphosphonate	1.56 (1.41–1.72)	1.57 (1.30–1.84)	1.30 (0.34–2.26)
Control	1.74 (1.58–1.91)	2.04 (1.74–2.35)	2.73 (1.30–4.16)
Rate ratio (95% CI)	0.86 (0.72–0.99)	0.76 (0.55–0.97)	0.52 (0.18–1.44)
from (O–E)/V	–27.1/174.9	–18.0/65.0	–2.4/3.6

In the last few centuries, medicine progresses have ensured an increasingly longer life expectancy and have allowed people to live with chronic diseases which were lethal in the past. As a consequence, the proportion of patients of all ages living with chronic comorbid conditions, and in particular of elderly patients, is rapidly increasing. Aging remains one of the single greatest risk factors for the development of new breast cancers. Approximately 50% of breast carcinomas occur in women ≥65 years, and more than 30% of breast carcinomas occur among women >70 years [1]. Older women represent the fastest growing segment of the population in the United States and in Europe [2]; therefore, during the coming decades, older women will represent an increased cohort of patients with newly diagnosed disease and survivors [3, 4]. In addition, recent advances in the field of oncology have also contributed to significantly improve disease outcomes for most type of cancers. As a consequence, oncologists have often to face issues related to breast cancer occurring in other malignancy survivors.

49.1 Aging and Assessment of Older Patients

Aging is characterized by a progressive decline in the functional reserve of multiple organ systems, an increase in the prevalence of functional dependence, comorbidity, and memory disorders and a decline in economic resources and social support [5, 6]. These changes influence treatment-related decision-making for older individuals because they imply a decrease in life expectancy and tolerance of cancer treatment. These factors are poorly reflected in chronological age alone and should be considered when determining optimal treatment approaches for this age-group [7].

A multidimensional comprehensive geriatric assessment (CGA) provides the most reliable information regarding life expectancy, treatment tolerance, social support requirements, and unsuspected conditions (e.g., dementia, depression, comorbidity) that may interfere with cancer treatment [8]. The CGA includes evaluation of functional status, comorbidity and pharmacy, socioeconomic conditions, cognitive status, emotional status, nutrition, and geriatric syndromes. The assessment of the functional status, other than with performance status, is defined as the measurement of a patient's ability to complete functional tasks, which range from simple self-care in activities of daily living (ADL, which includes feeding, grooming, transferring, and toileting) [9] to more complex instrumental activities of daily living (IADL, which includes shopping, managing finances, housekeeping, laundry, meal preparation, ability to use transportation and communicating by telephone, and the ability to take medications) [10]. Comorbidity is assessed by the number and the severity of comorbid conditions (comorbidity index), and pharmacy is assessed by evaluating the number of medications, appropriateness of medications, and risk of drug interactions. Socioeconomic conditions are assessed by evaluating the living conditions and especially the presence and adequacy of a caregiver. The cognitive status is evaluated through the Mini-Mental State Examination by Folstein and other tests, whereas the emotional status is evaluated through the Geriatric Depression Scale (GDS). Nutrition is assessed through the Mini-Nutritional Assessment (MNA). Geriatric syndromes are dementia, delirium, depression, falls, neglect and abuse, and spontaneous bone fractures.

Several studies have supported the effectiveness of CGA in improving functional status, reducing hospitalization, decreasing medical costs, and prolonging survival. In the older cancer patient, the CGA allows a gross estimate of life expectancy and of the functional reserve and tolerance of chemotherapy, the recognition of reversible comorbid conditions and special economic needs that may interfere with cancer treatment, and the management of nutrition and medications [11]. The CGA allows categorization into three stages of aging:

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_49

- "Fit" patients lack severe comorbidities, are functionally independent and are candidates for any form of standard cancer treatment.
- "Frail" patients have dependence in one or more activities of daily living, three or more comorbid conditions and/or one or more geriatric syndromes, and are candidate only for palliative treatment.
- Patients with intermediate characteristics are defined as vulnerable and may benefit from some special pharmacological approach, such as reduction in the initial dose of chemotherapy with subsequent dose escalations [12].

All patients aged 70 and older should be subjected to some form of CGA because the prevalence of age-related problems increases after this age [13, 14]. Since the CGA is a time-consuming approach, at least an abbreviated screening version should be performed [13, 15] with the full assessment being given only to those patients who screen positive in some domains.

49.2 Frailty

A key point in the patient evaluation in the onco-geriatric setting is the definition and identification of frailty, which includes being dependent on others, being at substantial risk of dependency and other adverse health outcomes, experiencing the loss of "physiological reserves," having many chronic illnesses, having complex medical and psychosocial problems, and having "atypical" disease presentations [11]. Current criteria for the recognition of frailty include age over 85 years, dependence in one or more activities of daily living, three or more comorbid conditions, and the presence of one or more geriatric syndromes [16].

Frailty is a reversible condition characterized by a high degree of susceptibility to external changes that require adaptation and compensation. When cancer is the external change, the main objective of frailty detection is to adopt compensatory strategies acting at different levels [11].

49.3 Biology of Breast Cancer in the Elderly

In general, breast cancer appears more indolent with increasing age [17–19]. Approximately, 70–80% of all breast cancers occurring in elderly patients express estrogen receptors, tend to grow slowly, are usually better differentiated, respond to hormonal treatments, and are associated with a longer disease-free interval and a slightly better overall prognosis [23]. There is, however, a 20–30% of patients who remain at high risk of relapse because of extensive nodal involvement or estrogen receptor-negative disease.

49.4 General Principles of Cancer Treatment in the Elderly

Although available clinical data demonstrate that treatment efficacy is not modified by age, elderly patients are underrepresented in clinical trials [20, 21]. In a review of SWOG trials, only 9% of elderly patients with breast cancer were entered into trials, despite 49% of all elderly cancer patients having breast cancer [22]. Likewise, in the Oxford Overview of 60 trials involving 29,000 women comparing chemotherapy with none, only 4% were 70 or older [23]. Older patients are more likely to have conditions that make them ineligible for clinical trials because of protocol exclusions mainly related to comorbidities or ageist trial designing [24]. Consequently, to date, most data concerning older women with breast cancer are derived from retrospective studies, which are often affected by selection bias [23].

The challenge of caring for older women is tailoring treatment to fit the patient. Although this is true for all patients, it is mostly relevant in elders, in whom comorbidity and functional loss can lead to undertreatment and shorter breast cancer-specific survival or to overtreatment and toxicity [25]. Older women with breast cancer are often affected by age-related comorbidities, which may limit treatment options [26]. Older women are less likely to receive treatment in concordance with guidelines, including surgery, radiotherapy, chemotherapy, and endocrine therapy, regardless of their breast cancer stage [27].

49.5 Adjuvant Treatment

49.5.1 Endocrine Treatment

Adjuvant endocrine therapy should be recommended to women whose breast cancer contains hormone receptors, regardless of age, menopausal status, involvement of axillary lymph nodes, or tumor size [28]. Tamoxifen has long been the most commonly used hormonal treatment, with data supporting a 5-year course rather than shorter periods [23]. However, only 1 year of treatment had a significant effect on disease-free and overall survival up to 21 years in elderly patients as shown by data from the International Breast Cancer Study Group (IBCSG) Trial IV [29].

Aromatase inhibitors have shown to reduce breast recurrence as compared to tamoxifen in a number of trials. Two analyses have been done specifically in elderly patients. In the MA.17 trial, the advantage conferred by extended letrozole after 5 years of tamoxifen was significant only in patients younger than 60 years. However, since there was no significant interaction between age and treatment for disease-free

survival or overall survival, extended adjuvant therapy with letrozole could be considered for healthy elderly patients [30]. In the Breast International Group (BIG) Trial 1-98, letrozole showed age-independent superior efficacy compared with tamoxifen [31].

In older patients, aromatase inhibitors are preferred to tamoxifen because of the lower risk of increased thrombosis and endometrial cancer, with similar effect on quality of life [30, 31]. However, aromatase inhibitors are associated with musculoskeletal syndrome, accelerated bone loss and increased fracture rate irrespective of age, as suggested prospectively in BIG 1-98. BIG 1-98 results showed significantly more grade 3–5 protocol-specified non-fracture adverse events for letrozole compared with tamoxifen in patients ≥75 years, whereas differences were not significant for thromboembolic or cardiac events [31]. Cognitive impairment has been described in association with adjuvant hormonal treatment, but data are sparse [32]. Bone loss associated with aromatase inhibitors is a particular problem in elderly patients, since preexisting decreases in bone mineral density and osteoporosis are prevalent. Vitamin D and calcium supplementation should be considered, especially since subclinical vitamin D insufficiency is common in elderly patients. Antiresorptive therapies are indicated for increasing bone mineral density and reducing fracture risk in elderly patients with osteoporosis [33].

In a recently published update of the meta-analysis by the Early Breast Cancer Trialists' Collaborative Group, aromatase inhibitors reduced recurrence rates by about 30% compared with tamoxifen. Moreover, 5 years of an aromatase inhibitor reduced 10-year breast cancer mortality rates by about 15% compared with 5 years of tamoxifen, hence by about 40% compared with no endocrine treatment [34].

In older patients with small hormone receptor-positive tumors, endocrine therapy with either aromatase inhibitors or tamoxifen is the mainstay of treatment [35]. However, the optimal way of using aromatase inhibitors or tamoxifen as endocrine treatment for early breast cancer remains uncertain. The American Society of Clinical Oncology Technology Assessment published recommendations for adjuvant treatment that included aromatase inhibitors, either upfront or as a sequential therapy consisting of tamoxifen followed by aromatase inhibitors in the treatment of postmenopausal women with endocrine responsive breast cancer [36]. In general, aromatase inhibitors may be preferable as initial treatment in most elderly patients because, unlike tamoxifen, they are not associated with endometrial carcinoma and do not increase the need for yearly gynecologic examinations in older women who have not had a hysterectomy. Although arthralgia and myalgia are less frequent in older patients treated with aromatase inhibitors, they can result in pain and functional loss and create a cause for discontinuing therapy [35].

49.5.2 Chemotherapy

Several randomized trials have shown that chemotherapy improves both disease-free and overall survival in women with early breast cancer, but a lesser absolute benefit from chemotherapy has been observed with increasing age. In fact, the proportional reduction in risk of recurrence and mortality seems to decrease with increasing age; however only 4% of patients included in the overview analysis were >70 years [23]. The optimal chemotherapy regimen, doses, and schedules for the adjuvant treatment of elderly patients have not yet been defined, while concern is increasing regarding the toxicity associated with chemotherapy in this patient population [37].

Only recently, specific trials addressing adjuvant chemotherapy in older women have been conducted, and their results are available. In the French Adjuvant Study Group 08 (FASG 08) trial, fit elderly women aged ≥65 years, with node-positive early breast cancer, were randomized to tamoxifen with or without weekly epirubicin. The 6-year disease-free survival showed a nonstatistically significant improvement (72.6% vs. 69.3% $p = 0.14$) in favor of combination arm; the relative risk of relapse in multivariate analysis was significantly higher in patients who received tamoxifen alone, compared with patients treated in combination (HR 1.93, $p = 0.005$) [38]. The IBCSG CASA trial evaluated pegylated liposomal doxorubicin and low-dose, metronomic cyclophosphamide and methotrexate in women ≥66 years with estrogen and progesterone receptor-negative breast cancer. After 2 years, the trial closed early, due to slow accrual. At a median follow-up of 42 months, 81% of patients were free of breast cancer recurrence [39]. The CALGB trial evaluated a standard regimen (AC or CMF) as compared with capecitabine in patients older than 65 years and showed the superiority of a standard adjuvant chemotherapy in women with hormone receptor-negative tumors [45]. The ICE trial completed the accrual of 1409 patients older than 64 years of age with node-positive or high-risk node-negative early-stage breast cancer who were deemed inappropriate for conventional treatment and who were randomized to ibandronate or the combination of ibandronate and six cycles of capecitabine. Results showed no difference between the two treatment arms for the primary endpoint of 3-year invasive disease-free survival and overall survival [40]. The ICE II trial randomized 400 women ≥65 years with high-risk breast cancer to standard arm (four cycles of EC or six cycles of CMF) vs. experimental arm (six cycles of weekly nab-paclitaxel plus capecitabine (PX)). Interim safety analysis revealed that EC or CMF were more tolerable than PX. The rates of invasive disease-free survival were equivalent between the two arms (HR 0.98, $p = 0.9597$) at 48 months [41]. The ELDA Trial randomized 302 patients with

node-positive or high-risk node-negative tumors to classical CMF or weekly docetaxel. At a 70 months median follow-up, weekly docetaxel did not show to be more effective than standard CMF. Hematological toxicity, mucositis, and nausea were worse with CMF; allergy, fatigue, hair loss, onychopathy, dysgeusia, diarrhea, abdominal pain, neuropathy, cardiac, and skin toxicity were worse with docetaxel. Quality of life was worse with docetaxel for nausea/vomiting, appetite loss, diarrhea, body image, future perspective, treatment side effects, and hair loss items [42]. The Weekly nab-paclitaxel (Abraxane®) Versus Epirubicin (WAVE) trial is an ongoing phase II trial evaluating activity and quality of life of women with early breast cancer who are elderly or unfit for a 3-week polychemotherapy regimen and who are randomized to either weekly epirubicin or weekly nab-paclitaxel both for 16 weeks.

The decision to recommend chemotherapy to an older patient with early-stage breast cancer is complicated and requires knowledge of life expectancy, the risks and benefits of the proposed treatment, and the patient's and family's goals for treatment [43]. In general, for healthy older patients with estimated survivals of 10 years or more, state-of-the-art treatments similar to those used for younger patients should be recommended. For patients with an average life expectancy of less than 5 years, the value of adjuvant endocrine therapy and certainly chemotherapy is likely to be minimal except in the case of patients with extremely high-risk disease [35].

In older patients with hormone receptor-positive, HER2-negative tumors, the absolute benefit in improving survival with the addition of chemotherapy to endocrine therapy is highly dependent on the risk of tumor recurrence. In general, the majority of patients with node-negative tumors will derive little benefit from chemotherapy. Patients with four or more nodes should receive chemotherapy if their life expectancy exceeds 5 years. Patients with a life expectancy of less than 5 years, irrespective of nodal involvement, are not likely to derive any benefit from chemotherapy [35].

For older patients with triple-negative breast cancer and a life expectancy exceeding 5 years, the major systemic treatment consideration is chemotherapy. Several chemotherapy regimens are appropriate in these patients [44]. In general, regimens such as doxorubicin and cyclophosphamide [45] or docetaxel and cyclophosphamide [46] are preferred. However, anthracyclines are associated with increased risks of cardiac toxicity and the development of acute myelogenous leukemia and myelodysplasia, whereas taxanes have substantial risks of peripheral neuropathy, a potential toxicity that can impede function and impair the quality of life of older patients [47]. It is essential to inform patients and families of potential major toxicities since for a few percent gain in survival, many older patients might decline chemotherapy if it is likely to affect their physical function [35].

49.5.3 Trastuzumab

Limited data are available on adjuvant trastuzumab in elderly patients. The combined NSABP B-31/NCCTG N9831 US trials of standard chemotherapy with or without adjuvant trastuzumab for 1 year involved 16% patients over 60 years old, and their benefit with trastuzumab was at least as good as for younger women (HR 0.51) [48]. Likewise, in an exploratory subgroup analysis of the HERA trial which also had 16% of patients over the age of 60, there was no significant difference in disease-free survival benefit in the older group compared with younger women [49]. However, the standard chemotherapy used in these trials is likely to be too toxic for many elderly or frail patients. Recently a large phase II study investigated adjuvant weekly paclitaxel for 12 weeks with trastuzumab in 406 "low-risk" patients with <3 cm, node-negative HER2-positive breast cancer, including 24% of patients aged 60–69 and a further 10% aged >70 (34% >60). This study showed outstanding disease control with an estimated relapse-free survival of 98% at 3 years [50].

A systematic review of prospective randomized trials in patients >60 years showed a significant 47% relative risk reduction in patients receiving trastuzumab compared to chemotherapy alone, with a 5% pooled proportion of cardiac events [51].

Older patients with HER2-positive tumors can benefit from chemotherapy and trastuzumab, the greatest absolute benefit being observed in patients with hormone receptor-negative, HER2-positive tumors [35]. The combination of weekly paclitaxel and trastuzumab is a reasonable option for elderly or frail patients with node-negative HER2-positive breast cancer [50]. More aggressive regimens should be considered for older patients with higher-risk breast cancer [52].

A major concern when offering chemotherapy and trastuzumab to older patients is the risk for cardiac toxicity [53], which is enhanced in anthracycline regimens. Before the initiation of chemotherapy, patients should have an estimation of left ventricular ejection fractions (LVEF) using either echocardiographic or nuclear medicine methods.

49.6 Neoadjuvant Treatment

Patients with locally advanced disease might be offered preoperative systemic therapy to render surgery feasible or to make breast conservation possible.

Most elderly patients have ER-positive HER2-negative breast cancers, for which neoadjuvant endocrine therapy can be extremely effective, possibly as effective as chemotherapy [54].

A Cochrane review showed a decrease in local progression with surgery plus endocrine treatment compared with primary endocrine therapy alone; however, no difference

was observed in overall survival. For optimal local control, surgery (with or without radiotherapy) plus adjuvant endocrine therapy is better than primary endocrine therapy. Evidence exists for disease control of 2–3 years with primary endocrine therapy [55]. Therefore, in patients with a short life expectancy (<2 years), considered unfit for surgery or refusing surgery, primary endocrine therapy might be considered.

Primary endocrine therapy studies have mainly used tamoxifen, although aromatase inhibitors could be preferable on the basis of neoadjuvant, adjuvant, and metastatic data [56–58]. The ESTEEM trial comparing primary anastrozole with surgery plus adjuvant anastrozole in women ≥75 years was closed because of low accrual. Clinical trials of primary aromatase inhibitors in frail older patients with ER-positive tumors are needed, but in view of the difficulty in recruiting for such a trial, it is reasonable to assess each individual for tamoxifen or aromatase inhibitors based on potential toxicity.

For patients with triple-negative breast cancer and good life expectancy, anthracycline and taxane regimens can be used [35]; however, no specific data is available in older patients.

For patients with HER2-positive disease, neoadjuvant therapy that includes pertuzumab in addition to trastuzumab provides the best chances for tumor reduction [59, 60]; however, specific data is lacking in older patients.

49.7 Metastatic Breast Cancer Treatment

Endocrine treatment is the treatment of choice for older women with ER-positive metastatic breast cancer [61]. Chemotherapy is indicated in older patients with ER-negative, hormone-refractory, or rapidly progressing disease. Elderly patients with metastatic breast cancer are expected to derive similar benefits from chemotherapy as younger patients. Single-agent chemotherapy is generally preferred to combination regimens, which are usually more toxic and provide, at most, a limited survival gain. Preference should be given to chemotherapy agents with better safety profiles (such as weekly taxanes, pegylated liposomal doxorubicin, capecitabine, and vinorelbine) that have been studied in older patients [62]. There is limited data on polychemotherapy in elderly patients. Combination oral chemotherapy (vinorelbine and capecitabine) was assessed in patients >70 years with advanced cancer, many with breast cancer, and was active and well tolerated [63]. Oral therapy is attractive since it eliminates the constraints and risks of parenteral therapy, but efficacy and tolerability can be compromised by interference with food (e.g., lapatinib), concomitant medications (e.g., capecitabine with warfarin), and errors in compliance. Dose reductions and schedule modifications are controversial but should be considered based on pharmacology and toxicity [61].

Patients with HER2-positive disease should receive HER2-targeted therapy and chemotherapy. In elderly patients with HER2-positive, ER-positive disease with a contraindication to chemotherapy, or without life-threatening disease, anti-HER2 therapy plus endocrine therapy is an option. In elderly patients with HER2-positive, ER-negative disease who are unfit for chemotherapy and without life-threatening disease, trastuzumab monotherapy could be reasonable. However, there are no specific efficacy or safety data in elderly patients. First-line trastuzumab monotherapy showed clinical benefit rates of around 40% [64]. Combination anti-HER2 plus hormone therapy (trastuzumab plus anastrozole, lapatinib plus letrozole) improves progression-free survival over hormone therapy alone in ER-positive, HER2-positive disease, but with more toxic effects and higher economic cost [65, 66]. Trastuzumab and lapatinib are equally effective in younger and older patients with metastatic breast cancer [61]. Data on trastuzumab in elderly women are limited, but a retrospective series showed that benefits and safety seem to be conserved in patients older than 60 years and in those older than 70 years [67]. Lapatinib plus capecitabine has similar efficacy in older and younger women [68]; however, elderly patients are less tolerant of diarrhea-associated dehydration and need close monitoring [69].

Bisphosphonates and denosumab are underused in elderly patients [33, 70]. Special considerations should be made for elderly patients, who might have renal impairment or might be taking concomitant medications for comorbid conditions. In this regard, there could be an advantage for denosumab in elderly patients. Because of noncompliance with oral bisphosphonates, intravenous or subcutaneous administration might be preferable [61].

49.8 Management of Frail Patients

With the expansion of the older population, the number of frail elderly and frail elderly with cancer is expected to rise. Approximately 400,000 frail elderly in the United States are affected by some form of cancer at any given time [16, 71]. Management of cancer in the frail person is mainly comprised of palliation. The use of opioids is complicated by delirium, constipation, and nausea, and these side effects may become so disturbing that an older patient may prefer to tolerate pain rather than the symptoms related to pain management [72]. However, recent drug developments offer options to the frail cancer patients. In addition to the use of bisphosphonates for bone metastases, new antitumor agents including capecitabine, low weekly doses of taxanes, liposomal doxorubicin, vinorelbine, and gemcitabine may be beneficial to these individuals while producing minimal toxicity.

49.9 Systemic Treatment for Other Malignancy Survivors

Cancer survivors can be affected by a number of health problems, but often their greatest concern is facing cancer again. In fact, certain types of cancer and cancer treatments can be linked to a higher risk of certain second cancers.

The most common second cancer seen in survivors of breast cancer is another breast cancer [73]. For some second cancers, shared genetic risk factors may play a role. For example, women with mutations in the BRCA genes have an increased risk of both ovarian cancer and breast cancer, as well as of other tumors [74]. Another risk factor shared by both breast cancer and other malignancies is aging. Moreover, prior cancer treatments, including radiation, chemotherapy, and certain drugs, also have risks associated with developing secondary and unrelated cancers. Finally, lifestyle (including diet, exercise, smoking, UV exposure, and alcohol intake) can have an impact on incidence of breast cancer as well as of other tumors. Women who have had breast cancer can get any type of second cancer, but they have an increased risk of ovarian, endometrial, thyroid, stomach, colorectal and lung cancer, melanoma of the skin, soft tissue sarcomas, and acute myeloid leukemia [75].

Patients surviving after a first tumor diagnosis and newly diagnosed with breast cancer present some treatment issues, mostly related to cumulative toxicities of treatments.

The most commonly associated toxicities from chemotherapy occur in tissues composed of rapidly dividing cells and may spontaneously reverse with minimal long-term toxicity. However, myocardium consists of cells that have limited regenerative capability, which may render the heart susceptible to permanent or transient adverse effects from chemotherapeutic agents. Such toxicity encompasses a heterogeneous group of disorders, ranging from relatively benign arrhythmias to potentially lethal conditions such as myocardial ischemia/infarction and cardiomyopathy [76]. For this reason, caution should be exerted in patients who received prior anthracyclines for other neoplasms, since their cumulative dose (450 mg/m^2 for doxorubicin and 900 mg/m^2 for epirubicin) should not be exceeded [77].

Neuropathy induced by chemotherapy is an increasingly frequent problem, for which neither prophylaxis nor specific treatment is available, and only symptomatic treatment can be offered. The most frequent chemotherapeutic drugs causing peripheral neuropathy are platin compounds, vinca alkaloids, taxanes, bortezomib, and thalidomide. The role of synergistic neurotoxicity caused by previously given chemotherapies and concomitant chemotherapies and the role of preexistent neuropathy on the development of peripheral neuropathy is not clear. As the number of long-term cancer survivors increases and a new focus on long-term effects of chemotherapy-induced neuropathies emerge, rehabilitation needs to be implemented to improve the patients' functions and quality of life [78].

Radiation and adjuvant chemotherapy for breast cancer are associated with a risk of myelodysplastic syndrome and acute myelogenous leukemia, which continues to increase beyond 5 years [79]. This risk is particularly evident with the use of alkylating agents, in particular cyclophosphamide, which is commonly used in breast cancer treatment. In order to minimize the risk of marrow neoplasms, cyclophosphamide cumulative dose should not exceed 36 g [80].

Tamoxifen increases the risk of endometrial cancer [81]. Women taking tamoxifen should be informed about the risks of endometrial proliferation, endometrial hyperplasia, endometrial cancer, and uterine sarcomas, and any abnormal vaginal bleeding, bloody vaginal discharge, staining, or spotting should be investigated. In a patient with prior history of endometrial tumor, tamoxifen is contraindicated, and other endocrine treatments should be prescribed instead.

Radiation therapy to the breast increases the risk of lung cancer, esophageal cancer, and sarcomas. The risk increases over time and is highest 15 or more years after breast cancer diagnosis [82]. Conversely, even 40 years after treatment, survivors of Hodgkin's lymphoma (HL) are at increased risk for breast cancer, which accounts for more than 40% of the excess risk of a second cancer among women with previous HL. As compared with mantle-field irradiation, radiation therapy with less-extensive supradiaphragmatic fields was associated with a substantially lower risk of breast cancer [83]. In patients with prior mantle-field irradiation for HL and newly diagnosed with breast cancer, re-irradiation of the breast can lead to tissue necrosis. For this reason, mastectomy remains the standard of care in most cases [84].

Conclusions

In elderly women with breast cancer, in addition to the existing evidence from clinical trials and retrospective studies, practitioners need to take into consideration the functional status, social support, patient preference, presence of comorbidities, and life expectancy when selecting optimal treatment, weighing the risks and benefits of all therapeutic options. There is no absolute age limit for the use of standard chemotherapy regimens. Rather, the use of such treatments should depend on disease characteristics, comorbidity, life expectancy, and patient preference. In general, standard treatments should be offered to "fit" elderly patients irrespective of age. However, standard adjuvant chemotherapy can be difficult for elderly or frail patients and is associated with an increased risk of serious morbidity and treatment-related mortality. Simple well-tolerated, short-duration, single-agent schedules may be preferable for elderly and/or frail patients who may prefer

to trade a very minor reduction in efficacy for a much easier treatment. There is an urgent need for further clinical trials of less toxic chemotherapy schedules which may be as effective as standard with very little trade-off in efficacy.

Part VIII

Radiotherapy

Conceptual Basis and Principles of Radiation Oncology

50

Roberto Orecchia

Radiation oncology is a wide discipline of human sciences that joints many of the conceptual basis of physics, biology, and medicine and is funded on the knowledge of the fundamental principles of (1) cancer and normal tissue molecular biology, (2) basic and medical physics and dosimetry, (3) physical and biologic interaction of radiation with normal and malignant tissues, (4) high-precision imaging, and (5) the effect of the combined use of radiations with other treatment modalities, such as surgery, drugs, and other physical energies. The multidisciplinary education of radiation oncologists is the foundation for a high quality of the patient's care.

50.1 Aim of Radiation Therapy

Radiation therapy is the clinical modality that transfers concepts and principles of radiation oncology in the clinical setting. Radiation therapy is a locoregional treatment suitable for the treatment of cancer and occasionally some benign diseases. To realize this goal, radiation therapy uses different sources of ionizing radiation. The most important characteristic of ionizing radiation is the localized release of a large amount of energy in the human tissues. This energy is able to break the chemical bonds of the atoms or molecules and initiate the chain of events that lead ultimately to a biologic effect, fundamentally the DNA damage.

Radiation therapy allows to deliver a precisely measured dose of irradiation to a defined volume of clinical interest, with the minimal damage as possible to the surrounding healthy tissue or organs. The goal is eradication of the disease (care), possibly with preservation of organ functions and form, and therefore, maintaining a high patient's quality of life, and, last by not least, at competitive cost when compared with other therapies [1]. Radiation therapy is also used for pain treatment and other symptoms relief, with the aim to perform palliative care in incurred disease, maintaining the patients comfort but also often prolonging their life [2].

Today, over 50% of patients with cancer will receive this treatment at some times during the management of their malignant disease, and radiation therapy is an integral part of the management of the most frequent cancers worldwide, including breast, lung, prostate, head and neck, and cervix [3]. In spite of the well-recognized role, radiation therapy is often absent from global health plans and receives limited funding [4]. As a result, there is a worldwide shortfall of radiation therapy services, especially in low-income countries, where more than 90% of the population lacking access to radiation therapy. But even in high-income countries, radiation therapy has frequently been used in suboptimal way, despite facilities being easily available. The growing incidence of cancer will require to increase the capacity of the radiation therapy services. In 2012, worldwide, more than 14 million new cases of cancer were reported, and this number is projected to reach about 25 million by 2030 [5]. In 2012, five cancers, lung, breast, colorectal, prostate, and stomach, comprised almost half the total incidence of cancer and caused more than 50% of the eight million cancer deaths. The incidence and profile of cancer vary between and within the different countries [6]. Country-specific variability in cancer incidence, as estimated in 184 countries worldwide, shows breast cancer as the leading cause of cancer in 73 countries, including parts of Central and South America, Africa, and Asia. Prostate cancer is the most frequent cancer in 34 countries, mostly those with high life expectancy and diffuse testing for PSA (Americas, northern and western Europe, Oceania). Cervical cancer is most common in 26 countries, mainly in low-income countries, as sub-Saharan Africa and in parts of South America. Lung cancer is the

most frequent cancer in 18 countries, including parts of eastern Europe, western Asia, northern Africa, and eastern Asia. Colorectal cancer incidence is highest in an almost equivalent number of countries, mainly in Europe and in eastern Asia. Radiotherapy is needed to treat most of these cancers as part of a course of evidenced-based, effective care.

In Europe, about four million new cancer patients are predicted in 2025, representing a 16% increase in the absolute number of cancer with respect to 3.4 million diagnosed in 2012 [7]. Also in Europe, the number of expected cases is not uniformly distributed across the different countries. This situation will require to treat by radiation therapy about two million of patients in 2025, with a majority of them having breast, lung, prostate, and head and neck cancers.

To treat cancer, radiation therapy can be used as sole treatment modality, to permanently eradicate the primary tumor and regional node metastasis, or in combination with surgery, both preoperatively, with the aim to inactivate a large proportion of tumor clonogenic cells and shrink inoperable or borderline operable tumors, or postoperatively, to eliminate residual subclinical cancer deposits on the tumor bed or positive margins remained in the tissues surrounding the resected area. The preoperative irradiation of a undisturbed area allows the use of smaller radiation portals and lower radiation dose than that recommended postoperatively. On the other side, a potential advantage of the postoperative approach is that the extent of the gross disease and microscopic margins is well defined, and radiation therapy can be specifically tailored to the involved sites. Regardless of whether radiation therapy is given before or after surgery, the time interval between the treatments is important to reduce the possibility of tumor cell repopulation. To overcome this problem and reduce the risk of any delay in the combined approach, intraoperative irradiation can be also considered, with the use of a high single dose at the time of surgery, directly at the tumor bed [8].

In locally advanced stages of cancer, radiation therapy is also frequently used in combination with chemotherapy. Induction or neo-adjuvant chemotherapy can be given weeks or months before radiation therapy to reduce the tumor volume and improve the global effectiveness of the treatment. Concurrent or concomitant chemotherapy is given during the course of radiation in a wide range of indications to enhance, as a sensitizer, the radiation effects on tumor. The optimal schedule of administration depends on the particular drug, and the benefit occurs only when the cancer cell killing effect is greater than the expected increase of toxicity on normal tissue. Adjuvant chemotherapy is used to eradicate occult distant cancer spread after the completion of radiation therapy and the achievement of local and regional control of the tumor. More recently, advances in the knowledge of molecular radiation biology are providing the rationale for combining radiation with new targeted drugs able to modulate signaling pathways, opening investigations on feasible and promising novel therapies [9].

50.2 Sources of Radiation

Radiation therapy has been used for more than 110 years for the treatment of patients [10]. Shortly after the discovery of X-rays in 1895, both low-energy X-rays and radium sources were used in Europe and America, and due to the poor penetration of these sources, mostly for the treatment of superficial tumors. During the early 1900s, early experiments in radiobiology were conducted, in parallel with the development of new machines. Clinical experience with these units suggested advantages of high-energy radiation (megavoltage) over the available low-energy generators (kilovoltage) at that time. High-energy radiotherapy delivered by ^{60}Co (cobalt) machines was developed in the 1950s and allowed to deliver the dose at depth, even with relatively limited penetration. The photons, with two picks of energy, respectively, at 1.17 and 1.33 MeV, are produced from the radioactive decay of the source. The intensity of the radiation decreases with time, and the ^{60}Co source must be changed every 5 years to avoid too long treatment time.

Such considerations have led centers to replace cobalt units with modern linear accelerators. These machines, developed since the 1960s, are multimodality and provide a wide range of photon and electron energies, from 4 MV up to 25 MV, with the guaranty of much greater penetration in the most deep-seated tumors and smaller penumbra. Clinically, 4–8 MV beams are the most useful providing a good balance between penetration and surface dose. In an era of personalized medicine, technical progress means that linear accelerators have been implemented with sophisticated tools, such as multileaf collimators, allowing to shape and modulate beams to conform to the exact shape of tumors, maximizing radiation dose deposition in the cancer, while sparing normal tissues from high doses, those most likely to evoke toxic effects.

One strategy to further improve the precision of radiation therapy, focusing more the dose in the target volume, is the use of heavy charged particles. This radiation modality is also named hadrontherapy. The most employed particle in clinical setting is protons. Protons have a mass of 2000 times that of the electrons and require to be accelerated at the therapeutic range of energy (up to 250 MeV) by very huge special machines, as cyclotron or synchrotron. Protons have the same biological effectiveness of photons. Other heavier particles, as carbon ion, produce more dense ionization and increase of three to four times the damage to the DNA of the cancer cells [11].

In addition to external beam sources, brachytherapy has been used since the early 1900s, placing radium sources.

Radium therapy was developed for about 40 years, mainly in Paris and Manchester. New sources were introduced after the Second World War, with iridium-192 and caesium-137. Exposure of the staff became a top priority, and in the following years, technological improvements allowed to realize the modern approach, with the placement of nonradioactive source carriers before, with more time to their accurate positioning, followed by the radioactive loading after. Today, brachytherapy is realized by sophisticated machines that allow the mobilization of sources from a protected storage safe via flexible transit tubes to various types of treatment applicators (after/remote loading). These techniques have expanded the scope and the range of applications of brachytherapy [12].

50.3 Radiation Therapy Planning

Planning is a critical step in the delivery of clinical radiation therapy. Treatment to be effective has to be delivered to the region of interest, using different techniques and regimens. Delivery of radiation therapy requires firstly the accurate definition and delineation of volume to be treated, into a precise anatomic context [13].

Conventionally, different sub-volumes have been identified. The GTV (gross tumor volume) is corresponding to the macroscopic feature and location of the disease, as shown by imaging. The GTV may be different when it is determined by different imaging modalities or when, using the same modality, different image viewing parameters are used. The CTV (clinical target volume) includes the GTV and the regional area at risk for the spread of the disease (subclinical disease) and constitutes the volume to be irradiated with an adequate dose to control the tumor. In case of previous resection of the tumor mass, it's possible to have a CTV without a GTV. The PTV (planning target volume) takes into account uncertainties related to the treatment, including patient's movement and variation in patient setup. The equally critical identification is reserved to identify organs at risk (OaRs), surrounding the tumor area. OaRs are by definition site-specific and require to be analyzed on individuals in terms of dose constraints, volume, and risk factors [14].

In the daily routine practice, CT scan is used to identify these volumes. CT images closely simulate the effects of radiation passing through the patient, being the CT voxel value, which reflects X-ray attenuation, depending on the electron density of the body tissues. Current technology of CT images, by spiral or helical acquisition, strongly reduces the time with the advantage of minimizing the magnitude of organ motion during the examination but sometimes also introducing motion artifacts. When appropriate, MR and PET images can be also imported into the planning to provide more sophisticated information, such as tumor metabolic activity [15].

Planning is strongly depending on complex computer algorithms to calculate the dose distribution due to the beam passing though the human body, including the altered electron density across different tissues. This pretreatment process has to be implemented on a daily basis on the linear accelerator, to guarantee accuracy and reproducibility. The importance of immobilization device, setup control, and electronic portal imaging is well recognized, in the frame of strict quality assurance programs. Currently, linear accelerators can be equipped with imaging modalities that allow the acquisition of anatomical images of the patient in treatment position or during the treatment. For the radiation source, megavoltage (MV) treatment beam or kilovoltage (kV) X-ray source can be employed; both can provide bi- or three-dimensional (cone beam CT) images.

Strategies to verify target shape, volume, and position and to correct the topographical inconsistencies with the original plan are part of image-guided radiotherapy (IGRT). IGRT uses, in addition to the previously mentioned tools, also other various devices, such as real-time ultrasound, optical tracking imaging, and fiducial markers placed on the body surface or implanted within the target (clips). In the case of substantial deviations from the original treatment plan that cannot be adjusted by means of couch, machine, or MLC shifts, it becomes necessary to replan and re-optimize the dose distribution. This kind of adaptive radiotherapy can be done offline, with a time lapse, or even online, with a fast replanning system to elaborate a new plan for the current treatment session. Besides inter-fraction motion, also intra-fraction motion has become relevant because of the relatively long time to deliver the dose. To overcome this problem, treatment rooms can be equipped with movement tracking systems to monitor and compensate for target motion during irradiation, due to uncontrolled physiological behavior, such as coughing or body relaxation. The MR linear accelerator (MR-linac) represents a further step toward a fully adaptive intra-fraction planning system. More precise tracking of target and organs at risk, thanks to advanced soft tissue visualization, should lead to narrower safety margins around the target and to smaller treated volumes, making it possible to further escalate the dose safely [16].

Radiation therapy is administered to the patients according to different regimens. The most used is named as "conventional fractionation," and according the current practice in America and Europe, this regimen is delivered in a large number of fractions, from 30 to 40, over 6 and 8 weeks, with a rest during the weekend. For most cancers, the curative treatment provides a fractional dose of 1.8–2.0 Gy, given once a day. The total dose is determined by the type and the size of the tumor and by the tolerance of critical structures encompassed in the target volume. Usually, the total dose is in the range of 70–80 Gy when the entire tumor mass is present and must be eradicated, and 50–65 Gy when the treatment is given to control the subclinical disease, after or

before surgery, or in the area at risk. Lower dose is prescribed in case of very sensitive tumors to radiation, such as seminoma, lymphomas, and other hematological malignancies.

There are many other different regimens, considered "altered fractionation," some of them based on empiric observations. In "hyperfractionation," the total dose is slightly increased, the size of the dose per fraction is significantly reduced, the number of fractions is increased, and the overall time is substantially unchanged, due to the possibility to give two fractions per day, with an interval between the two of at least 6 h. In "accelerated fractionaction," the overall time and number of fractions are reduced, and the dose per fraction increased, remaining the total dose either unchanged or somewhat reduced, depending on the extent of the overall time reduction. One of the most frequent applications of the concept of accelerated schedule is the use of the boost dose (and additional dose given to the tumor bed or to the mass) concomitantly to the normal schedule. Concomitant boost allows to reduce of 1 or 2 weeks the total time, increasing the dose per fraction on only a part of the treated volume. In "hypofractionation," the overall time and the number of fractions are strongly reduced, in some case at only one or few sessions. The higher dose per fraction can be a disadvantage for the increased risk in the severity of late response in normal tissue but also an advantage when this regimen is applied in palliative treatment or in highly precise techniques, such as stereotactic radiosurgery.

50.4 Clinical Radiation Biology

Radiation biology studies the sequence of events following the absorption of energy from ionizing radiation, the response of the normal and cancer cells and tissues to compensate, and the damage that may be produced [17]. When a radiation penetrates and releases its energy into a biologic tissue, a complex series of actions start. There are two possibilities of interaction, the direct or indirect ionization. The indirect mechanism is predominant with photons, as X-rays or gamma rays, that are considered sparsely ionizing radiations. Photons give up their energy in various interactions and then utilized to produce fast-moving electrons as secondary particles that interact with the most abundant cellular medium, water. The radiolysis (splitting) of the water involves a series of reactions that produces free radicals, causing, in their turn, reactions with normal component of the cells and target molecules, including DNA. The direct ionization is caused by charged particles (protons, ions, or electrons) as a result of the incident particle itself because of the relatively densely ionizing nature of most particulate radiations. When a particle causes ionization, it loses energy and may give off most of its energy just prior to stopping. This effect is referred as the Bragg peak.

The amount of energy deposited into the tissue is a function of distance along the track of the radiation. Considering this aspect, radiations are also divided according to different linear energy transfers (LET), and the amount of energy deposited in a unit of track, into high LET (densely ionizing, as particles) and low LET (sparsely ionizing, as photons). The value of LET is strongly correlated with the biologic effect of radiation (RBE—relative biological effectiveness). More energy is transferred to the tissue and higher is the entity of the damage. The RBE can vary slightly from tissue to tissue, and also when acute and delayed effects of radiations are compared, but in general, is assumed that RBE is equal to 1.0 for photons, 1.1 for protons, 3.0 for carbon ions, and up 5.0 for neutrons.

As previously described, exposure to ionizing radiations creates lesions within cellular DNA that cause a range of responses, including cell cycle arrest, apoptosis, reproductive death, and senescence. The consequences of these types of damage are quite different. Loss of a DNA base changes the sequence and causes alterations on protein synthesis, including mutations if the genetic material is involved. In case of single-strand break (SSB), and not repaired, a major damage can occur. In this plethora of lesions, there is evidence that the DNA DSB (double-strand break) is the most important in terms of tumor and normal tissue radiosensitivity. About 40 DSBs are induced in a cell for each Gy of absorbed dose, and these lesions are responsible for radiation-induced cell death, with a single unrepaired DSB sufficient to elicit this response. Several features of DSBs are more difficult to be repaired compared with single-strand breaks and other forms of genetic damage. The response to different types of DNA damage involves the recruitment of proteins needed for DNA repair with overlapping functions and other proteins with functions that are specific to a particular lesion or process. These proteins can also regulate, through either apoptosis or mitotic death, the subsequent fate of the cell or its progeny.

Abnormalities in the response have consequences for cellular radiation radiosensitivity as measured by clonal death and for spontaneous and radiation-induced genomic instability. This is the reason because cells and tissues can markedly vary in their expressed sensitivity. Generally, rapidly dividing cells that are poorly differentiated and with a long mitotic period are very sensitive, not dividing or slowly dividing cells are less radiosensitive or more radioresistant. Typical examples of very or radiosensitive cells are lymphocytes, spermatogonia, ovarian follicular cells, and cells of the intestinal epithelium, head and neck and gastric mucosa, and others. An intermediate grade of radiosensivity is manifested in fibroblasts and cells of the glandular epithelium of the breast and epithelium of other tissues, as pulmonary, renal, pancreatic, and thyroid. Radioresistant cells are mature hematopoietic, connective, bone and cartilage, and muscle and ganglion

cells. Because of the presence of a strong heterogeneity of cell lines, the radiosensivitity of a given organ can vary according to the mixture of various components.

The radiobiology of breast cancer is not easy to determine, because the main role of radiotherapy is the eradication of residual subclinical disease after mastectomy or breast conservation surgery, and tumor response cannot be directly observed. Also outside the patient, breast cancer has been difficult to study because of its resistance to growth in cell culture. Therefore, radiobiological data have been mostly derived from clinical studies. With respect to the dose–response relationship, the common standard is represented by 50 Gy in 25 fractions (conventional fractionation) to the whole breast/thoracic wall and, if indicated, to the regional lymph nodes. In case of breast-conserving surgery, or positive margins after mastectomy, an additional dose (boost) is often suggested, in the range of 10–16 Gy in 2 Gy fractions.

A remarkable set of data on the relationship between total dose, fraction size, and local control are available. The data were analyzed using the linear quadratic model, a nonconceptual model, but a robust empirical model of fractionation sensitivity. In this model, there are two assumed components of radiation damage characterized by the coefficients α and β. The α component results from a single ionizing event that simultaneously damages two individual targets. This damage cannot be repaired, and increases with dose, in linear pattern, and is influenced more by overall dose and not by fraction size. The β component is resulting from two ionizing events which separately damage two targets. These targets are sublethally damaged, and only the combination of them can form a lethal lesion. The β damage increases with the square of the instantaneous dose and is influenced by both overall dose and fraction size. The α/β ratio is a measure of how a tissue will respond to a change in total dose or fractionation (fraction sensivity). For early-reacting (days or weeks after radiation) normal tissues and tumors the α/β value is high, of 10 Gy or more. With late-responding (years after radiation) normal tissues, the α/β value is low, of 5 Gy or less. The value estimate for human breast cancer is in the range of 4–5 Gy. At this stage, it looks likely that breast cancer shares, on average, a similar sensitivity to fraction size as late-responding normal tissue.

On the basis of these data, to intercompare different regimens of radiation therapy, the biologically effective dose (BED) is a useful linear quadratic-based parameter. Equivalence in BED is the base to perform randomized clinical trial among different whole-breast radiation therapy dose schedules. Currently, a parallel standard of fractionation has been identified, in 40 Gy in 15 fractions or 42.5 Gy in 16 fractions, both over 3 weeks. Radiation therapy confined to the tumor bed (partial breast irradiation) in women with low-risk tumors treated by complete excision is an emerging strategy in several countries, but none of the current studies are designed specifically to test the importance of treatment time. In these schedules, the treatment times are highly compressed to one, with a dose of 20–21 Gy, to five fractions of 5.7–6.0 Gy each. There is a strong impact of the α/β value in the equivalence of BED. For example, assuming a value of 10 Gy, 21 Gy in single dose is equivalent to 56 Gy in conventional fractionation, but if we consider, as estimated breast α/β value, the value of 3.5–4 Gy, the BED increase up to more than 100 Gy. A comprehensive review of clinical tolerance and dose–effect correlations of the most commonly irradiated organs was organized in the Quantitative Analysis of Normal Tissue Effect in the Clinic (QUANTEC) project [18]. Models linking dose with toxicity and tumor control, based on radiobiological and mathematical principles, were used to predict the normal tissue complication probability (NTCP) and tumor control probability (TCP), enabling radiation oncologists to evaluate the potential treatment outcome [19].

50.5 Techniques for Radiation Therapy in the Breast

The efficacy of radiation therapy in increasing local and locoregional control and reducing breast cancer and overall mortalities is well established. From the point of view of radiation techniques, standard and new approaches were developed along the decades [20]. Today, modern techniques offer the ability to incorporate improved target imaging, accurate planning, and high-precision treatment delivery into the treatment design, also ensuring the possibility to use safely different schedules of fractionation [21].

In breast radiation therapy, the patients are traditionally placed in supine position, flat on the couch, or, more frequently, on an angled board with one or both arms stretched above the head. The advantage of the angled board is that the sternum can be brought horizontal, reducing angulation in the beam geometry. Other more sophisticated immobilization devices can be also used, to further reduce the setup uncertainties and limiting the intra-fractional motion. As example, patients can be positioned in a vacuum bag system, with their arms extended over their heads and holding a T-bar. The vacuum bag forms a template on which the patient can lie, with a high reproducibility of the position from treatment to treatment. Recently, prone positioning of patients was suggested for better sparing of normal organs, particularly in patients with large or pendulous breasts. Lung doses could significantly be reduced, whereas the sparing effect on the heart was less clear, because of anterior displacement of the heart in this position. Furthermore, the risk of acute skin reactions is reduced, because of the elimination of skin folds. The effect of this position on breathing motion is positive, with a smaller intra-fraction motion. On the other side,

patient setup variations can be wider, leading to an increased inter-fraction change. Dedicated breast boards were developed to establish a stable prone patient position with the breast hanging free from the thoracic wall, away from the target organs. Dose homogeneity can be improved by the prone technique, with some uncertainties at the medial and lateral borders of the breast, where the target coverage may be impaired, due to the limited accessibility for treatment fields in this position.

In the 2D technique, a standard field setup is used, with two opposed tangential fields at 180°, covering the breast, and field edges based on surface anatomy. To treat supraclavicular and axillary nodes, an anterior or anterior oblique field is used. The lower border of this field is matched to the upper border of the tangential beams. To treat mammary internal chain, a direct mixed photons and electron beams can be used or, as an alternative, modified wide tangent technique. For treatment planning, only a limited amount of contours of the patients' outline are available, with limited account for individual variations in patient anatomy. Today, 2D dose distribution with the standard technique is difficulty acceptable when the target volume becomes more complex and aberrations in dose homogeneity occur. Wedges are used for missing tissue compensation, but can only adjust for dose heterogeneity in a two dimensional plane, and optimal dosimetry is not achieved for a significant number of patients. Furthermore, the inclusion of the locoregional lymph nodes in the target volume makes treatment planning more difficult, due the high inhomogeneity of the dose distribution at the match lines of the different fields.

Currently, the challenge is to minimize normal tissue complications, improve cosmetic outcome, and reduce the overall treatment time without losing treatment efficacy. Technological advances allowed the development of new techniques that are able to improve the radiation dose distribution and dose delivery.

The definition of three-dimensional conformal radiation therapy (3D-CRT) concerns the geometric matching of the irradiated volume to the target to be treated. 3D-CRT allows the integration of CT scan information in the planning system, enabling the design of radiation fields that are based on patient-specific 3D anatomy. Special devices, such as multileaf collimators implemented in linear accelerators, can deliver these conformal beams to the patient. Individualization of treatment results in a more optimal dose distribution reducing inhomogeneity due to individual variability in the curvature of the chest wall, separation of the heart from the breast target, and size and shape of the remained breast tissue. The achievement of these goals can be assessed by inspection of the 3D dose distribution, by the interpretation of dose–volume histograms for the outlined structures, and by the calculation of the conformity index that exactly describes the fraction of the planned target volume covered by the treated volume. Using these tools, the amount of data to be evaluated when judging the adequacy of a treatment plan can be significantly reduced. In breast-only irradiation, the 3D alignment of the tangential beams allows improved shaping and coverage of the breast tissue and reduction of the volume of the irradiated heart and lung tissue. In locoregional breast irradiation, the problems of inhomogeneous dose distribution that can frequently occur at the match lines between the breast and lymph node fields can be solved with 3D techniques, by the use of asymmetric collimation or, using full CT scan data, the customization on the patients' anatomy. Comparisons between different locoregional 3D techniques show that every technique has advantages and disadvantages, and the decision which technique to use should be patient-specific, considering tumor-, patient-, and treatment-related characteristics, taking into account the quality and the attitude of the radiation therapy tools and team. For some patients in which the summation of the dose from the uniform selected beams is not acceptable, more advanced techniques such as intensity-modulated radiation therapy may be beneficial.

Intensity-modulated RT (IMRT) is a treatment technique that allows an optimal modulation of the intensity of the beams, ideally divided into the individual rays within each beam ("beamlets"). The control of the fluence of each beam improves dose distribution, enabling a real customized design of the target volumes. IMRT plan requires special calculation algorithms able to guarantee computer-aided optimization methods. The current standard for radiation treatment planning uses some form of the convolution algorithm to calculate photon beam dose. Still more accurate dose calculations can be achieved by using Monte Carlo models, which used more in research that in clinics because of the need for more computational power with this system. To compute and optimize the IMRT dose distribution, a process of inverse planning is required. In the conventional treatment plan, radiation is given with spatially multiple uniform fields, with an ultimate goal to give a uniform and conformal dose at a specified predefined target. In the inverse planning process, the beam intensities needed to deliver the dose distribution that would achieve the desired clinical objectives are first determined. In practice, the planner specifies the dose distribution within the patients, and an inverse planning algorithm computes the optimum beam modulation to produce that distribution. For example, the dose to organ at risk can be defined as less than some maximum allowable dose, incorporating these dose–volume constraints in the optimization scheme ("no more than 20% of the total lung volume may receive more than 20 Gy). IMRT is based on different types of delivery (step and shoot, sliding windows, volumetric arc therapy, and Tomotherapy®). The dose distribution can be painted around the target volume with a steep dose gradient. For IMRT, the dose distribution is characterized by a concavity at the edge of the higher doses that fits well with breast conformation and spares OARs. Several techniques for

IMRT in breast cancer have been developed, varying from fairly simple conventional tangents to complex setups with multiple fields. For the irradiation of the breast alone, all these techniques improved dose uniformity and reduced doses to the heart and lung. Since the multi-field solutions often suffer from increased low doses to the surrounding normal tissues, most investigators propose a technique using two conventional tangential fields. A large amount of the dose is given by parallel-opposed open beams; a part of the dose is given by several MLC-shaped segments, each delivering a small amount of monitor units ([10]). These segments are generated to compensate for missing tissue and block organs at risk. The IMRT technique allows the simultaneous delivery of different dose levels to different target volumes within a single treatment fraction: this approach is defined as the "simultaneous integrated boost technique" (SIB). The SIB technique is of particular interest because it can be used to yield higher doses to the critical area (boost volume) without increasing the overall treatment time after breast-conserving surgery. The application of IMRT in the treatment of locoregional BC is more challenging. Due to the complex target volume, more advanced IMRT techniques are proposed, using multiple beams and inverse planning. There is no agreement in the orientation and amount of beams among the different planning studies. Up to 11 beams, covering an arc of 180–360°, are advocated. In general, all techniques were able to improve the dose distributions, compared to non-intensity-modulated 3D-CRT plans. Some IMRT techniques are good at sparing one structure, whereas others are better at sparing other structures. Depending on the technique used, increased doses to the contralateral breast, contralateral lung, esophagus, thyroid, and humeral head are reported. The optimal geometric beam arrangement is determined by the anatomy of the patient, the location of the target structures, and the desire to minimize radiation dose to healthy tissues. Therefore, the choice of the best technique must be patient-specific. Due to the use of sharp dose gradients in IMRT, the effects of patient setup errors and breathing motion on the dose distributions are more important and must be taken into account, when evaluating the potential gains of IMRT over 3D-CRT. Furthermore, the benefits of IMRT must be weighed against the increase in overall low radiation dose. In multiple beam IMRT, more monitor units are needed to deliver the desired dose. This results in more leakage radiation and a higher total-body dose. IMRT is often associated with image guidance (IGRT) to measure and correct positional errors of radiation fields immediately prior and during treatment delivery.

In order to reduce the breathing motion, a respiratory gating technique can be associated with IMRT. In this technique, the radiation treatment is synchronized with the patients' individual breathing pattern. The radiation beam is turned on only during a prespecified phase of the respiratory cycle, thereby modifying the relative position of the target structures and normal organs in the radiation field. Gating for breast irradiation seems to be most favorably done in the inspiration phase. During the inspiration, the distance between the breast and the heart is enlarged and the lung density is reduced. To perform a gated treatment, dedicated devices are available that can record the patients' breathing pattern, allow for coaching of the patients to achieve the desired breathing pattern (deep inspiration breath hold or deeply free breathing), and gate the CT scan and treatment machine in the desired phase of the respiratory cycle. In breast locoregional treatment with wide tangential fields and IMRT compensation, the use of a moderate deep inspiration breath hold (mDIBH) technique can result in large benefit in reducing the dose at the heart.

Accelerated partial breast irradiation (APBI) is a technique designed to treat only the tissue surrounding the cavity after lumpectomy. A reduction in treatment volume allows for the delivery of larger treatment fractions in a shorter time period, usually from 1 to 10 days. A variety of treatment techniques are developed to deliver APBI. Interstitial multicatheter brachytherapy requires the highest level of skill but also offers the most flexible and adaptable approach. Multiple catheters are placed in the breast tissue surrounding the surgical cavity at 1–2 cm intervals. Interstitial brachytherapy can be administered with either a low-dose rate (LDR), a pulsed dose rate (PDR), or a high-dose rate (HDR) technique. Common dose delivery regimens for LDR and PDR are 45–50 Gy in 3–6 days and for HDR 32–34 Gy in 8–10 twice-daily fractions. Intracavitary balloon brachytherapy represents a simplification of multicatheter techniques. It relies on the placement of a radioactive source within a special balloon catheter device (Mammosite®) that fits inside the surgical cavity and treats 1 cm of tissue surrounding the cavity. MammoSite® employs only HDR regimens, with a typical fractionation of 34 Gy in ten fractions, twice daily. The major drawback to the use this technique is standard spherical dose distribution that can result in an overdosage to the skin. Therefore, it is mandatory to have a skin source distance of at least 10–15 mm. This limits the indication to deep-seated central surgical cavities in large breasts. More recently, other types of balloons were introduced, with multiple or stepping sources. They allow more flexibility in adapting the dose distribution to the shape of the cavity. In intraoperative radiation therapy (IORT), a single fractional dose (±20 Gy), targeted at the tumor bed, is delivered during surgery, using electrons in the energy range of 6–12 MeV or low energetic X-rays (50 kV). A major advantage of this approach is the complete skin sparing and the possibility to avoid the exposure of the underlying lungs and heart by shielding the thoracic wall with a lead/aluminum plate. A disadvantage is that radiation is completed before the final pathology report is known and that this information cannot be incorporated in the patient selection criteria. 3D-CRT

with and without intensity modulation is also used to perform APBI. Multiple beams are used to deliver 34–38 Gy in ten twice-daily fractions. Advantages of 3D-CRT/IMRT over the other APBI approaches include the non-invasiveness and the improved dose homogeneity with potential reduction in normal breast tissue toxicity. On the other hand, target volume definition and localization can be more difficult. Stereotactic radiation therapy (SRT) in breast cancer provides excellent results mainly in the treatment of metastases; it delivers a high dose/fraction for good local control, it exploits the steep dose gradient to improve tolerance, and it delivers the treatment in few fractions for an optimal quality of life. This technique can be also used in the treatment of primary tumor. The minimal treatment volumes and high-dose conformity are reminiscent of high-dose-rate interstitial brachytherapy without its known technical challenges and invasive requirements making CK-SAPBI quite appealing. Stereotactic APBI offers additional advantages of fewer treatments delivered and increased patient comfort due to lack of a second surgical procedure to place the brachytherapy applicator. Potential disadvantages are the fiducials required to track target motion. Fiducial migration can occur after placement, or fiducial tracking can be suboptimal in patients with poor breast integrity and large postoperative seromas. Some bioabsorbable tissue markers are now available in the attempt to overcome these limitations. Within the radiation landscape, proton therapy for APBI is still in its infancy, but the dose deposition characteristics of these particles make them very well suited for highly conformal treatments, with the potential for far less integral dose to the patient and greater avoidance of normal structures (heart, lung, and contralateral breast). Some preliminary reports seem promising, also in the case of extensive radiation fields.

50.6 Future Perspectives

In the radiotherapy setting, technological innovation has led to remarkable improvements in every phase related to treatment, from simulation to planning to delivery, with the aim of minimizing normal organ toxicity and improving local control [22]. The optimization of dose distribution limits the hot spots, areas receiving a higher dose than that prescribed, which could give rise to severe late effects. This phenomenon known as “double trouble” in conventional fractionation turns into “triple trouble” in the case of hypofractionation, where dose/fraction size is increased. Reducing exposure to the organs at risk (OARs) by means of precise 3D reconstruction decreases toxicity and paves the way to safe dose escalation. The combination of dosimetric data and data regarding clinical toxicity makes it possible to chart complex dose–response relationships and to define specific tolerance doses for OARs. Positive findings that reflect how technological advances translate into medical benefit are represented by the rise in local control, with its effect on survival, and by the ever lower cardiac toxicity. An essential aspect of the advances in physics and technology is expressed in the quality of treatment execution. High conformability means high sensitivity to any changes occurring in the patient during the course of radiotherapy. Displacement of the target due to organ motion, anatomical changes in the patient’s body, or inaccurate setup affects dose distribution, leading to inadequate target coverage or excessive irradiation of the OARs. This is of particular concern when dose escalation or hypofractionation is used. Moreover, innovative therapies, such as alternative radiation schedules or target agents, pose new challenges and increase the complexity. Biologic and molecular studies need for a better understanding of the phenomena related to tumor control and side effects.

Whole-Breast Irradiation Following Breast-Conserving Surgery for Invasive Breast Cancer

51

Anna Kirby

51.1 The Rationale for Whole-Breast Irradiation

Irradiation of the whole breast in women who have undergone breast-conserving surgery (BCS) has long been a standard of care in the treatment of early breast cancer. This practice is predominantly based on the local control and survival gains demonstrated by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analyses [1, 2]. These are based on data from 10,801 women treated in 17 randomised trials of BCS plus or minus whole-breast irradiation (WBI) and demonstrate that the addition of WBI to BCS approximately halves the risk of local recurrence at 10 years (from 35% to 19%) and reduces the risk of breast cancer death at 15 years by around one sixth (from 25% to 21%). In women with pathologically node-negative disease (n = 7287), the risk of local recurrence was reduced from 31% to 16% at 10 years and the risk of breast cancer death from 21% to 17% at 15 years. In women with node-positive breast cancer (n = 1050), radiotherapy reduced the 10-year risk of local recurrence from 64% to 43% and the 15-year risk of breast cancer death from 51% to 43%. Consistent with previous meta-analyses, the prevention of four local recurrences at 10 years prevented one breast cancer death at 15 years.

In terms of risk factors for local relapse, on univariate analysis, the EBCTCG meta-analysis reports an association between the risk of local recurrence and young age, tumour size, grade and lymph node status [1]. Multivariate analysis of outcomes in a combined analysis of the EORTC 10801 and DBCG-82TM studies (both of which tested breast conservation surgery and whole-breast irradiation against radical mastectomy) also found an association between the risk of local relapse and young age and grade but not tumour size or lymph node status [3]. An additional association was found with the presence of lymphovascular invasion.

The EORTC boost trial demonstrated that addition of a boost dose to the tumour bed improved local control rates even further [4, 5]. Five thousand three hundred eighteen women were randomised to standard WBI to a dose of 50 Gy in 25 fractions plus or minus a boost to the tumour bed of 16 Gy in 8 fractions. Outcomes have now been reported at median follow-up of 17 years [5]. The addition of the boost dose reduced the 20-year risk of ipsilateral breast recurrence from 16% to 12% ($p < 0.0001$). The greatest absolute risk reduction was in women of 40 years or under whose risk of local recurrence at 20 years was reduced from 36% to 24% (p = 0.003) and in whom the likelihood of requiring salvage mastectomy was reduced by 41% at 10 years [4]. For patients with grade 3 disease, the addition of the boost dose reduced the risk of local relapse from 18.9% to 8.6% at 10 years ($p = 0.01$) [6]. For the study population as a whole, there was no significant difference in overall survival at 20 years (59.7% in the boost group versus 61.1% in the no boost group ($p = 0.323$)) [5]. The risk of severe fibrosis however was increased in the boost group (5.2% versus 1.8% at 20 years ($p < 0.0001$)) [5].

With regard to other indications for a tumour bed boost, recently published consensus guidelines conclude that there is no clear evidence that escalating the dose to the tumour bed reduces the risk of ipsilateral breast tumour recurrence in women whose excision margins are close but clear of ink [7]. For women with focally positive margins however, a recent analysis of outcomes in 8485 women treated with breast conservation surgery and whole-breast irradiation at the Netherlands Cancer Institute, where focal margin positivity is not an indication for re-excision and where 79% of patients receive a tumour bed boost, no increased risk of local recurrence has been found at a median follow-up of 9 years suggesting that a tumour bed boost may safely replace re-excision in this scenario [8].

51.2 The Risks of Whole-Breast Irradiation

Alongside the local control and survival benefits of whole-breast irradiation, the EBCTCG meta-analyses have also demonstrated a small but significant increase in the risk of non-breast cancer-related mortality. The 2005 EBCTCG update demonstrated an absolute increase in non-breast cancer-related mortality of 1% at 15 years post-radiotherapy [1], the majority of which is attributable to cardiac disease [1, 9]. A recent case-control study in women treated with radiotherapy for breast cancer has demonstrated a linear relationship between the mean radiation dose to the heart and the risk of major coronary events (MCEs) (including ischaemic heart disease death, myocardial infarction and coronary revascularisation procedures) [10]. The risk of MCEs was reported to increase by 7.4% per Gray (Gy) mean heart dose with no apparent threshold below which a woman is at no risk of radiation-induced heart disease. The proportional increase in risk was similar in women with and without cardiac risk factors, and the increased risk began within the first 5 years after administration of radiotherapy. It is not yet clear which cardiac substructures, when irradiated, contribute the most to the risk of cardiovascular disease, but evidence from myocardial perfusion [11] and coronary angiography studies [12, 13] suggests that the left anterior descending coronary artery is a key structure in the pathogenesis of radiation-induced heart disease.

Death from second malignancy in the lung accounts for <10% of non-breast cancer-related deaths [1]. The relative risk of death from a second malignancy in the lung ranges from 1.5 to 2.8 at 15 years [14, 15], with odds ratios of up to 37.6 in smokers [16]. Data on secondary lung malignancy deaths in 9000 women irradiated between 1935 and 1971 [14] suggest a dose-response relationship with an incremental relative risk of 0.2 per Gy to the ipsilateral lung (equating to nine cases of second lung malignancy/year/10,000 women receiving 10 Gy to the lung and living to 10 years). The SEER registry cohort demonstrates a similar relationship between mean lung dose and risk of second lung malignancy in women irradiated between 1973 and 2001 [9].

The EBCTCG meta-analysis also demonstrated a significantly increased incidence of contralateral breast cancer in irradiated women (9.3% versus 7.5% at 15 years, $p = 0.02$) [1], with the main excess risk appearing at years 5–14 following radiotherapy. A study of 708 cases (women with asynchronous bilateral breast cancer) and 1399 controls (women with unilateral breast cancer) from the US Women's Environment, Cancer, and Radiation Epidemiology Study found that radiotherapy increased the risk of second primary contralateral breast cancer only in those irradiated under 45 years of age [17]. Although the majority of contralateral breast cancers arise in the upper outer quadrant [18], a higher proportion was found in the inner quadrants in previously irradiated women. In women aged <40 years, those who received >1 Gy of radiation to the index quadrant had a 2.5-fold greater risk of contralateral breast cancer than unexposed women (95% CI 1.4–4.5) [17]. The dose-response relationship was also significant (excess relative risk per Gy of 1.0, 95% CI 0.1–3.0). The results suggest that attempts should be made to limit the mean contralateral breast dose to <1.0 Gy in young women undergoing radiotherapy for breast cancer.

With regard to other tissues, the EBCTCG study [1] reported a 20% increase in incidence of second primary malignancies (SPM) in irradiated women compared to unirradiated women (standardised incidence ratio (SIR) = 1.20). This equates to approximately 35 second malignancies per 10,000 women at 10 years (not including lung cancers) and around 60 second malignancies including lung cancers. Significant excess risks were found for the oesophagus (SIR = 2.06), soft tissue sarcoma (SIR = 2.34) and leukaemia (SIR = 1.71), but not for melanoma, bone sarcoma, colorectal, stomach, kidney, uterus and thyroid cancers. Roychoudhuri [15] also found excess risks of myeloid leukaemia (RR = 2.0) and oesophageal cancer (RR = 2.2) in women following whole-breast radiotherapy. Two small studies have estimated sarcoma incidence following breast radiotherapy to be 0.2% at 10 years [19, 20], the majority arising in the breast and chest wall. The incidence of SPM is markedly increased in women irradiated under 40 years of age [21, 22]. With increasing use of systemic therapy in recent years, the incidence of second malignancy may increase further, with one study reporting a 4% incidence of second malignancy at 10 years following treatment with chemo- and radiotherapy [23].

Otherwise, direct irradiation of breast tissue, ribcage and muscle has been shown to increase long-term morbidity and reduce quality of life [24]. Results from the UK START trial suggest that 20% of patients experience some breast shrinkage, 40% breast hardness, 40% a moderate or marked change in breast appearance following radiotherapy and 40% some degree of chest wall discomfort [24, 25], all of which have the potential to increase long-term physical and psychological morbidity.

Given the increasing number of long-term breast cancer survivors [26], radiation-induced mortality and morbidity could impact upon millions of women worldwide. A current priority in breast radiotherapy then is to reduce long-term morbidity and mortality without compromising local control, and optimal technical approaches for doing so are discussed further below (see section 51.5.4).

51.3 Are There Groups of Women in Whom the Risks of Whole-Breast Irradiation Outweigh the Benefits?

Local recurrence rates have fallen considerably since the women in the EBCTCG meta-analysis studies were treated [27] such that the absolute gains of whole-breast irradiation are likely to be considerably lower than reported previously. The reduction in relapse risk with era of treatment is illustrated in Fig. 51.1 and is likely to reflect improvements in early diagnosis, systemic therapies and surgical and radiotherapeutic techniques [28].

To date however, it has not been possible to identify a group of women in whom the risk of local recurrence is so low as to be able to routinely omit whole-breast radiotherapy. The PRIME II study [29] randomised 1326 women of 65 years and older with ER-positive tumours <3 cm, clear margins and negative nodes treated with breast conservation surgery and endocrine therapy to whole-breast irradiation (40–50 Gy in 15–25 fractions) versus no radiotherapy. At a median follow-up of 5 years, local relapse rates were 1.3% (95% CI 0.2–2.3) in the whole-breast radiotherapy arm and 4.4% (2.4–5.7) in the no radiotherapy arm. Five-year overall survival was 93.9% (CI 91.8–96.0) which was the same in both groups. Whilst these data are encouraging that there might be a group of women in whom the local control benefits are small enough to consider omitting radiotherapy, it should be borne in mind that the life expectancy of an otherwise fit and healthy 65-year-old woman living in the UK is 16–20 years [30] such that the longer-term local control and survival benefits of breast radiotherapy remain of interest.

Other work has used molecular and/or genetic profiling to help identify women at the very lowest risk of relapse. For example, luminal A and B molecular subtypes have been shown to be associated with a lower risk of local relapse than triple-negative and Her-2-enriched molecular subtypes [31], whilst the Oncotype DX recurrence score has also been shown to be able to identify a group of women with a 10-year risk of local relapse below 5% [32]. Forthcoming research (the UK PRIMETIME study) will omit radiotherapy in women considered to be at lowest risk of relapse based on a combination of clinical features and IHC4 testing with the aim of confirming the group of women in whom radiotherapy might be safely avoided.

51.4 Dose and Fractionation

The radiation dose and fractionation used in many of the early surgery versus surgery plus radiotherapy trials for breast cancer was 50 Gy in 25 fractions [33] such that this became the standard of care for many years. More recently however, the START trials [34] and a Canadian study of hypofractionation [35] have changed the standard of care in many countries.

Four thousand four hundred fifty-one women were treated within the START trials between 1999 and 2002. All women had undergone complete surgical excision of breast cancer and were otherwise treated with chemotherapy and/or endocrine therapy according to standard protocols. Women in the START-A trial were then randomised to 50 Gy in 25 fractions over 5 weeks versus 41.6 Gy or 39 Gy given in 13 fractions over 5 weeks. Women in the START-B trial were randomised between 50 Gy in 25 fractions over 5 weeks

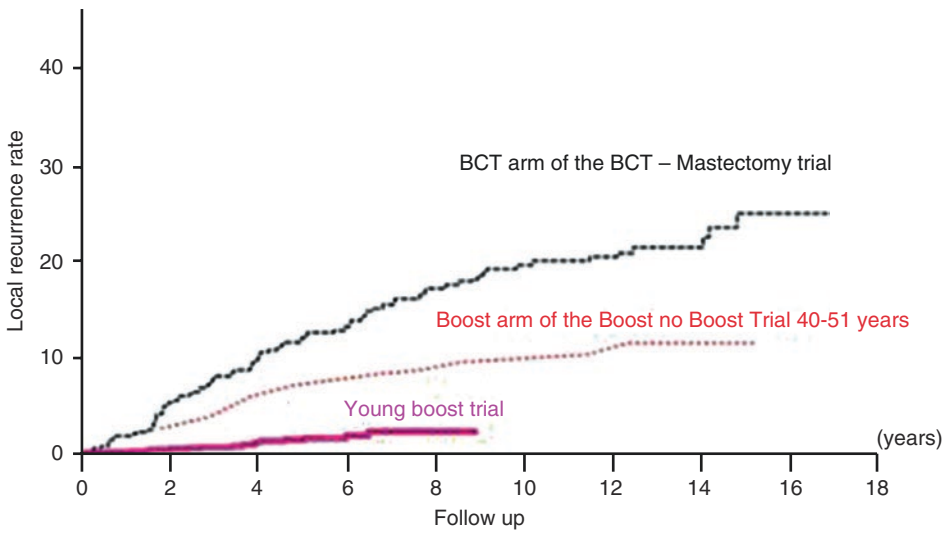

Fig. 51.1 Locoregional recurrence rates in the consecutive EORTC 10801, EORTC 22881-10882 and Young Boost Trials. Reproduced with permission (from Poortmans, The Breast, 2017, 295–307)

versus 40 Gy in 15 fractions over 3 weeks. At a median follow-up of almost 10 years, loco-regional relapse rates did not differ significantly between the groups [34]. However, breast firmness, skin changes and breast oedema (or swelling) were significantly less common in the 39 Gy group of START-A and 40 Gy group of START-B as compared to the 50 Gy group in each study.

Meanwhile, the Canadian study randomised women undergoing whole-breast irradiation to 50 Gy in 25 fractions over 5 weeks versus 42.5 Gy in 16 fractions over 3 weeks [35]. The 10-year risk of local recurrence was 6.7% in the 50 Gy in 25 fraction arm and 6.2% in the 42.5 Gy in 16 fraction arm (absolute difference 0.5%, 95% confidence interval −2.5 to 3.5). 71% of the standard fractionation patients were reported to have a good or excellent cosmetic outcome at 10 years as compared to 70% in the control group (absolute difference 1.5%, 95% confidence interval −6.9 to 9.8).

In the light of these three studies, the standard fractionation for whole-breast irradiation has in many countries become 40 Gy in 15 fractions. It is unlikely though that the limits of hypofractionation have been reached. The UK FAST study randomised 915 women with node-negative early breast cancer to 50 Gy in 25 fractions versus 28.5 Gy and 30 Gy delivered in five weekly fractions of 5.7 Gy and 6.0 Gy, respectively. At a median follow-up of 3 years, changes in photographic breast appearance were comparable between the 50 Gy in 25-fraction and 28.5 Gy in 5-fraction regimens and significantly milder than the 30 Gy in 5-fraction regimens [36]. There were only two local recurrences at 3 years, both of which were in the 50 Gy in 25-fraction arm of the study, but mature late effect and local control data are awaited.

The UK FAST-Forward study has gone on to randomise women between 40 Gy in 15 fractions and 26 or 27 Gy in 5 fractions over 1 week. This trial closed to recruitment in 2014 such that 5-year local control data will not be reported before 2019. In the meantime however, acute toxicity has been reported to be comparable between the three fractionations [37].

51.5 Technical Approaches to Whole-Breast Irradiation

51.5.1 Target Volume Definition

Most whole-breast irradiation continues to be delivered adjuvantly such that the gross tumour volume (GTV) has been excised leaving the tumour bed as a surrogate for the GTV. Studies testing the accuracy of clinical methods against orthogonal X-ray imaging localisation of clips for defining the tumour bed itself show that clinical methods result in a geographical miss and/or unnecessary normal tissue irradiation in up to 50% of patients [38–41]. To overcome the inaccuracies of clinical methods, several imaging modalities have been tested, most of which rely on the identification of seroma which may either be variable in volume [42] or, in patients who have undergone oncoplastic surgery [43], misrepresent the true tumour bed. Insertion of radio-opaque markers into the excision cavity walls overcomes some of the limitations described above. Tumour bed clips inserted according to protocol in pairs at the four radial, superficial and deep cavity margins according to a defined protocol [44] provide additional localisation information compared to kV-CT imaging alone, leading to modification of whole-breast tangential field borders in 43% of patients [45]. Clips inserted under direct vision do not migrate [45], and serial CT imaging also suggests that clips serve as stable surrogates for the TB over time [46].

The clinical target volume (CTV) for whole-breast irradiation should include the whole of the glandular and subcutaneous breast tissue although results of partial breast irradiation studies (discussed in chapter 55) suggest that, for lower-risk breast cancer, it may no longer be necessary to include the entirety of the ipsilateral breast tissue in the CTV. In any event, most protocols exclude the skin and scar from the CTV by limiting the CTV to within 5 mm of the skin surface [47].

The CTV to planning target volume (PTV) margin will depend mainly on set-up errors and respiratory motion. In the context of supine whole-breast irradiation, a number of studies [48–55] have used electronic portal imaging to quantify the extent of positional errors and patient movement. Systematic errors range from 1.0 to 14.4 mm (the worst figures being associated with a lack of arm immobilisation) and random errors from 1.7 to 5.8 mm. Intra-fraction errors range from 0.8 to 3.2 mm [48, 49, 51]. Errors vary between departments, partly due to different immobilisation devices, such that institutions are recommended to use their own set-up data if possible [56]. Data from the Royal Marsden show that changes in breast volume (peaking early in the treatment course at ~105% of the initial whole-breast volume) and set-up errors are adequately encompassed by a 5 mm margin [57, 58] (mean set-up error = 1.2 mm, standard deviation = 2.5 mm, generating a CTV to PTV margin = (2.5 × 1.2) + (0.7 × 2.5) = 4.75 mm based on the van Herk formula [59]). A further margin of 5 mm to allow for the effects of respiratory motion has been deemed adequate in the majority of patients [58] generating a total CTV to PTV margin of 10 mm.

51.5.2 Position and Immobilisation

Patient positioning and immobilisation are crucial to minimising set-up errors. A supine position on an angled board with adjustable arm supports is standard in many centres.

This set-up technique is compatible with most modern CT scanners and is associated with satisfactory set-up errors [57, 58]. The use of arm supports has been shown to be superior to using an angled board alone [54]. Coverage of lymph node regions has been shown to be more homogeneous when both arms are raised above the head as compared to a single arm being raised [60].

Patients with large pendulous breasts or large breast separations can be poor candidates for the standard supine treatment position [61] because dose distributions across the treatment volume are inhomogeneous [62] resulting in fibrosis [63] and poor cosmesis [64] and because gravity tends to pull breast tissue laterally, such that large volumes of nontarget tissue must be irradiated in order to adequately encompass target tissue [65]. Treatment of larger-breasted women in a bra has been shown to significantly reduce radiation doses to heart and ipsilateral lung albeit at the expense of increased grade 2 acute skin toxicity [66]. The reproducibility of bra-based techniques however is yet to be established.

Use of a prone treatment position in WBI can improve dose homogeneity within breast tissue [67, 68], reduce wedge requirements with consequent reduction of scattered dose and reduce dose to the lung [69–72], particularly in women with larger breast cup sizes (≥D) [70], but also in women of average breast cup size (median C) [71, 73]. However, data regarding the effects of prone positioning on cardiac doses are conflicting. Buijsen et al. demonstrated a reduction in heart V_{30Gy} from 7.3% (supine) to 2.4% (prone) in women of D cup and above [70]. However, other studies have failed to demonstrate a statistically significant reduction in mean heart dose between supine and prone free-breathing techniques with Varga et al. [74] reporting mean heart doses of 2.9 Gy for supine 3D-conformal RT and 2.2 Gy for prone treatment ($n = 83$, no significant difference) and Mulliez et al. [75] reporting mean heart doses of 2.0 Gy for supine inverse-planned multi-field IMRT and 1.5 Gy for prone tangential field treatment ($n = 60$, no significant difference). Other authors advise caution in using the prone position based on the fact that the heart falls forward in the prone position [76] such that, in smaller-breasted women (C cup and below), the prone position may even increase the heart dose as compared to supine free-breathing [77]. It should also be borne in mind that coverage of level I and II axillary lymph nodes by tangential fields is reduced in the prone position [78].

In terms of reproducibility, some centres use prone radiotherapy in routine practice and have achieved excellent reproducibility albeit using more complex verification protocols than standard electronic portal imaging [79–81] such as daily cone-beam CT [79] or imaging of breast tissue markers [80]. Other groups have reported reduced deliverability and reproducibility of prone compared to supine treatment [82–84]. In one of these studies [83], prone positioning was compared to supine voluntary breath-hold in larger-breasted women (D cup and above). The study was stopped early due to the dosimetric superiority of supine breath-hold and the poor reproducibility of prone positioning although, for most patients, the mean heart dose was below 1 Gy regardless of technique suggesting that prone treatment is a safe approach in the hands of those who can reproduce the position reliably. Insertion of radio-opaque markers into the excision cavity walls overcomes some of the limitations described above. Tumour bed clips inserted according to protocol in pairs at the four radial, superficial and deep cavity margins according to a defined protocol [44] provide additional localisation information compared to kV-CT imaging alone, leading to modification of field borders in 43% of patients [45]. Clips inserted under direct vision do not migrate [45] and serial CT imaging also suggests that clips serve as stable surrogates for the tumour bed over time [46].

51.5.3 2D vs. 3D Planning

Whole-breast radiotherapy planning techniques have improved considerably since the women included in the EBCTCG meta-analysis were treated, precipitated by demonstration of the clinical benefits of radiotherapy technological advances [85, 86] and also through implementation of technological advances into routine practice through departmental participation in clinical trials [87]. The Royal Marsden Breast dosimetry study randomised 306 women to whole-breast irradiation planned using three-dimensional intensity-modulated radiotherapy (3D IMRT) or two-dimensional radiotherapy (2D RT) using standard wedge compensators [85]. Women were treated to 50 Gy in 25 fractions with a boost to the tumour bed of 11.1 Gy in 5 fractions. At a median follow-up of 5 years, a change in photographic breast appearance was seen in 58% of the 2D RT patients compared to only 40% of the women allocated 3D IMRT, and significantly fewer patients in the 3D IMRT group developed clinically palpable induration. No significant differences were found however in patient-reported breast pain or quality of life. More recently, the Cambridge intensity-modulated radiotherapy (IMRT) study treated 1145 women between 2003 and 2007, randomising 815 women with inhomogeneous dose on standard wedged tangents to standard radiotherapy versus simple IMRT [86]. Fewer patients in the simple IMRT group (57%) developed suboptimal overall cosmesis compared to those treated with standard RT (63%), but there were no differences in breast shrinkage, firmness or swelling between the groups. Once again, patient-reported outcome measures (PROMs) (assessed using global health and breast symptom-specific questionnaires) showed no benefit of simple IMRT over standard radiotherapy [88]. Across the whole study population, the overall rate of adverse

outcomes reported using PROMs was low at 5 years (6% reported breast pain, 4% skin problems, <0.5% breast swelling, 15% change in breast appearance, 13% breast shrinkage and 8% breast firmness).

51.5.4 Heart-Sparing Whole-Breast Radiotherapy Techniques

As discussed in Sect. 51.2, the main mortality risk from whole-breast irradiation is radiation-induced heart disease. Although, in the majority of women, the benefits of whole-breast irradiation will outweigh the risks [89], data relating the likelihood of major coronary events to mean heart dose [10] suggests that we should maintain heart doses as low as reasonably achievable. Simple heart-sparing approaches include optimising beam angles and/or using multileaf collimation shielding to reduce the volume of heart tissue included in tangential fields. Where such approaches are used, it is recommended that target volumes be formally delineated to ensure that the tumour bed and surrounding tissues receive an adequate radiation dose [90].

IMRT and arc therapy approaches can be used to conform high-dose regions more closely to the breast CTV so as to reduce the volume of heart tissue treated to higher doses. Jin et al. [91] reported values for the volume of heart receiving 20 Gy or more (V_{20Gy}) of 5.6% for standard tangential wedged fields, 4.3% for forward-planned IMRT (F-IMRT), 2.1% for seven-field IMRT (7-IMRT) and 2.0% for tangential inverse-planned IMRT (T-IMRT) suggesting a benefit from the inverse-planned approaches. However, the more complex the field arrangement, the larger the low-dose bath of radiation such that the mean heart dose may conversely be increased by multi-field IMRT approaches. Predominantly tangential approaches may be more successful in reducing mean heart dose with the same authors reporting mean heart doses of 3.7 Gy for tangential fields, 3.2 Gy for F-IMRT and 4.4 Gy for seven-field IMRT, whilst T-IMRT reduced mean heart dose to 2.2 Gy.

The advantages and disadvantages of prone positioning on heart doses have been discussed in Sect. 51.5.2. A simpler and perhaps more widely implementable approach is to treat patients in deep-inspiratory breath-hold (DIBH) whereby the diaphragm pulls heart tissue inferiorly, posteriorly and medially away from the whole-breast radiotherapy fields. DIBH techniques reduce mean heart dose by around 50% [92–95]. For example, Wang et al. [94] reported a reduction in mean heart dose from 3.2 Gy using forward-planned IMRT in free-breathing to 1.3 Gy for forward-planned IMRT in breath-hold.

There are several available technical approaches to delivering radiotherapy in breath-hold ranging from maintaining the patient in breath-hold externally (e.g. using the Active Breathing Coordinator™ (ABC) device (Elekta, Crawley, UK)) to delivering radiotherapy only when the patient is in the inspiratory phase of their breathing cycle (e.g. the Varian Real-Time Position Monitoring gating solution (Varian Medical Systems, Palo Alto, USA)). Gating solutions can be delivered with or without the use of goggles providing visual feedback to the patient on where they are in their breathing cycle. Alternative technologies include AlignRT® (Vision RT Ltd., London, UK) which uses 3D optical surface imaging to verify that the patient's breath-hold is consistent. There are capital and resource costs associated with each of these techniques however such that, in some health economies, the implementation of breath-hold techniques has been slow (Royal College of Radiologists' Breast Radiotherapy Audit, UK, 2012, Imogen Locke, personal communication). In the light of this, a simple voluntary breath-hold technique has been developed which requires little more than a standard linear accelerator and a felt-tip pen [96]. This voluntary breath-hold technique has been shown to be as heart-sparing and reproducible as an ABC-based technique, as well as being faster to deliver and more acceptable to patients and radiographers [97].

Proton beam therapy (PBT) is not yet widely available for the treatment of breast cancer outside Northern America. Planning studies have shown that PBT can reduce mean heart doses in women undergoing radiotherapy to the whole breast (mean heart dose 12 Gy for 3D-conformal RT versus 1 Gy for PBT) [98]. With regard to other toxicities, the only phase I randomised comparison of PBT versus photon treatment is in women undergoing accelerated partial breast irradiation to 32 Gray in eight fractions delivered twice daily). This reports, at a median follow-up of 7 years, increased skin telangiectasia (69% versus 16%, $p = 0.0013$) and pigmentation changes (54% versus 22%) for PBT versus photon therapy [99]. As yet there is no equivalent dataset for women undergoing standardly fractionated whole-breast irradiation, but current trials are ongoing. In terms of cost-effectiveness, the earliest report comparing PBT and conventional whole-breast irradiation suggested that PBT may be cost-effective in women at highest risk of cardiac toxicity [100]. More recent work however suggests that the PBT is only modestly more cost-effective than standard photon-based whole-breast irradiation [101].

Alternatives to whole-breast irradiation such as partial breast irradiation [102] (including intraoperative radiotherapy) are also able to reduce mean heart doses and are discussed in Chaps. 55 and 56, respectively.

51.5.5 Verification

The UK Intensity-Modulated Partial Organ Radiotherapy (IMPORT) trialists have compared breast radiotherapy verification techniques, firstly establishing the feasibility of

using implanted markers to verify the position of the tumour bed during a course of breast radiotherapy [103]. Gold seeds were useable for verification in 42/32 (98%) patients and, using either an extended no-action level (eNAL) protocol [104] or an online correction protocol, were compatible with a set-up margin of 5 mm (i.e. a total CTV to PTV margin of 10 mm including respiratory motion). More recent work from the same group suggests that eNAL protocols including a total of five imaging sessions (within a 15 fraction course of breast radiotherapy) can reduce total CTV-PTV margins to 6 mm compared to a no-correction or no-action level protocol [105]. Implanted markers can be imaged using a number of technologies including megavoltage CT and kilovoltage cone-beam CT. Titanium clips are most visible on the latter and can be satisfactorily imaged for the purposes of set-up verification using partial arc scan geometries which are more compatible with supine set-up techniques than full arc scans [106]. With regard to the clinical benefits of pursuing a more rigorous verification protocol, reduced CTV to PTV margins have been shown to be associated with modest reductions in doses to breast, lung and heart tissues [107].

Conclusions

For the majority of women, the benefits of whole-breast irradiation continue to outweigh the risks although work continues to identify those women whose risk of relapse is low enough that the irradiated volume can be reduced or in whom radiotherapy can be avoided altogether. Where whole-breast irradiation is given, the majority of centres continue to treat supine, using implanted markers to aid target volume delineation and using techniques such as breath-hold to reduce heart doses in left breast-affected women. Hypofractionation together with three-dimensional planning techniques and improved verification have all helped to reduce the acute and late side effects of whole-breast irradiation.

Whole-Breast Radiation Following Breast-Conserving Surgery in Noninvasive Cancer

52

Beryl McCormick

52.1 Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS) is considered a risk factor for the development of a future cancer in either breast, once the LCIS has been identified on breast biopsy. LCIS identifies a patient as having an increased risk, and may be the gateway into special surveillance programs; however, there is no data supporting treatment of the LCIS diagnosis with breast radiation.

In 1992, a subtype of LCIS, labeled pleomorphic LCIS, was first described by Eusebi et al. [1]. Since that time, a number of articles have been published regarding this entity; although its pathology, imaging, and molecular features are well described, there is no data on outcomes with specific treatments. Please refer to the pathology section of this textbook for more information.

52.2 Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS) is a common breast cancer diagnosis in regions of the world with breast cancer screening programs or access to mammography for screening. In the United States in 2013, this diagnosis accounted for 20–25% of all new breast cancers [2]. With the recognition that results of the two local treatments were similar in early prospective randomized trials comparing breast-conservation surgery and whole-breast radiation to mastectomy for invasive cancers [3, 4], the practice of offering women with DCIS a similar local treatment option developed.

52.2.1 Early Prospective Clinical Trials

The National Surgical Adjuvant Breast and Bowel Project (NSABP) cooperative group was the first to initiate a prospective clinical trial assessing the value of whole-breast radiation after breast-conservation surgery for women with DCIS. Part of the rationale for this new study followed a central pathology review of women in the practice-changing B-06 trial, comparing mastectomy, breast-conservation surgery, and breast-conservation surgery with whole-breast radiation for women with early invasive breast cancers. Seventy-eight women enrolled in that study were actually found to have a diagnosis of DCIS on central pathology review, and in a separate report the NSABP noted "local breast recurrences were similar for women with DCIS and those from this cohort" (with invasive disease), strongly suggestive of a similar approach with breast-conservation surgery for both diseases [5].

The trial design for the NSABP B-17 study compared whole-breast radiation to none, following breast-conservation surgery, for 818 women with DCIS; reflecting the era of the trial, women were eligible whether the method of detection of their DCIS was by physical exam or by mammogram only. All pathology subtypes of DCIS were included, with the only pathology stratification factor being the presence or absence of LCIS along with the DCIS. Tumor-free margins were also required, and the cohort randomized to receive whole-breast radiation was given a dose of 50 Gy without a boost. Figure 52.1 shows the results of this trial with a median follow-up time of 90 months [6]. The women assigned to receive radiation had a highly significant decrease in ipsilateral breast tumor recurrence, both invasive and in situ, although no differences in survival endpoints were observed.

Shortly after, the European Organisation for Research and Treatment of Cancer (EORTC) reported the results of a nearly identical study, EORTC 10853, of 1010 women with DCIS, again comparing radiation to none following

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_52

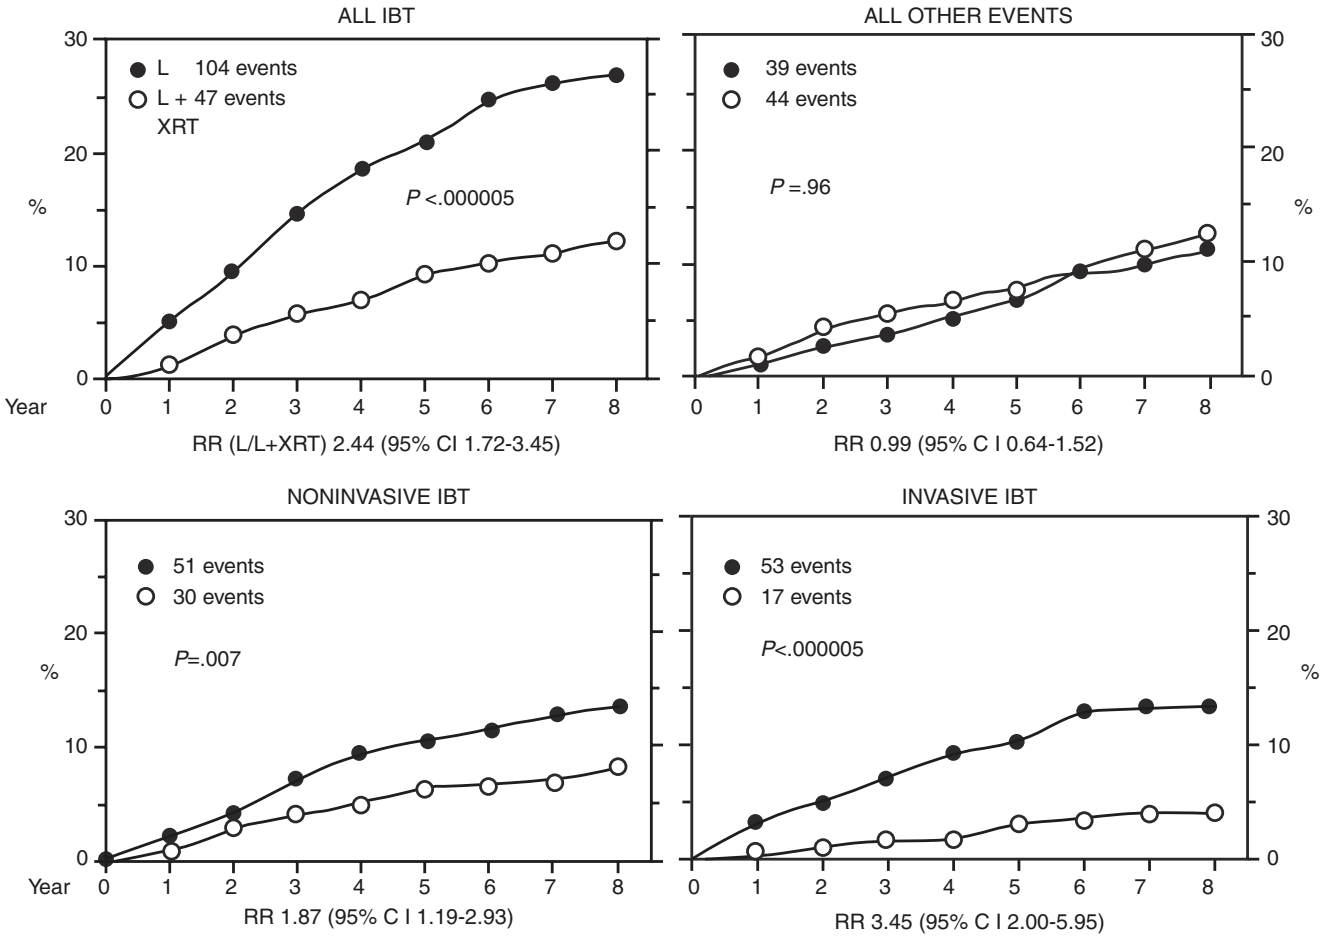

Fig. 52.1 Cumulative incidence of all ipsilateral breast tumors, by pathology type, and all other breast events in NSABP B17. *Open circles* represent patients who were randomized to receive whole-breast radiation, and *closed circles* those treated with surgery only

breast-conservation surgery. Consistent with the results of the B-17 trial, a 47% reduction in local failure in the ipsilateral breast was noted at 10 years for those women assigned to the whole-breast radiation arm of the trial. The dose was 50 Gy without a boost. Figure 52.2 from that study shows the positive effect of the radiotherapy in all clinical and pathologic subsets of patients included in the study [7].

52.2.2 Clinical Trials Focused on Subtypes of DCIS

The Swedish Breast Cancer Group opened a study of whole-breast radiotherapy versus none, focused on those women in the country's national screening program; as a result of the trial design, almost 80% of the women enrolled had no symptoms, but only screen-detected DCIS. There were 1067 women enrolled in the trial, and those assigned to receive whole-breast radiotherapy were given a dose of 50 Gy in 25 treatments, or 54 Gy in "two series with a gap of two weeks." Fig. 52.3 demonstrates the effect of radiotherapy on reducing the risk of local recurrences, with a median follow-up of 5.2 years for the women on study [8]. This decreased risk is consistent with both the EORTC and the NSABP B 17 studies.

In 1997 the Eastern Cooperative Oncology Group (ECOG) opened a clinical trial with prospective observation only, confined to specific risk stratum of DCIS. The low-intermediate group consisted of women with biopsy-proven low- or intermediate-grade DCIS, which was nonpalpable, did not exceed 2.5 cm in greatest diameter, and had a minimal margin width of 3 mm. ECOG acknowledged the results of prior prospective randomized trials favoring the use of radiotherapy but hypothesized that "a combination of size of lesion, grade, and surgical margin width might define a subset of patients at low risk of local failure without radiation" [9]. The study required

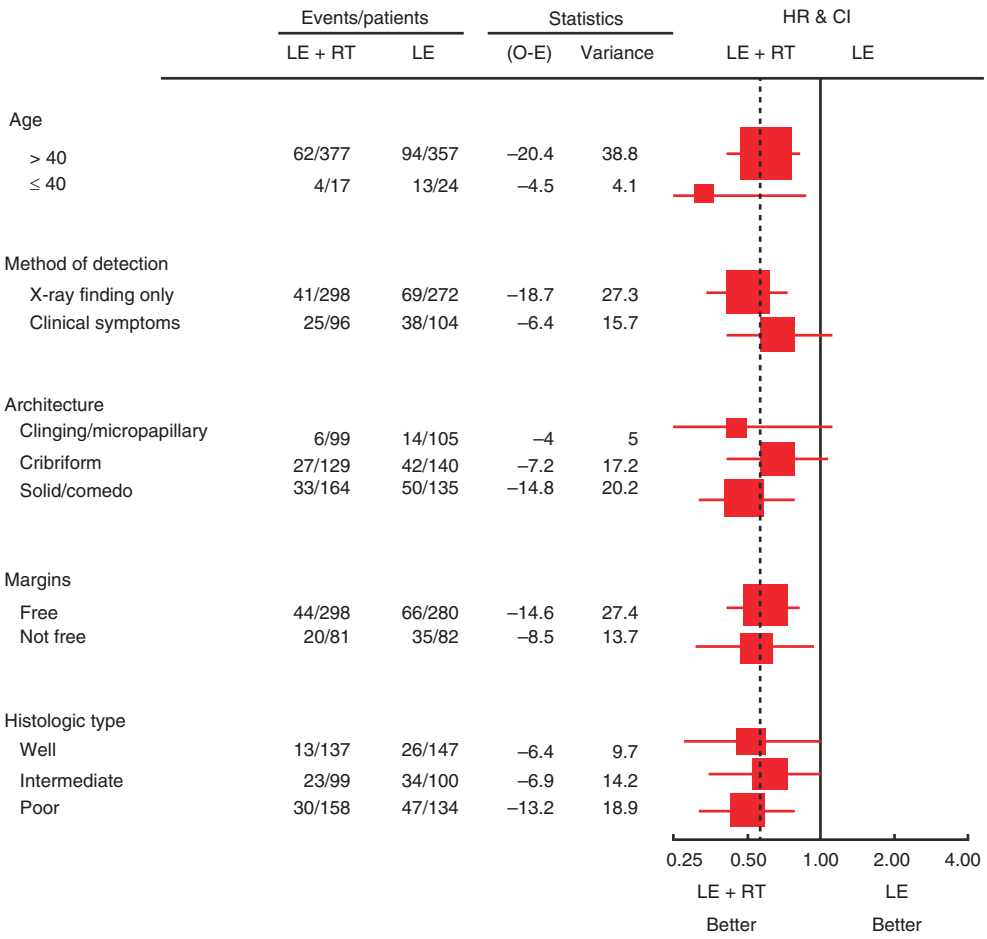

Fig. 52.2 Effect of radiotherapy on local control by subgroup in European Organisation for Research and Treatment of Cancer (EORTC) 10,853. *LE + RT* patients randomized to receive radiotherapy, *LE* those with surgery only

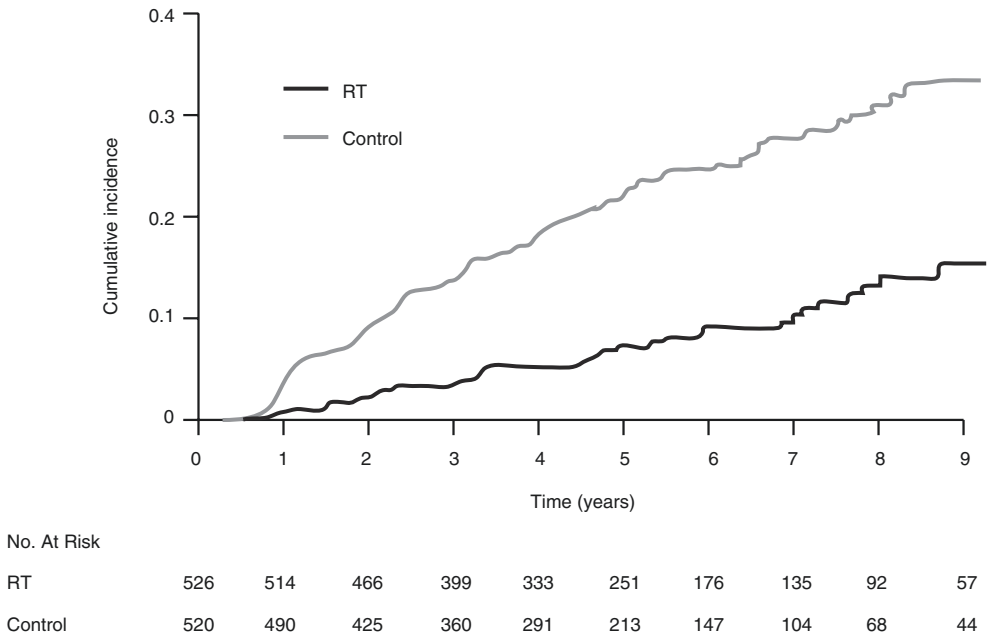

Fig. 52.3 Cumulative incidence of all ipsilateral recurrences in the SweDCIS trial. $P = <0.0001$ log-rank test

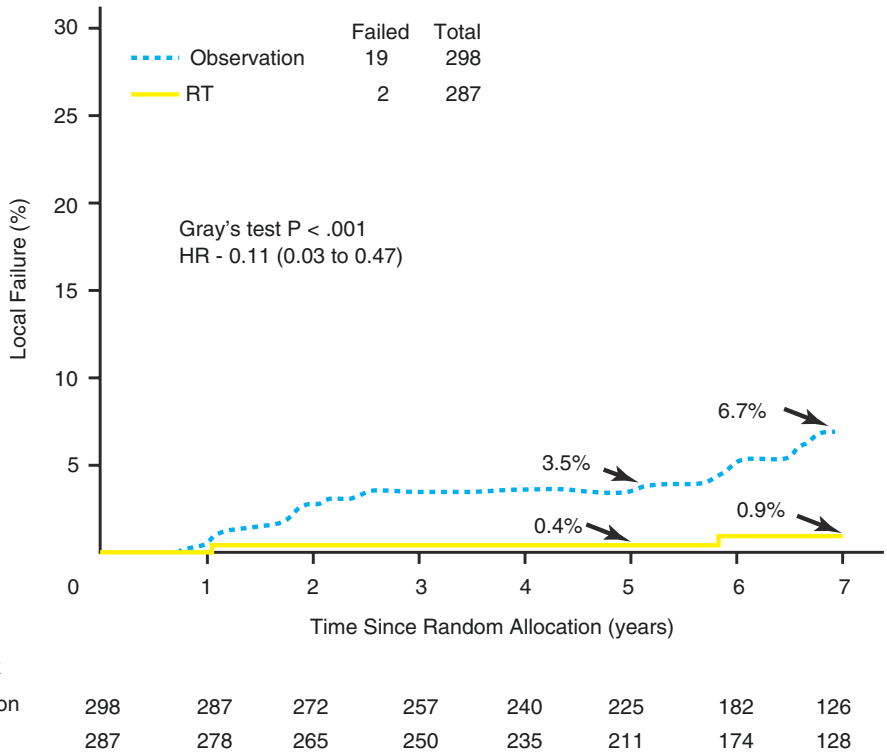

Fig. 52.4 Local failure in the ipsilateral breast of patients in the Radiation Therapy Oncology Group (RTOG) 9804 trial

central pathology review and allowed for the use of tamoxifen, which was used by 30% of patients on the study. A second, high-risk stratum consisted of women with high-grade DCIS, also nonpalpable with a maximum size of 1 cm and the same margin criteria as the "low-intermediate"-risk group. With a median follow-up time of 12.3 years, the local recurrence at 12 years was 14.4% in the low-intermediate-risk stratum and 24.6% in the high-risk stratum. The authors concluded that "individual patients and their physicians will need to decide if these 12-years risks are acceptable and to judge whether or not to add adjuvant treatment after surgical incision" [10].

The Radiation Therapy Oncology Group (RTOG) focused on the same low-intermediate-risk subset of DCIS patients as the ECOG study above, but this group's trial design was a prospective randomized study comparing radiation to none, for nonpalpable DCIS, also excised with a margin of 3 mm or greater, and measuring no larger than 2.5 cm in greatest diameter. Based on results of the NSABP's B-24 DCIS study showing an advantage in terms of improved local control with the addition of tamoxifen to whole-breast radiation [11], the study opened requiring tamoxifen use for 5 years in both study arms. The use of tamoxifen was made optional with the publication of the UK, Australian, and New Zealand radiotherapy and tamoxifen trial [12], resulting in an overall use of tamoxifen in the RTOG study of about 70% [13].

For those women assigned to receive radiotherapy in the RTOG study, the dose was originally 50 Gy in 25–28 fractions, but an amendment allowing for the use of 42 Gy in 16 fractions was added. Although this study was closed prior to meeting its targeted accrual, the addition of whole-breast radiation in reducing the rate of ipsilateral local failure was highly significant. Figure 52.4 shows those results, with a median follow-up time of 7.17 years. Disease-free and overall survival in the RTOG study and in all the prospective trials discussed above showed no differences with or without the use of whole-breast radiation.

52.2.3 Decision Making for Whole-Breast Radiation Following Conservation Surgery

As more information about the various subtypes of DCIS is appreciated, particularly with regard to outcomes from interventions, it becomes clear that the conclusion of the early prospective clinical trials, that radiotherapy improves local control and should be the standard of care, is open to some interpretation; a thoughtful discussion between the patient with DCIS and her doctors to explain risks and benefits of whole-breast RT is required. Patients need to understand that radiotherapy always lowers the risk of ipsilateral local failure, but has no measurable impact on breast cancer-related survival.

Clearly the risk of local failure is influenced by patient age, size and presentation method of the DCIS, extent of surgical resection, and pathologic characteristics of the DCIS subtype. What is the specific risk for a given patient? Several nomograms have been developed using clinical and pathologic parameters to estimate local recurrence risk; the Memorial Sloan Kettering nomogram, using ten parameters, has been validated in several DCIS populations and is a good example of such a tool [14]. Presenting the patient with a good estimate of her risk for recurrence is important when discussing the risks versus the benefits of radiation. Different patients view risk differently; two patients with the same nomogram score will often choose different local treatments. For those that choose to forego whole-breast RT, careful follow-up must be emphasized.

52.2.4 Radiation Techniques and Common Side Effects

Whole-breast radiotherapy for women with DCIS is similar to that for a patient with an early invasive cancer. The entire breast receives the dose planned through two tangent fields; 50 Gy in 25 fractions over 5 weeks' time has been the standard for many years. But the RTOG trial discussed above allowed for hypofractionation of 42 Gy in 16 fractions, and neither of the two local failures observed in the RTOG study were in the women treated with this fractionation [13]. Of note, none of the prospective randomized trials discussed above used a boost, or additional radiation to the lumpectomy bed following the completion of the whole-breast radiotherapy portion, and thus this is not needed if negative margins have been achieved.

Careful treatment planning is essential, since the heart and lungs are normal organs located close to the target breast volume. Planning should begin with a noncontrast computed tomography simulation, to localize breast target volume, and the location of the lungs, heart, and other normal organs with the patient in the treatment position. This can be either supine or prone or in the decubitus position, depending on her anatomy and the experience of the department. Great care is taken to reproduce the patient's position each day for treatment, so the treatment beams are targeting the breast with minimal dose to the ipsilateral lung. In most cases, the heart can be shielded from the primary beams, either with favorable anatomy or with special heart-avoidance techniques such as deep inspiration breath holds [15].

The most common systemic side effect is fatigue. Other common side effects are limited to the breast being treated and include temporary skin discoloration and dryness, similar to a mild sun exposure; hyperemia; mild swelling or edema of the breast; and sometimes myositis of the chest wall muscles behind the breast. Lung and heart side effects and late effects are rare with good treatment planning. Although not usually evident unless further surgery is required, radiation also can affect the elasticity of the skin, and impact on the need for breast reconstruction if a mastectomy is required later to address a local failure in the treated breast.

Postmastectomy Radiation Therapy of Early Breast Cancer

53

Birgitte Vrou Offersen and Mette Skovhus Thomsen

53.1 Introduction

Postmastectomy radiation therapy (PMRT) in high-risk breast cancer patients reduces the risk of locoregional recurrence and improves disease-free and overall survival. Three hypotheses have been proposed regarding the natural history of early breast cancer. The first hypothesis was proposed by Halsted in 1894 and stated that the tumour spreads from the primary site either by direct permeation or through the lymph nodes to distant sites, thus emphasizing the importance of optimal local therapy [1, 2]. The systemic hypothesis was proposed by Fisher in 1980 and stated that the disease has already given rise to distant spread at the time of clinical presentation [3] and that the lymph nodes were a marker of but not a source of distant spread. Thus systemic therapy was the treatment of choice. In 1984 data from Koscielny et al. challenged the systemic hypothesis, because the risk of distant metastases strongly correlated with tumour size in patients treated with locoregional therapy but not chemotherapy [4]. Therefore the spectrum hypothesis was proposed in 1994 by Hellman [5], and it states that "metastases are a function of tumour growth and progression. Lymph node involvement is of prognostic importance not only because it indicates a more malignant biology, but also because persistent disease in the lymph nodes can be the source of distant disease" [5]. This implied that optimal locoregional control is of importance also for the risk of distant spread.

53.2 Value of PMRT in High-Risk Breast Cancer Patients

The value of PMRT has been evaluated in several randomized trials conducted over the last 60 years, but it was only in 2005 established in an overview analysis that PMRT in addition to improved locoregional control also results in improved overall survival [6]. Three well-conducted randomized trials dominated the results in the overview analysis, two from the Danish Breast Cancer Cooperative Group (DBCG), the DBCG 82 b&c trials, and one from Vancouver, Canada [7–9]. These three trials were initiated because adjuvant chemotherapy became standard therapy for high-risk premenopausal patients in the late 1970s and tamoxifen became standard in high-risk postmenopausal patients, and since no overall survival gain had been documented from PMRT, it was expected that PMRT was no longer necessary.

The DBCG 82 b trial was a Danish multicentre randomized trial including 1708 high-risk premenopausal patients treated with CMF and randomized to +/−PMRT in the period 1982–1989 [7]. All patients had a partial axillary dissection with median 7 nodes removed. The high-risk criteria were tumour size larger than 5 cm, and/or positive axillary nodes, and/or invasion of the skin or pectoral fascia. The CMF was given intravenously every 4 weeks for eight cycles in patients randomized to PMRT and nine cycles in patients randomized to no PMRT. The target of the PMRT was the chest wall and regional lymph nodes in the axillary and supra-/infraclavicular areas and ipsilateral internal mammary nodes. The dose prescribed was 48–50 Gy in 22–25 fractions in 5–51/2 weeks. With 10-year median follow-up, the locoregional recurrence rate (first site of recurrence alone or together with distant failure) was 9% in PMRT + chemotherapy patients in contrast to 32% in patients treated with chemotherapy alone. The corresponding survival rates were 54% and 45%, respectively, in favour of PMRT + chemotherapy ($P < 0.001$).

In parallel to the DBCG 82 b trial, the DBCG 82 c trial was conducted in 1982–1989 [8]. This study included 1375 high-risk postmenopausal patients with age <70 years but otherwise the same risk criteria as for the DBCG 82 b trial. The surgical strategy was the same as in the DBCG 82 b trial, but the systemic therapy was tamoxifen 30 mg for 1 year. With median follow-up of 10 years, the locoregional recurrence rate was 8% in PMRT + tamoxifen patients compared to 35% in tamoxifen-only patients. The corresponding

10-year survival rates were 45% and 36%, respectively, in favour of PMRT + tamoxifen ($P = 0.03$).

Both DBCG trials have been criticized for the limited extent of surgery with only median 7 removed nodes and also for the inferior systemic therapy since CMF is considered low-dose-intensity chemotherapy and tamoxifen for 1 year is not sufficient. It was therefore an open question if the benefit of the PMRT was due to compensation for suboptimal surgery and/or suboptimal systemic therapy or if the PMRT was an independent contributor to locoregional tumour eradication.

The recurrence pattern in the DBCG 82 b&c trials has been reported with 18-year median follow-up, and compared to patients not receiving PMRT, patients receiving PMRT had significantly fewer locoregional recurrences, lower risk of distant metastasis after locoregional recurrence, lower risk of simultaneous locoregional recurrence and distant metastasis and lower risk of any distant metastasis [10]. Therefore these data supports the spectrum hypothesis proposed by Hellman, by demonstrating that optimal locoregional control results in fewer distant failures.

Similar to the DBCG 82 b trial, a trial was conducted in Vancouver, where 318 premenopausal high-risk patients were treated with CMF and randomized to +/−PMRT in the period 1978–1986 [9]. Only patients with stages I and II with positive nodes were included. A median number of 11 nodes were removed from levels I and II. CMF-based therapy was given for 12 months initially, but from 1981 it was modified to 6 months. The PMRT was delivered between the fourth and fifth cycle of chemotherapy, and the chest wall received 37.5 Gy and the mid-axilla and internal mammary nodes 35 Gy, all in 16 fractions using a cobalt 60 unit. After 15-year median follow-up, the locoregional recurrence rate was 13% for patients treated with PMRT + CMF versus 33% in CMF-only patients ($P = 0.003$). The corresponding survival rates were 54% versus 46%, respectively ($P = 0.07$).

Other randomized trials testing PMRT in patients also treated with systemic therapy have been reported [11–18]; however, it is difficult to compare the trials directly because differences are seen in radiation doses, number of fractions, treatment techniques, use of megavoltage or orthovoltage equipment, timing of radiation and systemic therapy as well as variation in the systemic therapy (different drugs, dose intensity, duration). But overall the trials demonstrated a reduction in locoregional recurrence risk with PMRT, whilst the gain in overall survival was not always clear. This may however be attributable to relatively few patients in the trials and differences in patient selection criteria and observation time and perhaps also because some studies may have used treatment techniques which resulted in increased risk of heart disease and heart death [19]. Importantly the three trials demonstrating the largest survival gain from PMRT (the DBCG 82 b&c trials and the Vancouver trial) did not find any excess cardiac mortality [9, 20, 21].

53.3 Overview Analyses of Effect of PMRT

In 2005, an overview analysis based on individual patient data from randomized PMRT trials was published [6], and in 8500 patients operated with mastectomy and axillary clearance for lymph node-positive breast cancer and randomized to +/− PMRT, a significant reduction in local recurrence at 5, 10 and 15 years was identified. Local recurrence at 5 years was seen in 22.8% of patients with no PMRT in contrast to 5.8% with PMRT; thus the absolute gain was 17.1%. The 15-year absolute gain in breast cancer mortality was 5.4% (risk reduction from 60.1% with no PMRT versus 54.7% with PMRT). Despite these results many guidelines have been reluctant to recommend PMRT to patients operated for pN1 disease (one to three positive nodes) [22–25]. Therefore a meta-analysis focusing on the gain from PMRT in pN1 patients was published in 2014 [26]. The analysis was based on individual data from more than 3700 patients operated with axillary dissection of at least levels I and II and irradiated with PMRT including the chest wall and the supraclavicular and/or axillary fossa and the internal mammary nodes. For 1314 patients with pN1 disease, PMRT reduced the locoregional recurrence ($P < 0.0001$), the overall recurrence (relative risk (RR) 0.68, 95% CI 0.57–0.82, $P < 0.0001$) and the breast cancer mortality (RR 0.80, 95% CI 0.67–0.95, $P = 0.01$). Of these, 1133 patients were treated in trials with systemic therapy (CMF or tamoxifen), and in these patients PMRT reduced locoregional recurrence ($P < 0.0001$), overall recurrence (RR 0.67, 95% CI 0.55–0.82, $P < 0.0001$) and breast cancer mortality (RR 0.78, 95% CI 0.64–0.94, $P = 0.01$). For 1772 patients with more than three macrometastases, PMRT reduced locoregional recurrence ($P < 0.0001$), overall recurrence (RR 0.79, 95% CI 0.69–0.90, $P = 0.0003$) and breast cancer mortality (RR 0.87, 95% CI 0.77–0.99, $P = 0.04$) [26]. The relative gain from PMRT using any first recurrence and breast cancer mortality as endpoints was the same in patients with one versus two to three macrometastases, and it was not possible to identify a subgroup of patients in the pN1 cohort who did not have a significant gain from PMRT.

It should be noted that the patients included in the trials of this meta-analysis were treated decades ago according to the routines of those days, and therefore they may not reflect the patients of today. For example, patients today most often present with screen-detected clinically node-negative cancer, and therefore they are operated with sentinel node biopsy, which was not used previously. Also modern systemic therapy is more effective than CMF or 1-year tamoxifen, and therefore the recurrence risk of modern patients may be smaller than in the meta-analysis, resulting in a smaller absolute gain in recurrence from PMRT. On the other hand, due to higher quality in PMRT today with detailed target definition and CT-based dose planning, the proportional gain from PMRT may be higher than demonstrated in the meta-analysis.

However, as data is maturing and accumulating in favour of PMRT in all node-positive patients and patients with large tumours pT3pN0 (>50 mm), European guidelines now recommend PMRT to these patient categories [27, 28].

53.4 What Is the Target of PMRT?

Since the turn of the millennium, most RT departments have changed to CT-based dose planning. Previously simulator-based techniques were used based on bony structures to guide the field arrangement. Modern PMRT is based on target definition on CT scans of the patient in treatment position. A consensus guideline for target delineation in early breast cancer was reached in ESTRO (the European Society for Radiotherapy and Oncology) in 2015, and it has gained use in most European countries [29]. According to this guideline, lymph node volumes are delineated around the large veins, because lymph nodes follow the veins. There is general consensus that in PMRT the target includes the chest wall and the regional nodal areas around the breast region, thus levels I, II, III and IV (previously called the supraclavicular lymph nodes), the interpectoral nodes and the internal mammary lymph nodes. Depending on the extent of the lymph node dissection, inclusion of levels I and II varies, for example, in some institutions levels I and II are omitted from the RT fields if >10 lymph nodes were removed from a node-positive axilla.

The inclusion of the internal mammary lymph nodes (IMN) and the medial supraclavicular lymph nodes has been in focus recently. Three large studies have investigated the benefit on recurrence in patients with and without RT of these lymph nodes [30–32]. The EORTC 22922/10925 trial randomized 4004 patients (25% had PMRT) to +/− RT of the internal mammary nodes and the medial supraclavicular lymph nodes in the period 1996–2004 [30]. At 10 years, improvements of 1.6% in overall survival (hazard ratio (HR) 0.87, 95% CI 0.76–1.00, $P = 0.05$), and 1.9% in breast cancer mortality (HR 0.82, 95% CI 0.70–0.97, $P = 0.02$) were observed with RT. Overall the study population had a low risk of IMN metastasis, because 44% had node-negative disease but central/medial tumour location and 43% had pN1 disease. In the MA.20 trial, only breast-conserving therapy was provided (thus no PMRT), and 1832 patients were randomized to +/−regional nodes RT including the IMN [31]. At 10 years, locoregional disease-free survival was improved by 3.0% (HR 0.59, 95% CI 0.39–0.88, $P = 0.009$), and distant disease-free survival was improved by 3.9% (HR 0.76, 95% CI 0.60–0.97, $P = 0.03$). However, no significant improvement was seen in overall survival (1.0%, HR 0.91, 95% CI 0.72–1.13, $P = 0.38$) or breast cancer mortality (2.0%, HR 0.80, 95% CI 0.61–1.05, $P = 0.11$). The DBCG-IMN study was not randomized but a nationwide prospective population-based cohort study in 3089 patients, and 66% had PMRT [32]. In 2003, the DBCG RT committee decided that all patients operated for a right-sided lymph node-positive or T3N0 breast cancer should receive RT of the IMN in addition to their PMRT, whilst patients treated for a left-sided breast cancer should not receive RT to the IMN. This was decided because at that time no data showed a gain in prognosis from RT of the IMN, and in left-sided patients, RT of the IMN would cause relatively high dose in the heart, thus increasing the risk of heart disease. The analysis included patients treated in 2003–2006 in Denmark. After a median of 8.9 years, the 8-year overall survival rates were 75.9% with IMN RT versus 72.2% without IMN RT. The adjusted HR for death was 0.82 (95% CI 0.72–0.94, $P = 0.005$). Breast cancer mortality was 20.9% with IMN RT versus 23.4% without IMN RT (adjusted HR 0.85, 95% CI 0.73–0.98, $P = 0.03$). The risk of distant failure was 27.4% with IMN RT versus 29.7% without IMN RT (adjusted HR 0.89, 95% CI 0.78–1.01, $P = 0.07$). The effect of IMN RT was more pronounced in patients with high risk of IMN metastasis, and no subgroups could be identified, where the IMN RT could be omitted. A meta-analysis on these studies is awaited, but many RT centres have changed their guidelines to recommend IMN RT based on these data.

53.5 Dose and Fractionation

Traditionally the dose for PMRT has been 45–50 Gy in 25–28 fractions of 1.8–2.0 Gy per fraction, 5 fractions per week. If the surgery was no radical, an additional boost of 10–16 Gy in 5–8 fractions was added. However, after the publication of results from patients operated with breast-conserving technique mostly for node-negative disease from Canada and England, where shorter fractionation schemes were used (40–42.5 Gy in 15–16 fractions, 2.67 Gy per fraction), some countries (England and Holland) have started a more widespread use of the shorter fractionation for PMRT also [33, 34]. This is based on extrapolation of results from patients treated with whole breast radiotherapy and only to a very limited extent patients operated with mastectomy. No randomized data supports the use of hypofractionation (use of doses >2.0 Gy per fraction) in PMRT patients, so trials testing it are awaited.

53.6 Treatment Technique

The treatment techniques for PMRT have changed significantly during the previous decades reflecting the technological development from orthovoltage equipment and cobalt units to megavoltage electron accelerators with multi-leaf collimators (MLC) and advanced imaging devices. In the early days of PMRT when the treatment fields were planned

on a simulator, the techniques for accelerator treatment were typically a combination of electron and photon fields [35–37]. Treatment techniques with electron fields only, either multiple static fields [38] or an arc technique [39], have also been applied. In 2002 Pierce et al. presented a dosimetric comparison of seven different techniques for PMRT of the chest wall and IMN [40]. Their conclusion was that no single treatment technique fulfilled the criteria of good target coverage with minimal organ at risk exposure. However, of the techniques studied, they found that the best compromise was obtained with the partially wide tangent technique (PWTF). This was also found in a later comparison between the PWTF technique and the technique combining electron and photon fields [41]. Furthermore, with CT-based planning the former technique was faster both to plan and when the fields were delivered at the accelerator. Figure 53.1 shows an example of the widely used mono-isocentric technique with two wide tangential half-beam fields covering the chest wall and IMN

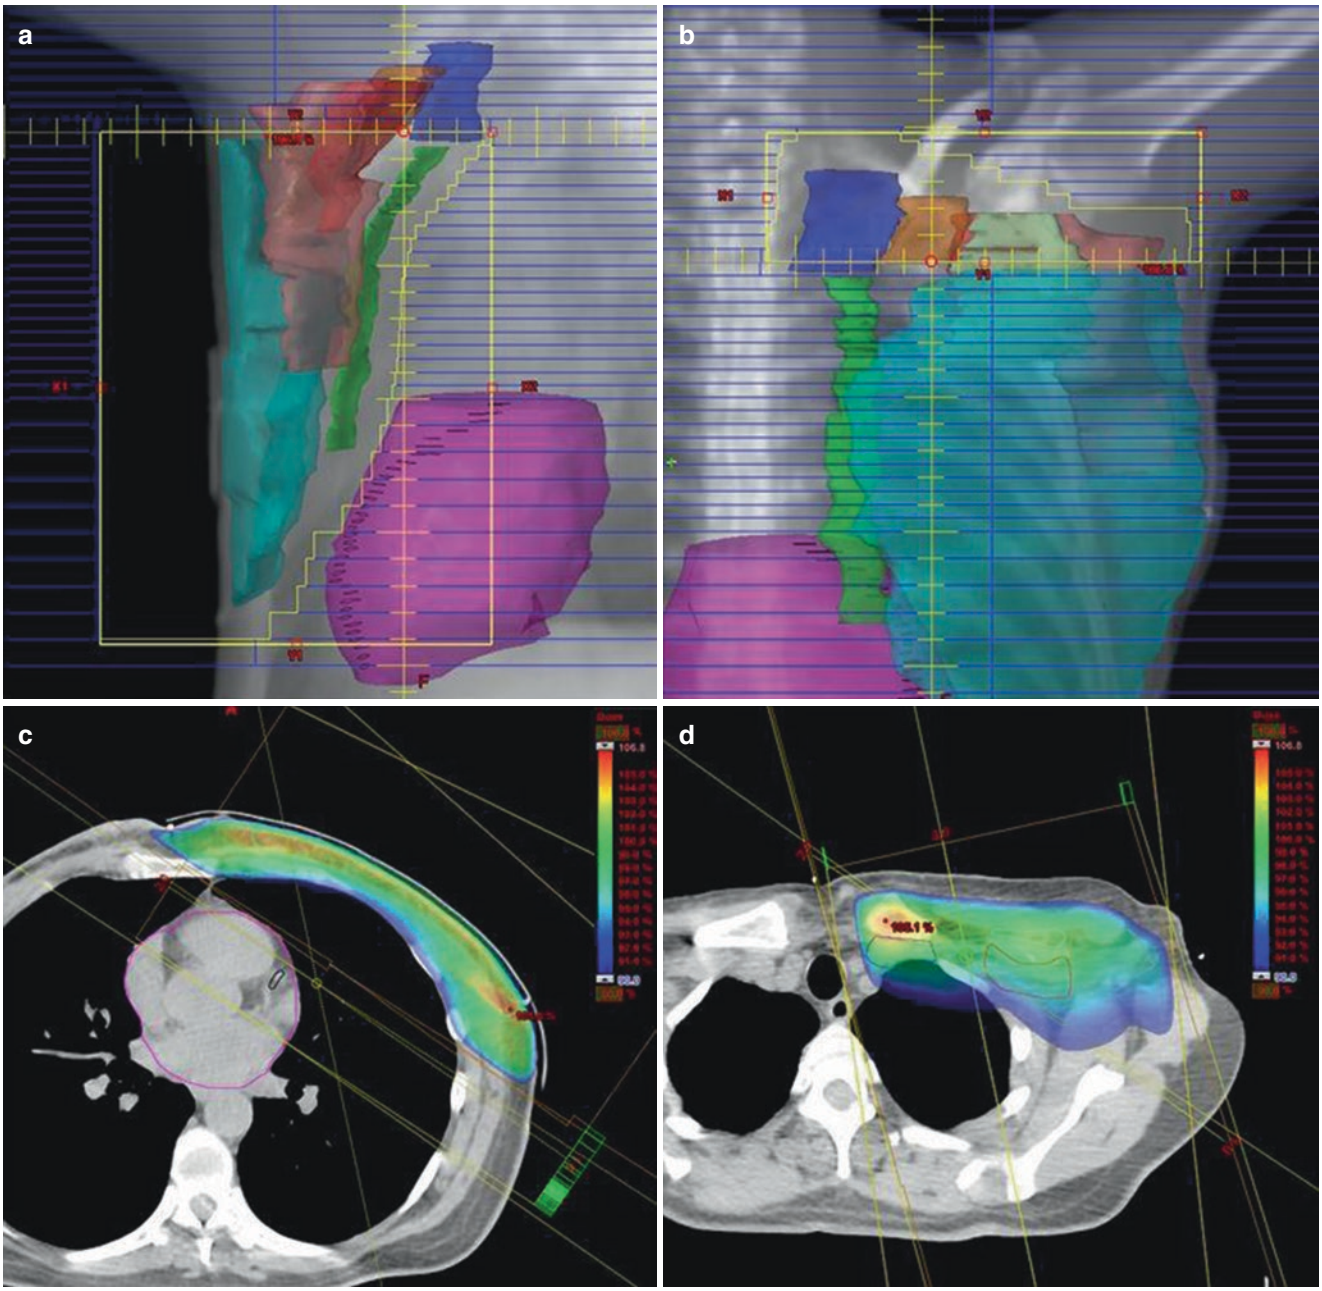

Fig. 53.1 The mono-isocentric PWTF technique with beam's eye view of one of the half-beam tangential fields (**a**) and the slightly oblique AP half-beam field (**b**). The transversal CT slices show the dose distribution at the heart level (**c**) and in the supraclavicular region (**d**). The structures shown are CTVn_L1, *pink*; CTVn_L2, *red*; CTVn_L3, *orange*; CTVn_L4, *blue*; CTVn_intpect, *light green*; CTVn_IMN, *green*; CTVp_chestwall, *turquoise*; heart, *magenta*; and LADCA, *black*

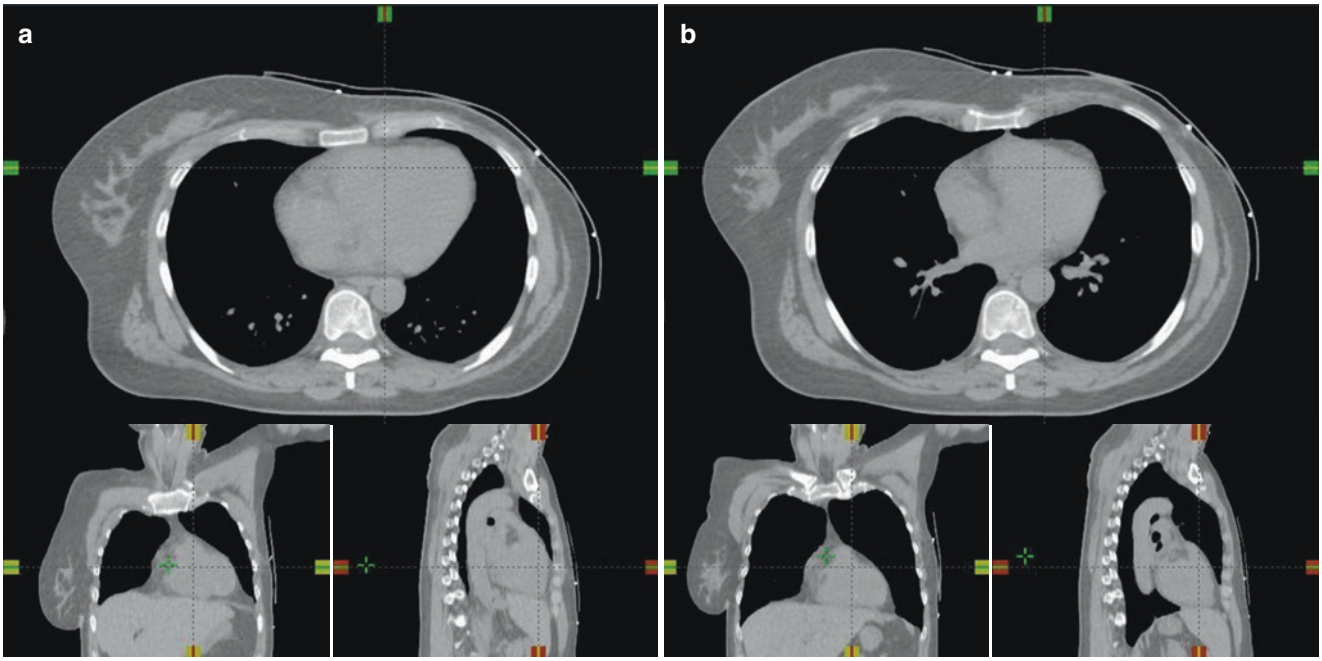

Fig. 53.2 CT scan of a patient in (**a**) free breathing and (**b**) deep inspiration breath hold

and two slightly oblique AP-PA half-beam fields covering the lymph nodes in the supraclavicular region.

One of the challenges in PMRT is to obtain a sufficient dose to the target and a minimum dose to the lung and heart. The cardiac and pulmonary complication probabilities can be reduced by using breathing-adapted RT (BART) techniques [42], and also the target coverage is improved when the patients are planned and treated in deep inspiration breath hold [43, 44]. Figure 53.2 shows the anatomical differences between free breathing and deep inspiration breath hold CT scans.

When using BART the chest wall movement is limited during treatment compared to a patient treated in free breathing. Therefore it might be expected that the setup error is smaller in BART. However, it was found that the primary benefit of BART is the separation of the heart from the target rather than a reduced setup error [45].

Apart from 3D conformal radiotherapy techniques (3DCRT) for PMRT, more advanced photon field techniques such as multiple field IMRT, helical tomotherapy and volumetric arc techniques have also been applied [46–48]. All these advanced techniques produce treatment plans which might reduce the high-dose volume in the lung and heart; however, they often increase the dose to the contralateral breast. Especially in patients younger than 40 years, it is important to limit the dose to the contralateral breast to less than 1 Gy because of an increased risk of second primary breast cancer [49]. Abo-Madyan et al. [50] have studied the risk of second cancer in the contralateral breast and both lungs after 3DCRT, IMRT and VMAT. They found that the risk of a radiation-induced second cancer was 34–50% larger after IMRT and VMAT compared to 3DCRT. The risk of inducing a second primary lung cancer after 3DCRT was determined by Grantzau et al. [51]. They found that the small absolute risk increased linearly with dose and, furthermore, that patients with a history of cigarette smoking had a significantly higher radiation-induced risk than non-smokers indicating the importance of quitting smoking before RT.

PMRT can also be carried out by using protons [52]. By using protons an appropriate chest wall and IMN coverage can be obtained with an improved cardiac sparing compared to conventional treatments by photon/electron beams. One of the challenges in proton therapy is to create a treatment plan which is robust, i.e. that the delivered dose distribution is only slightly dependent on setup uncertainties and patient breathing motion.

53.6.1 Bolus

When megavoltage photons are used, the most superficial parts of the irradiated volume will receive a lower dose due to the skin-sparing effects of this radiation. To compensate for this, a bolus of a given thickness and extension may be placed on the chest wall. For PWTF irradiation with 6 MV photons, at least 3 mm bolus is necessary to obtain an adequate dose in the PTV [53]. A survey in 2004 [54] showed significant regional differences in the use of a bolus in PMRT. Eighty-two percent of the American respondents used always a bolus, whereas the corresponding figures for

the Australasian and European respondents were 65% and 31%, respectively. There was also a wide variation in bolus thickness and in the application of the bolus every day versus on alternate days. The rationale for using a bolus in PMRT is that by increasing the dose to the skin, the risks of local recurrences are reduced. In a small study with 254 patients, Tieu et al. [55] have investigated the effect of bolus in PMRT on local recurrence. They did not find any difference between the group with a whole chest bolus compared to the group with either a parascar bolus or no bolus.

53.6.2 Breast Implants

After mastectomy a breast reconstruction with expanders and implants may be carried out. One option is to use a one-stage implant-based reconstruction with immediate implant replacement at the time of mastectomy. However, this means that if PMRT is indicated the RT will be performed on the implant. Kronowitz [56] made a literature survey showing that most of the patients undergoing implant-based reconstruction before irradiation kept the implant; however, it was also observed that irradiation resulted in a significant need for unplanned or larger corrective surgery. This may be due to radiation-induced modifications of silicone [57].

53.7 The Future of PMRT Is More Individualized Therapy

It has been established that the effect of PMRT is heterogeneous, so that in patients with ERpos/PRpos/HER2neg cancer, the 5-year gain in locoregional recurrence translates into a gain of the same magnitude at 15-year overall survival, whilst in ERneg/PRneg/HER2neg patients, the high-risk reduction in 5-year locoregional recurrence does not translate into any improved 15-year overall survival [58]. Much effort has been spent to identify a biomarker or molecular profile to help stratifying a more individualized approach to PMRT, and it was only recently that the first genetic profile predicting the benefit from PMRT was successfully identified and validated in an independent data set [59, 60]. It is to be expected that this profile and other profiles will gain more interest in the future to further individualize PMRT.

In many countries screening mammography is now standard, and it has caused a dramatic decrease in the frequency of mastectomy, because tumours today are smaller and more patients are node negative. Therefore the use of breast conservation has increased considerably. For example, in the DBCG-IMN study reporting on node-positive patients treated in the period 2003–2007, two thirds of the patients were operated with mastectomy, whilst today less than one third of new breast cancer patients are operated with mastectomy [32].

In that perspective it can be expected that the use of PMRT will decline and hopefully be prescribed in a more individualized way in the future. Based on available evidence from randomized trials, the current strategy is, however, that PMRT should be offered to patients operated with mastectomy for any node-positive breast cancer or large node-negative (pT3-4N0) breast cancer.

Concurrent Use of Radiation Therapy and Targeted Molecules in the Breast Cancer Treatment

54

Youlia M. Kirova and Alain Fourquet

54.1 Anti-HER2 Molecules and Radiotherapy

Several molecules can be administrated: trastuzumab, lapatinib, pertuzumab, and TDM1. The current work will present mainly the results of principal studies concerning the clinical experience of some of these molecules in association with the radiotherapy, data which could impact the everyday practice.

54.1.1 Radiotherapy and Trastuzumab

54.1.1.1 Adjuvant and Neoadjuvant Treatment

Human epidermal growth factor receptor 2 (HER2) overexpression has been observed in 20–25% of patients treated for breast cancer (BC) [1]. Amplification of the gene coding for this receptor is significantly correlated with poor prognosis in terms of local control and overall survival [2, 3].

Trastuzumab (T) (Herceptin®; Genentech, San Francisco, California) is a humanized chimeric antibody presenting antitumoral activity induced by specific binding to the extracellular domain of HER2. In the management of BC overexpressing HER2, the oncologic efficacy of T in terms of progression-free and overall survival has first been shown at a metastatic stage [4] and then in an adjuvant setting [5, 6]. However, higher incidences of cardiovascular events (CVE) have been reported in patients exposed to T [5, 6]. Significant decrease of the left ventricular ejection fraction (LVEF) and symptomatic congestive heart failure (CHF) were the most frequently observed adverse effects.

In early-stage BC, adjuvant radiotherapy (RT) improves the locoregional control as well as the overall survival compared to breast-conserving or radical surgery alone [7, 8]. However, these benefits are counterbalanced by an increased risk of cardiovascular mortality attributable to this treatment [7]. Preclinical studies have demonstrated a radiosensitizing effect of trastuzumab (T) in vitro and in vivo [9].

The concurrent administration of T with breast RT was evaluated in retrospective [10–12] and prospective clinical studies [13–15]. The objective of this review work was to prospectively assess the toxicities and the oncologic efficacy of T concurrent with adjuvant RT for nonmetastatic BC. More data is available in the association between radiotherapy and chemotherapy [16, 17].

The prospective series of the Institut Curie in 308 consecutive patients and median follow-up of 50.2 months (range: 13.0–126.0) [18] have shown the skin toxicities are close to those previously reported: 82% of acute grade 1 radiodermatitis, 13% of grade 2, 6% of late grade 1 telangiectasia, and 16% of late grade 1 skin fibrosis [13]. Some internationally accepted definitions of the irradiated volumes of the lung and heart were used in some works to obtain better assessment of the results [19, 20].

In a multicenter retrospective study on 146 patients with a median follow-up of 16 months, Belkacémi et al. [10] reported grade 2 and higher radiodermatitis in 51% of patients, occurring during or after RT. The differences compared to the results reported here can be explained by treatment in lateral position using previously published isocentric lateral decubitus (ILD), a technique developed in order to reduce skin toxicities without altering local control [21, 22]. The modalities of irradiation of the internal mammary nodes (IMN) can also contribute to a lower incidence of esophageal toxicity than that described by Belkacémi et al. [10, 23], i.e., 12% of grade 2 and higher esophagitis. Small-field electron boost to the chest wall and IMN following mastectomy reduces the photon dose [22, 24].

Shaffer et al. [11] evaluated the early cardiotoxicity of T in 59 patients; among them 44 were treated with concurrent breast RT. T was interrupted due to LVEF decrease in 6 of the patients treated by RT (13.6%) and in 5 of the 27 patients (18.5%) treated on the left breast. Three patients developed symptomatic CHF, following left breast RT. This retrospective study was mainly criticized for the heterogeneous techniques of irradiation and the short median follow-up (15 months).

Halyard et al. [25] studied the incidence of the cardiac toxicity of T concurrent with breast RT in the patients included in the North Central Cancer Treatment Group N9831 randomized trial. The cohort was composed of 1938 patients; among them 1418 (73.2%) were treated by RT. Median follow-up was 3.7 years. The three-year cumulative incidence of CVE was 1.7% when T was initiated concurrently with paclitaxel and 2.7% in the case of a sequential treatment. No increased cardiovascular toxicity was demonstrated in patients treated by concurrent RT and T and/or by left-sided RT. Similar findings were also observed after IMN irradiation but on a limited cohort (44 patients).

The cardiotoxicity related to the treatment by T and breast RT was also studied in the patients followed in the HERA trial [26]. T was administered sequentially to the irradiation. Median follow-up was 3.6 years. According to the HERA criteria, the incidences of significant LVEF decrease and of symptomatic CHF were higher in patients treated by T than in the observation group (3.6% versus 0.6% and 1.9% versus 0.1%, respectively). A retrospective multicenter study assessed the cardiac adverse events of T administered sequentially to RT on 499 patients [27]. An asymptomatic LVEF decline strictly superior to 10% and below 20% was described in 20% of patients. The incidence of symptomatic CHF was 3%. Considering these works, the concurrent administration of T with breast RT doesn't seem to induce a significantly increased cardiotoxicity compared to a sequential treatment.

If the Institut Curie study shows limited toxicities after a median follow-up exceeding 4 years, these data have to be verified in the long term. Indeed, radiation-induced cardiac toxicity can be observed up to 20 years after the completion of the treatment [28]. Although LVEF is the parameter commonly used in daily practice, other factors have been studied to determine the risk of cardiotoxicity induced by RT. Taylor et al. [29] assessed the predictive value of the MHD to estimate the physical and biologic doses to the heart in 50 patients. They demonstrated a strong linear correlation between the MHD and the mean heart dose: for every 1 cm increase in the MHD, the mean heart dose increased by an average of 2.9% of the tumor dose [28]. In 30 patients treated for left-sided BC, Hurkmans et al. [19] highlighted a mathematical relationship between the MHD and the Normal Tissue Complication Probability (NTCP) of the heart. When the MHD was below 1 cm, the heart NTCP was estimated to be less than 1%. NTCP increased considerably to values greater than 2% when the MHD exceeded 2 cm.

Intensity modulated RT (IMRT) could improve protection of the heart during breast RT. A dosimetric study of 15 patients with MHD greater than 10 mm compared cardiac exposure to irradiation delivered by helical tomotherapy, IMRT using five to seven beams, and conformal RT [30, 31]. Mean MHD was 17 mm. Cardiac and left ventricular volumes receiving a dose of 35 Gy or more were significantly reduced using helical tomotherapy (0.5%) or IMRT (0.7%) than conformal RT (3.6%).

In conclusion, according to this review of the literature, toxicities related to the concurrent combination of T and locoregional breast RT were acceptable when adapted techniques are used. The oncologic efficacy of this treatment was also confirmed. Longer follow-up is warranted to confirm these results. The results of the studies are given in (Table 54.1).

Table 54.1 Comparison of the toxicity rates reported in patients exposed to concurrent trastuzumab with locoregional breast radiotherapy

	n	Median follow-up		Acute epithelitis (%)			Acute esophagitis (%)		Late skin reactions (%)		Late esophagitis (%)		LVEF decrease	CHF

(i) Trastuzumab administered concurrently with paclitaxel, (ii) trastuzumab delivered sequentially with paclitaxel

54.1.1.2 Concurrent Use of Radiotherapy and Trastuzumab in the Metastatic Disease

It was shown that the trastuzumab can be used concurrently with the whole brain radiotherapy in case of multiple metastases [32].

54.1.2 Double Blockade of the HER2 Receptor with the Combination of Trastuzumab and Pertuzumab and Radiotherapy

Several molecules can be administrated: trastuzumab, lapatinib, pertuzumab, and TDM1. Pertuzumab is a recombinant humanized IgG antibody which prevents the heterodimerization of HER2 receptor with HER3 which occurs after ligand binding and is a potent association for intracellular signaling [33]. Trastuzumab binds to the extracellular domain of HER2 and blocks its cleavage and the ligand-independent signaling [33]. Both can be involved in antibody-dependent cell-mediated cytotoxicity (ADCC) [34]. Double blockade of the HER2 receptor with the combination of trastuzumab and pertuzumab has a synergistic effect in vitro and in animal models [34, 35]. First studies in phase I and II with combination showed an acceptable toxicity profile [36, 37]. Digestive disorders with diarrhea can occur frequently. The main concern about toxicity is cardiac dysfunction. HER2 pathway is important for the homeostasis of cardiomyocytes [38, 39]. Left ventricular ejection fraction (LVEF) should be thoroughly controlled before anti-HER2 treatment initiation and regularly (every 3 months at least) along administration.

Baselga et al. showed in phase III an improvement in overall survival in the pertuzumab arm associated with chemotherapy with docetaxel and trastuzumab in a population of 808 patients with breast cancer presenting unresectable locoregional relapse or in first metastatic line. Progression-free survival was 18.5 months in the pertuzumab-trastuzumab-docetaxel group versus 12.4 months in the group with trastuzumab-docetaxel alone (HR: 0.62; 95% CI (0.51–0.75) $p < 0.0001$) [40]. This study named CLEOPATRA led to the approval of pertuzumab in this indication. Pertuzumab is currently evaluated in neoadjuvant and adjuvant indications in the BERENICE (NCT02132949) and APHINITY (NCT01358877) studies.

Pertuzumab has to be associated with trastuzumab during the same period of treatment, as maintenance therapy until progression in metastatic stages and for 1 year in the adjuvant setting. As a consequence, the question of the tolerance of concomitant systemic treatment with radiation therapy arises and needs to be addressed in the adjuvant context mainly but also in the metastatic setting. Adjuvant radiation therapy showed a benefit on reducing the risk of locoregional relapse and overall survival and proved itself as a standard of care [7, 8].

In controlled metastatic disease, locoregional treatment with surgery and/or radiotherapy can improve the overall survival. This was shown by Le Scodan et al. in 2008 in a population of 581 patients. Among them, 320 received a locoregional treatment consisting in exclusive radiotherapy (78%), surgery of the primary tumor followed by radiotherapy (13%), or surgery alone (9%). These patients had an overall survival at 3 years of 43.4% versus 26.7% in the group of patients who had no locoregional treatment ($p = 0.00002$). Locoregional treatment was also an independent prognostic factor (HR: 0.70; 95% CI, 0.58–0.85 $p = 0.0002$) [41]. Several other studies supported the same results [42]. Symptomatic radiotherapy is the other indication of radiation in a metastatic setting.

In vitro, a radiosensitizing effect was demonstrated in breast cancer cell lines with HER2 treatment [9]. A part from a case report [42], there are very few data on the combination of double blockade HER2 and radiation.

The series of the Institut Curie (in a population of nonselected patients) are the unique published study assessing the tolerance of the combination trastuzumab-pertuzumab and radiotherapy in patients treated for HER2+ breast cancer outside clinical trial for metastatic and/or locally recurrent unresectable disease [43]. This first exploratory study of the combination pertuzumab, trastuzumab, and radiotherapy showed in population of 23 consecutive female breast cancer patients with median age of 47 years (range: 33–85) with known cardiovascular risk factors that the observed toxicity was manageable with reversible symptoms [43]. All patients received docetaxel, pertuzumab, and trastuzumab as the first-line protocol. For docetaxel, doses were initiated at 75 mg/m^2 and then increased to 100 mg/m^2 at cycle 2 if well tolerated. For three patients, docetaxel was replaced by paclitaxel to decrease toxicity. All patients had a good partial or complete response after 6– 8 cycles enabling a maintenance protocol with pertuzumab and trastuzumab. Hormonal therapy was given concomitantly with maintenance treatment by pertuzumab and trastuzumab in six patients (26%), but only one started the hormonal therapy during the radiotherapy. Six patients (26%) previously received anthracyclines with a median cumulated total dose of 493 mg. Another potentially cardiotoxic treatment was 5FU with a median cumulated dose of 2900 mg (6pts., 26%) and history of adjuvant trastuzumab with a median cumulated dose of 6675 mg (3pts., 13%). Three patients underwent palliative radiation therapy as following antalgic bone irradiation (2 pts.) or whole brain radiotherapy (1 pt.). Most patients (20 pts., 87%) experienced locoregional radiotherapy. Notably, there was a high rate of IMN treatment with 9 pts. (39%) concerned. For 15 patients, radiotherapy was preceded by breast and lymph node surgery. Median follow-up was 7.3 months (1.2–18.9) after the start of RT and 13.8 months after the diagnosis (6.3–23.4). Observed main toxicities were five interruptions of radiotherapy (22%); of them, two were for personal issues, and one was necessary to allow urgent neurosurgery for medullary compression and in two cases for local

treatment of grade 2 or 3 radiodermatitis. Concerning skin toxicity, in 16 cases (70%) were grade 0 or 1 radiodermatitis observed. One grade 3 occurred in a 72-year-old patient treated for a contralateral relapsing inflammatory tumor of the right breast T4dNxM1 with pulmonary metastasis. Radiotherapy was performed in the right breast and the whole lymph node areas as a neoadjuvant treatment with a linear accelerator of 6MV with standard fraction of 2 Gy in ILD. A grade 3 reaction appeared at the dose of 40 Gy requiring stopping the treatment for five fractions. This patient presented two risk factors of skin toxicity with an elevated BMI of 36 and an inflammatory tumor. The observed cardiac toxicity in two patients (9%) was an asymptomatic grade 2 decrease of LVEF requiring no treatment discontinuation, and one presented a grade 3 decrease requiring a 3-month discontinuation. Neither acute cardiac failure nor symptomatic cardiac insufficiency was reported. Their common characteristics were menopausal status and age over 50 years. Two of them had a history of right-sided breast cancer and received previous radiotherapy including the IMN and anthracyclines treatment. Patients presenting a grade 2 had a decrease of LVEF of 19% and 11% compared to the initial examination. Their LVEF remained superior to 50% and they were asymptomatic. Maintenance treatment with pertuzumab and trastuzumab was continued. A part from their age (51 and 64 years) and menopausal status, these patients had no cardiovascular risk factors. One of them was treated 3 years before for a right-sided breast cancer HER2 positive and received adjuvant chemotherapy after a breast-conserving surgery with a cumulated dose of epirubicin of 480 mg and 6695 mg of trastuzumab. She underwent previous adjuvant radiotherapy in the right breast, the IMN, and the supra- and infraclavicular lymph nodes. She presented in 2014 a diffuse metastatic relapse and had a symptomatic irradiation to [T9 to L1] vertebrae at the dose of 15 Gy in five fractions of 3 Gy with a 3D conformational technique concomitantly to the treatment with P and T. The second patient had no history of early-stage breast cancer and was treated for T4Nx M1 (mediastinal and retroperitoneal lymph node metastases). This patient underwent irradiation to the chest wall and all the locoregional lymph nodes (IMN, supra- and infraclavicular lymph nodes, axilla) after a radical mastectomy. The technique used was tomotherapy: total dose was 50 Gy. The mean dose to the heart was 6.2 Gy. The patient who presented grade 3 decrease of the LVEF was a 68-year-old woman. Her cardiovascular risk factors were menopause and previous smoking. She was treated 15 years ago for cancer of the right breast T1N1 HER2−. She underwent breast-conserving surgery and adjuvant chemotherapy with 702 mg of cumulated epirubicin. She had previous adjuvant radiotherapy of the right breast, the IMN, and the supra- and infraclavicular area. She presented in 2014 with a metastatic disease to the liver, the bone, and lungs. She had a symptomatic radiation of the left scapula and the T8 to T11 vertebrae at the dose of 15 Gy in five fractions of 3 Gy concurrent to pertuzumab and trastuzumab treatment. The technique was conformational 3D. The mean dose to the heart was 4.46 Gy. The decrease of LVEF was 25%. The nadir of her LVEF was 40% and was measured over 50% 2 months later. She remained asymptomatic and had no criteria of severe cardiac event. Two patients were presented with grade 1 radiation pneumonitis diagnosed occasionally at the CT scan; they did not require any specific treatment. She underwent radiotherapy of the right breast at the dose of 50 Gy with standard fractionation. Mean dose to the lung was 9.09 Gy. Two cases of grade 1 esophagitis were reported in this study. Eighteen patients (78%) were in good partial to complete response at the time of last follow-up clinics.

In this first study of the concurrent use of radiation therapy and pertuzumab-trastuzumab association, the observed toxicity was expected, manageable, and similar to the reported association of radiotherapy-trastuzumab alone. Results of randomized trials in locally recurrent and metastatic tumors are needed with longer follow-up and prospective design to confirm our results.

Currently there is no data about the association between radiotherapy and TDM1.

54.2 Anti-angiogenic Treatment (Bevacizumab) and Radiotherapy

In the metastatic setting, there is a little data in the literature about the association of radiotherapy and bevacizumab [44, 45], especially in the treatment of brain metastases.

Following the encouraging results of bevacizumab in combination with chemotherapy in many metastatic tumor settings, bevacizumab has been developed in the adjuvant setting in breast cancer especially in the context of the BEATRICE trial. The BEATRICE trial (NCT00528567) is a phase III trial designed to evaluate the efficacy and safety of the combination of bevacizumab and chemotherapy in the adjuvant setting in patients with triple-negative breast cancer [46]. Patients included in the trial were randomized to either the standard treatment arm comprising standard adjuvant chemotherapy alone or followed by radiotherapy according to the standard practice of each center or the experimental arm comprising standard chemotherapy combined with bevacizumab either alone or followed by radiotherapy. BEATRICE randomization was stratified according to type of surgery, lymph node status, chemotherapy, and hormone receptor status. The dose of bevacizumab administered had to correspond to the equivalent of 5 mg/kg per week, and the duration of bevacizumab therapy was 1 year. The primary objective of this study was to determine the disease-free survival in each of the two arms. Patient inclusion has ended and the trial is currently underway. During this trial, patients included in the experimental arm received bevacizumab concurrently with local ± regional

radiotherapy of the breast. However, the long-term effects of this concurrent combination on the skin, healthy breast tissues, lung, and heart included in breast and lymph node irradiation volumes are unknown. The only available data are derived from the retrospective comparative study by Goyal and colleagues based on 14 patients who received concurrent bevacizumab and radiotherapy and matched with controls [47]. The results of this study demonstrated the good safety of concurrent bevacizumab and radiotherapy with no acute locoregional toxicity ≥ grade 3 according to the CTCAE v3 scale. However, the study by Goyal and colleagues only reported the acute toxicities of the combination and no data on late toxicities are available at the present time.

The objectives of the French multicenter TOLERAB study [48, 49] were to evaluate, in the cohort of patients included in the BEATRICE trial treated by concurrent bevacizumab and radiotherapy and in the cohort of patients treated by radiotherapy alone, (1) acute locoregional toxicity, (2) the cosmetic result for patients managed by breast-conserving therapy, and (3) late locoregional toxicity. Eighty-four patients who had participated in the BEATRICE trial were included in this French multicenter cohort study between October 2007 and November 2012. The cohort without bevacizumab and the cohort with bevacizumab comprised 45 patients and 39 patients, respectively. Evaluation 1 year after completion of radiotherapy was available for all patients, and acute and late locoregional toxicities of radiotherapy were able to be compared between the 45 patients who received adjuvant radiotherapy alone and the 39 patients who received the concurrent bevacizumab and radiotherapy combination.

The baseline evaluation is comprised of recording of medical history, WHO performance status, physical examination, and a laboratory work-up. Patients were evaluated once a week during radiotherapy, 4 weeks after completion of radiotherapy, and then every 3–6 months thereafter. Data concerning the locoregional toxicity of treatment included acute radiation dermatitis, acute esophagitis, pain, and radiation fibrosis, lymphedema of the arm, ulcerations, telangiectasia, dysphagia, dyspnea, plexitis, pericarditis, and myocardial infarction. Acute toxicity was graded according to the Common Toxicity Criteria for Adverse Events version 3 or CTCAE v3. According to this system, acute toxicity is graded from grade 1 (minor toxicity) to grade 5 (death). In this study, acute toxicities were considered to be severe for grades greater than or equal to 3. In the bevacizumab arm, 67% of patients were postmenopausal. The majority of patients (62%) were between the ages of 40 and 60 years. The left breast was affected in 56% of cases. Clinical stages of breast cancer were distributed as follows: 49% stage I and 51% stage II. The most common histological type was invasive ductal carcinoma (87% of cases), histological grade was generally high (grade 3 in 85% of cases), and all patients had triple-negative breast cancer. Among the 39 patients who received concurrent bevacizumab and radiotherapy, 35 (90%) received radiotherapy to the breast alone at a median dose of 50 Gy plus a boost to the tumor bed at a median dose of 16 Gy, and 4 patients (10%) received chest wall radiotherapy at a median dose of 50 Gy. Radiotherapy of the draining lymph nodes was performed in 19 patients (49%); this radiotherapy concerned the supraclavicular nodes in 44% of cases and the internal mammary nodes in 31% of cases. The median duration of radiotherapy was 49 days for breast radiotherapy with a boost to the tumor bed ± lymph nodes and 38 days for radiotherapy of the chest wall ± lymph nodes. The median interval between surgery and radiotherapy was 184 days. Among the 45 patients who did not receive concurrent bevacizumab with radiotherapy, 38 (84%) received radiotherapy to the breast alone at a median dose of 50 Gy plus a boost to the tumor bed at a median dose of 16 Gy, and 7 patients (16%) received chest wall radiotherapy at a median dose of 50 Gy. Radiotherapy of the draining lymph nodes was performed in 21 patients (47%); this radiotherapy concerned the supraclavicular nodes in 44% of cases and the internal mammary nodes in 31% of cases. The median duration of radiotherapy was 49 days for breast radiotherapy with a boost to the tumor bed ± lymph nodes and 38 days for radiotherapy of the chest wall ± lymph nodes. The median interval between surgery and radiotherapy was 186 days. No significant difference was observed between the two arms [49]. The early and late results of the study are given in Table 54.2. Late toxicities at 1 year after the completion of radiotherapy were available for 38 patients (97%) in the bevacizumab arm and 40 patients (89%) in the arm without bevacizumab, respectively. Grade 1–2 toxicities reported in the bevacizumab arm were pain in seven patients (18%), fibrosis in three patients (8%), telangiectasia in two patients (5%), and dyspnea in one patient (3%). No grade 3–4 toxicity was observed. Grade 1–2 toxicities reported in the arm without concurrent bevacizumab were pain in six patients (15%), fibrosis in two patients (5%), lymphedema in two patients (5%), and paresis in two patients (5%). No grade 3–4 toxicity was observed. In this work studying population of the BEATRICE randomized trial, we compared the acute and late toxicity rates between the experimental arm comprising concurrent bevacizumab (39 patients) and the standard arm without bevacizumab (45 patients). A low rate of toxicity was observed in both arms, and no significant difference was observed between the two arms in terms of acute toxicities, cosmetic results, and late toxicities. These results concerning acute toxicity are therefore comparable to those reported by Goyal and colleagues while also providing an analysis of esophageal toxicity, cosmetic effects, and late toxicity [47]. Currently, the evaluation of the results at 3 and 5 years is running [48, 49]. These results of this multicenter study with 1-year follow-up indicate the acceptable toxicity of concurrent bevacizumab and locoregional radiotherapy for breast cancer. Nevertheless, these results need to be confirmed with longer follow-up. However, continuation of concurrent bevacizumab and radiotherapy cannot be recommended for metastatic breast cancer in the absence of data beyond 1 year.

54.3 New Directions: Targeted Therapy with Olaparib (PARP Inhibitor) and Radiotherapy

54.3.1 For BRCA Mutation-Positive Breast Cancer

PARP inhibition is a novel approach to targeting tumors with deficiencies in DNA repair mechanisms. PARP enzymes are essential for repairing DNA single-strand breaks (SSBs). Inhibiting PARPs leads to the persistence of SSBs, which are then converted to the more serious DNA double-strand breaks (DSBs) during the process of DNA replication. During the process of cell division, DSBs can be efficiently repaired in normal cells by homologous recombination repair (HR). Tumors with HR deficiencies (HRD), such as serous ovarian cancers and breast cancer, cannot accurately repair the DNA damage, which may become lethal to cells as it accumulates. In such tumor types, olaparib may offer a potentially efficacious and less toxic cancer treatment compared with currently available chemotherapy regimens. Olaparib (AZD2281, KU-0059436) is a potent polyadenosine 5′diphosphoribose [poly(ADP-ribose)] polymerization (PARP) inhibitor (PARP-1, PARP-2, and PARP-3) that is being developed as an oral therapy, both as a monotherapy (including maintenance) and for combination with chemotherapy and other anticancer agents. Olaparib has been shown to inhibit selected tumor cell lines in vitro and in xenograft and primary explant models as well as in genetic BRCA knockout

models, either as a stand-alone treatment or in combination with established chemotherapies. Cells deficient in homologous recombination DNA repair factors, notably BRCA1/2, are particularly sensitive to olaparib treatment. Cellular DNA is continually subject to damage, which coordinated pathways act to repair, thereby maintaining genomic integrity and cell survival [50–52]. The poly(adenosine diphosphate [ADP]-ribose) polymerases (PARPs) are a large family of multifunctional enzymes, the most abundant of which is PARP-1. It plays a key role in the repair of DNA single-strand breaks through the repair of base excisions [53, 54]. The inhibition of PARPs leads to the accumulation of DNA single-strand breaks, which can lead to DNA double-strand breaks at replication forks. Normally, these breaks are repaired by means of the error-free homologous recombination double-stranded DNA repair pathway, key components of which are the tumor-suppressor proteins BRCA1 and BRCA2. PARP inhibitors such as olaparib show promising results in clinical trials, especially in triple-negative breast (or ovarian) cancer with *BRCA* mutations [53].

54.3.2 PARP Inhibitors Activity in Triple-Negative Breast Cancer (TNBC) Without BRCA Mutation

The challenges of TNBC are in fact more fundamental than insensitivity to current available therapeutics. TNBC shares clinical and pathological features with hereditary BRCA1-related breast cancers and in sporadic TNBC; deregulation of *BRCA1* has been frequently observed together with other defects in homologous recombination pathways [54]. Preclinical studies have shown that breast cancer cell lines with a triple-negative phenotype are more sensitive to PARP1 inhibitors compared with non-TNBC cells and that PARP inhibition synergizes with gemcitabine and cisplatin in triple-negative cells but not in luminal cancers [55]. All these lines of evidence provide a strong rationale for developing a new therapeutic approach to TNBC based on targeting the DNA repair defects via PARP inhibition in these cancers that the most aggressive are the inflammatory, locoregional advanced, and metastatic breast cancer.

54.3.3 Mechanisms of Radiosensitization by Olaparib

- *Molecular mechanism—increase of double-strand breaks*:
  DNA is the principal target for the biologic effects of radiation. For radiotherapy, this comprises single-strand breaks (SSBs) and double-strand breaks (DSBs). SSBs are not directly cytotoxic but during DNA replication may generate potentially lethal DSB by collapse of stalled replication forks [56]. Radiation-induced SSBs are primarily repaired by base excision repair, of which poly(ADP-ribose) polymerase-1 (PARP-1) is a key component. PARP-1 binds to SSB, activating poly ADP-ribosylation of itself and other proteins, triggering recruitment of repair factors and release of PARP-1 from the damaged site. PARP inhibitors inhibit SSB repair, and the unrepaired SSBs generate collapsed replication forks which give rise to potentially lethal DSB, leading to radiosensitization [57].
- *Cellular mechanism—radiosensitization during the S phase*:
  Experiments using synchronized HeLa cells showed that radiosensitization induced by PARP inhibition is specific of the S phase of the cell cycle and involves stalled replication forks [58]. Under these conditions, prolonged contact with ANI ended in the formation of de novo DNA double-strand breaks hours after irradiation, evoking collision with uncontrolled replication forks of DNA lesions whose repair was impaired by inhibition of the PARP catalytic activity. The data suggest that increased response to radiotherapy by PARP inhibitors may be achieved only in rapidly growing tumors with a high S-phase content.
- *Tissular mechanism—vasoactive effects contributing to tumor reoxygenation*:
  Recently, at least two new generation PARP inhibitors (AG014699 and AG14361) have been reported to have vasoactive properties, and AG14361 has been shown to enhance the response to radiation [59, 60]. The new generation PARP inhibitors, including olaparib, are all structurally related to nicotinamide which can prevent intermittent vascular shutdown in tumors. Senra et al. showed in preclinical studies that olaparib is a more potent vasorelaxant than nicotinamide, and its effects are maintained during treatment with drug alone and when drug and radiation are combined in a fractionated treatment schedule [61].

54.3.4 Results of In Vivo Studies of Olaparib with Concurrent Radiotherapy in Triple-Negative Breast Cancer Xenograft

Results from Inserm U612 have shown that olaparib radiosensitizes TNBC models [62]. The BRCA2−/− HBCx-17 and the wild-type HBCx-12A xenografts were subcutaneously transplanted into the flanks of nude mice. In both TNBC models, individual group comparisons showed that treatment with 4-[(3-[(4-cyclopropylcarbonyl) piperazin-4-yl] carbonyl)-4-fluorophenyl] methyl (2H) phthalazin-1 alone for 4 weeks markedly inhibited tumor growth compared with the untreated controls. Treatment with radiotherapy alone also resulted in significant growth inhibition, whereas combination of 4-[(3-[(4-cyclopropylcarbonyl) piperazin-4-yl] carbonyl)-4-fluorophenyl] methyl (2H) phthalazin-1 and radiotherapy showed the best treatment response.

The association between radiation therapy and systemic treatment can be an interesting treatment option in cases with refractory and rapidly progressive disease [63].

These results have shown that this association could be an interesting therapeutic option in the breast cancer and currently two phase I studies are running in Europe: in the Institut Curie for locally advanced, metastatic TNBC and in NKI Amsterdam for nonoperable BC. These studies will be followed with great interest.

As general conclusion, we can add that new targeted treatments are coming rapidly in the treatment of breast cancer, and it is urgent to evaluate the efficacy and toxicity of their association with the radiotherapy in the clinical studies. Highly performing radiotherapy techniques must be used. Parallel biological studies are needed to find the predictors of the tumor responses.

Accelerated Partial Breast Irradiation

55

Nina N. Sanford and Alphonse G. Taghian

55.1 Rationale

Multiple randomized studies have conclusively demonstrated that adjuvant radiotherapy improves local control in patients with early-stage breast cancer who are treated with breast-conserving surgery (i.e., lumpectomy) [1, 2]. Furthermore, two subsequent trials assessing the additional benefit of adding a boost to the tumor bed showed a statistically significant reduction in ipsilateral breast tumor recurrence with greater absolute benefit in patients of younger age [3, 4]. On the basis of these randomized studies, whole breast radiation therapy over 5 weeks followed by a boost over 1 week has become a standard of care in many countries across the world.

Nevertheless, despite the many advantages of this treatment paradigm, there are also notable disadvantages to a 6-week course of adjuvant radiotherapy, notably inconvenience and cost. As a result, a proportion of patients who have undergone lumpectomy elect to forgo adjuvant radiotherapy, which can have serious consequences on their cancer-specific survival and overall survival. Two US studies showed that between 14 and 20% of women do not receive radiotherapy after undergoing breast-conserving surgery [5, 6]. In countries with scarce radiation availability, even for patients who wish to undergo radiotherapy, such a prolonged treatment course can lead to delays in initiating treatment.

One approach to overcome these concerns is to shorten the course of radiotherapy. Two large randomized trials assessing the outcome of hypofractionated whole breast radiotherapy over 15 or 16 fractions have demonstrated similar local regional relapse rates and cosmetic outcomes as compared to standard fractionation over 25 treatments [7, 8]. However, similar to whole breast radiotherapy, hypofractionated irradiation treats the entire breast resulting in unnecessary radiation to nontarget breast tissue in selected patients, as well as exposure to surrounding normal structures including the heart and lung. In addition, with the inclusion of a tumor bed boost, this treatment schedule still requires approximately 1 month of daily radiotherapy.

Accelerated partial breast irradiation (APBI) drastically shortens the radiation treatment schedule to 1 week or less by further increasing the dose per fraction. In order to safely deliver a high daily radiation dose and minimize normal tissue injury, the volume treated is reduced to the tumor bed plus a margin. The rationale for directing radiation to the tumor bed is that in patients who have undergone lumpectomy, greater than 80% of recurrences will involve the site of original disease [2, 9]. Thus, the hypothesis behind APBI is that by increasing the dose per fraction to condense treatment while reducing the irradiated volume, an excellent therapeutic ratio can be achieved. In addition to improving patient convenience and access, other potential advantages of APBI include (1) reduction in acute and long-term toxicities due to less radiation dose exposure by normal tissues (i.e., radiation pneumonitis, coronary artery disease for left-sided cancers), (2) reduction in overall treatment expenditure, and (3) eligibility in select patients who recur locally to undergo a second course of breast conservation therapy with re-irradiation (as opposed to recurrence after whole breast irradiation where mastectomy is often the only local treatment choice).

55.2 History

The first trials assessing APBI were conducted more than 20 years ago in the United Kingdom. In a large study involving 708 patients who underwent lumpectomy and were randomized to whole breast with regional nodal irradiation versus fractionated external beam electron radiotherapy to the tumor bed alone using a direct electron field, the 8-year local recurrence rate was 25% for patients treated with partial breast irradiation and 13% for patients receiving whole breast irradiation

[10]. In addition, cosmetic outcomes were worse in the APBI group with higher rates of fibrosis and telangiectasias. In a second smaller study, 27 patients who underwent breast-conserving surgery received an iridium-192 brachytherapy implant that delivered 55 Gy on a continuous basis over 5 days [11]. At a median follow-up of 6 years, local relapse was 37%. As a result of the high local recurrence rates, further research on APBI was abandoned for the next few years.

Beginning in the late 1990s, there was renewed interest in APBI with the hope that due to advancements in imaging systems, pathologic analysis, radiation treatment planning, and more rigorous patient selection, the outcomes of APBI could be significantly improved upon. These modern APBI techniques and studies will be described in further detail in subsequent sections of this chapter.

55.3 Radiobiology

Historically, assumptions regarding tumor and normal tissue sensitivity to fraction size have been derived from data on squamous cell cancers. An α-β ratio of 3 is assumed for most normal tissues, while the majority of tumors are thought to have an α-β ratio of 10. Suggestion that breast tumors may have a lower α-β ratio thus making them more sensitive to fraction size stems from the UK START A trial, which randomized women into three fractionation schedules that are isoeffective when α-β ratios of 6 and 1.8 were assumed for breast tumor and normal tissues, respectively. The three treatment regimens were 50 Gy in 25 fractions (control arm), 39 Gy in 13 fractions, and 41.6 Gy in 13 fractions, all delivered over 5 weeks. After a median follow-up of 9.3 years, there was no statistically significant difference in the rate of local-regional relapse between the 41.6 Gy and 50 Gy arms or the 39 Gy and 50 Gy arms. Normal tissue toxicities including moderate or marked breast induration, telangiectasias, and edema were less common in the 39 Gy group than in the 50 Gy group. A meta-analysis of the START A and the START pilot trial provided an adjusted α-β ratio of 3.5 [7]. The α-β ratio for late-responding breast tissues ranged from 3.5 for breast shrinkage to 4.7 for breast edema. Similarly, the Canadian hypofractionation trial randomized women to either 50 Gy in 25 fractions or 42.5 Gy in 16 fractions and also found comparable local control in both arms, suggesting a lower α-β ratio (between 3 and 4) for breast tumors [8]. There was also suggestion that hypofractionation in this study was associated with decreased acute toxicity and improved quality of life attributed to decreased skin and breast side effects, decreased fatigue, and improved convenience [12]. A recent randomized trial including 287 women comparing conventionally fractionated versus hypofractionated whole breast radiotherapy also found that rates of acute toxicity, fatigue during treatment, and at 6-month follow-up were statistically significantly lower in the hypofractionated arm [13].

Table 55.1 Comparison of BED values for various dose fractionation schedules

Protocol schedule	Tumor control (α-β = 4 Gy)	Tumor control (α-β = 10 Gy)
Standard		
2 Gy × 25	75	60
2 Gy × 30	90	72
2 Gy × 33	99	79
APBI		
3.85 Gy × 10	76	53
3.4 Gy × 10	63	46

BED biological effective dose

With a lower tumor α-β ratio, small increases in fraction size can produce significant changes in radiotherapy effect. A comparison of BED values for three standard whole breast irradiation protocols and 12 different hypofractionated APBI regimens found that assuming an α-β ratio of 10, the BED for tumor control was higher with standard fractionation [14]. However, using an α-β ratio of 4, the BED values of most APBI protocols resulted in tumor control BEDs closer to 50 Gy standard treatment, although lower than BEDs for regimens treating to a total of 60Gy or 66Gy (Table 55.1).

However, the BED equation does not take into account treatment frequency. It is hypothesized that accelerated therapies may prevent tumor proliferation and repopulation during therapy, suggesting another advantage to APBI. It is also important to note however that these calculations are based off of imperfect radiobiological modeling systems and that the BED equation, in particular, is thought to be less valuable at higher doses per fraction. The true efficacy and safety of APBI can therefore only be demonstrated through large, well-designed, patient studies.

55.4 Patient Eligibility

Appropriate patient selection is critical in determining the success of APBI. Outside of the clinical trial setting, APBI is currently restricted to patients with the low risk disease. Patient and disease characteristics often used to categorize an individual as low risk include older age, small tumor size, no extensive intraductal component (EIC), estrogen receptor (ER) positive, and node negative. These patients are felt to have some risk of harboring residual disease in proximity to the tumor bed but very little possibility of harboring residual microscopic disease in remote locations in the ipsilateral breast or lymph nodes. There is no uniform consensus on which patients are appropriate for APBI with ongoing trials seeking to better define and potentially broaden eligibility. Shown in Table 55.2 are criteria from four large organizations including ASTRO, European, American Brachytherapy Society, and American Society of Breast Surgeons. In later sections of this chapter, we contrast these guidelines to the eligibility criteria

Table 55.2 Eligibility criteria for APBI

of randomized Phase III trials, including the NSABP B39/RTOG 0413 trial, which are generally more liberal, thus allowing the inclusion of higher-risk patients.

55.5 APBI Techniques

Although all APBI treatments share the singular aim of condensing breast radiotherapy to 1 week or less by increasing the dose per fraction of radiation while decreasing the target volume, there are multiple approaches to accomplishing this goal. These methods differ in several ways including treating time, radiation dose, and, perhaps most importantly, in the volume of breast tissue irradiated. Each has distinct advantages and challenges. Often, more than one approach can be successfully employed, and the treatment of choice depends on technical availability and physician and patient preference. Currently, the four principle methods of APBI include (1) multicatheter interstitial brachytherapy, (2) balloon-based brachytherapy (MammoSite), (3) external beam radiotherapy, and (4) intraoperative radiotherapy.

55.5.1 Multicatheter Interstitial Brachytherapy

Multicatheter interstitial brachytherapy (MIB) was the first APBI technique developed and, as a result, has generated the longest follow-up data at this time. Initially, MIB was performed at the time of lumpectomy and used as a boost prior to standard whole breast irradiation. Over the subsequent decades, the technique has evolved to its current indication as the sole radiation treatment after lumpectomy.

The general strategy of MIB is to place under anesthesia multiple needles or tubes across the tumor bed. The specific catheter orientation is individualized for each tumor to use as few catheters as possible in an arrangement that is comfortable for the patient while adequately dosing the tumor. Generally, 15–25 catheters are required per patient. Image guidance, which can be achieved with ultrasound, stereotactic mammogram, or, more commonly, CT, is performed at several stages including before catheter insertion to select the optimal approach, at periodic intervals during insertion to confirm placement, and at the end of insertion to transfer to brachytherapy planning software. During treatment planning, the target volume, which is usually the tumor cavity plus a 1–2 cm margin, is delineated so that the optimal dwell times can be determined. General dosimetric goals include ensuring that at least 90% of the target receives 90% of the prescribed dose while preventing excess dose inhomogeneity by limiting the volume of breast tissue (target or nontarget) receiving 200% and 150% of the prescribed dose [19–21].

The dose can be delivered using continuous low-dose rate (LDR) brachytherapy, usually with iodine-125, or with high-dose rate (HDR) brachytherapy. HDR brachytherapy is now more frequently employed because it allows for better control of dosimetry and permits delivery of treatment on an outpatient basis. One HDR fractionation and source that is commonly used is 34 Gy in 3.4 Gy BID fractions with iridium-192. All treatment catheters remain in the patient's breast for the entire duration of the treatment course. As opposed to MammoSite and 3DCRT, MIB can be used in almost all cavity sizes, shapes, and locations within the breast, and dose distribution can be individually tailored to minimize hotspots (Fig. 55.1). Disadvantages however

include requiring specialized training with results that are highly operator dependent. In addition, the procedure is resource intensive and requires anesthesia support and occasionally time in the operating room.

In reviewing the literature on MIB summarized in Table 55.3, it is important to recognize that there are significant discrepancies in treatment techniques which have evolved considerably over time. In addition, breast imaging and pathologic analysis have also improved; thus, comparisons of study outcomes are likely not valid. Furthermore, most of the published data are from single institution Phase I/II studies.

55.5.2 MammoSite

The MammoSite applicator, another form of brachytherapy, was initially developed in the early 2000s with the goal of simplifying partial breast brachytherapy, thereby making it more accessible and reproducible. It utilizes an HDR source, usually iridium-192, at the center of an inflatable balloon applicator that is placed inside the surgical cavity following breast-conserving surgery. The device is inflated to fill the entire tumor bed and deliver a high dose of radiation that rapidly falls off covering approximately 1 cm of the surrounding breast tissue. Conformality, which describes the fit of the balloon inside of the cavity, is closely related to the degree of target coverage (Fig. 55.2). The recommended minimal acceptable coverage is D90 of 90%.

Advantages of MammoSite over multicatheter interstitial brachytherapy include that it is relatively easier to use, the dosimetry is simpler, and the insertion process is less traumatic for the patient. This simplicity however also leads to several drawbacks. Notably, the premade single catheter balloons cannot be customized for irregularly shaped surgical cavities or those too close to the chest wall or skin surface. The dosimetry in these circumstances may be unacceptable, precluding a small proportion of patients from treatment with MammoSite. This limitation has been partially circumvented via the design of elliptical shaped balloons and the availability of multiple dwell catheters.

The initial MammoSite study included 70 patients in a prospective Phase I/II trial [34]. Eligibility criteria included age ≥45 years, tumor size ≤2 cm but with post-lumpectomy cavity ≥3 cm, invasive ductal histology, negative lymph nodes, and negative margins. Patients with extensive intraductal component (EIC), with lobular histology, or with underlying collagen vascular disease were excluded. Patients were also ineligible if they were found to have cavities that were too large (acceptable diameters were 4–5 cm), had poor balloon-cavity conformance, or inadequate balloon-skin distance, all factors that would lead to unfavorable dosimetry. These anatomic variables were assessed using CT imaging after device placement. A dose of 34 Gy in 3.4 Gy twice daily fractions was prescribed to a point 1 cm from the balloon surface which corresponds to a surface dose of 225% for a 4 cm balloon. The procedure could be performed at the time of lumpectomy for patients enrolled preoperatively and up to 10 weeks after surgery. Of the 70 patients enrolled, 43 were ultimately treated with MammoSite brachytherapy. The treatment was well tolerated with the most common side effects associated with placement including mild erythema, drainage, pain, and ecchymosis. Toxicities during radiotherapy were similar and also included mild erythema and pain along with dry desquamation. At 1 month, 88% of patients had good-to-excellent cosmetic outcome. There was an association between skin spacing, defined as the distance between the balloon and the skin, and cosmesis: patients with skin spacing of 5–7 mm had higher rates of telangiectasias than those with spacing ≥7 mm (67% vs. 29%,

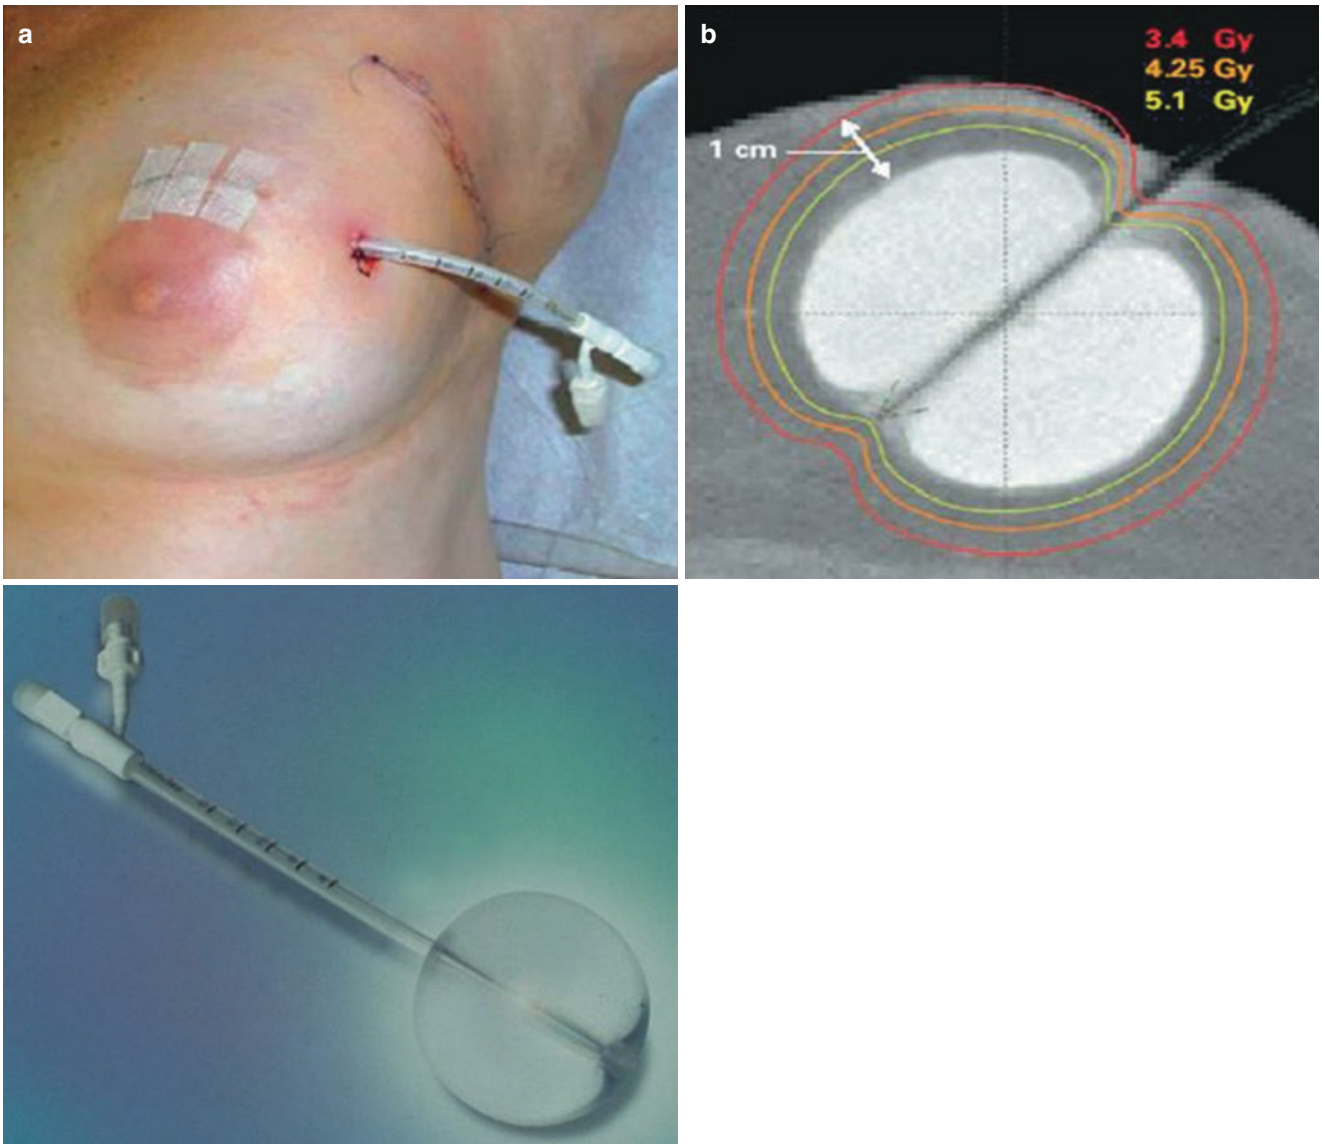

Fig. 55.2 MammoSite system showing balloon placement externally (**a**) and internally (**b**) with dosimetric coverage. The target volume, defined as 1 cm from the balloon surface, is outlined in red. Bottom image (**c**) shows the classic MammoSite applicator [22]

$p = 0.03$). The results of this pilot study lead to FDA approval of MammoSite in May of 2002.

Since that time, over 50,000 women worldwide, including a small proportion of patients with DCIS only, have been treated with MammoSite. The most significant adverse effect that has been seen with greater clinical experience is balloon rupture, with rates that have varied significantly across studies. When this occurs, the balloon is replaced, and the patient is replanned resulting in a short treatment delay. Another potential side effect is persistent seroma, which is more common in patients with higher body weight and adversely affects cosmetic outcome [70]. However, overall results using MammoSite have been excellent, as summarized in Table 55.4. Yet some critiques of these studies, in particular the largest MammoSite registry trial (1449 patients), include (1) possible selection bias due to the voluntary enrolment in the registry study, (2) potential for underreporting of toxicities and tumor recurrence because the data was gathered from multiple institutions, and (3) lack of central pathology review. Nevertheless, the results of these studies in aggregate suggest excellent efficacy and cosmetic outcomes with MammoSite as shown in Table 55.4.

Other single-entry brachytherapy applicators are strut-adjusted volume implant (SAVI) and Contura. SAVI, which was FDA approved in 2006, is a device consisting of a bundle of thin catheters that can be custom fit to the excision

cavity. Contura consists of a central lumen and four other lumens, offering a total of 40 dwell positions, encased in a polyurethane balloon. Initial reports on outcomes in patients treated with these devices show excellent local control with acceptable toxicity [44, 45].

55.5.3 External Beam Radiotherapy

External beam radiation therapy is the only noninvasive method of APBI and can be delivered using IMRT or 3D conformal techniques with photons only, combined photons/electrons, or protons. 3D conformal radiotherapy (3DCRT) with photons is currently the most popular technique for delivery of APBI. With the elimination of an additional surgical procedure, 3DCRT is more convenient and with fewer potential complications as compared to invasive techniques. Another potential advantage is improved dose homogeneity within the target volume, which may be associated with superior cosmetic results. Target localization however can occasionally be difficult, especially if the patient develops a large seroma postoperatively or conversely, if a significant amount of time has elapsed between surgery and radiotherapy such that the lumpectomy cavity has been absorbed. This occasionally results in an overestimation (less commonly, underestimation) of the clinical target volume (CTV) to ensure adequate coverage, although clips placed at the time of lumpectomy have been shown to improve the accuracy of cavity delineation [46–48]. An additional PTV margin must be added to account for chest wall movement with respiration, ultimately leading to a larger treated volume than with the other APBI techniques described.

The basic steps for designing and delivering external beam APBI, per NSABP B-39/RTOG 0413 protocol, include the following:

- *Define the clinical target volume and organs at risk on planning CT scan*. A treatment planning CT scan with the patient in the supine position is obtained. The excision cavity is delineated based on clear visualization on CT or with the assistance of surgical clips, if available. Normal structures contoured include the skin, ipsilateral and contralateral breast, thyroid, lungs, and heart.
- *Define CTV and PTV expansions to account for internal motion and daily setup error*. The CTV is a uniform 1.5 cm expansion around the excision cavity, limited to 5 mm from the skin surface and by the posterior breast tissue extent (chest wall and pectoralis muscles are excluded). A 1 cm margin is added to the CTV to create the PTV. The PTV is then copied to a PTV_EVAL which is edited to exclude the portions outside the ipsilateral breast, the first 5 mm of tissue under the skin, and, if applicable, the chest wall, pectoralis muscles, and lung.
- *Determine an appropriate beam arrangement*. Any beam arrangement and number of beams is allowed, as long as necessary dose volume constraints are met. The most common technique is via a 3-, 4-, or 5-field noncoplanar beam arrangement. No bolus to improve anterior target coverage is permitted. For target coverage, 90% of the prescribed dose should cover ≥90% of the PTV_EVAL. The dose limitations for normal tissues are as follows:
  - Uninvolved normal breast: <60% should receive ≥50% of the prescribed dose, and <35% should receive 100% of the prescribed dose.
  - Contralateral breast: no point should receive ≥3% of the prescribed dose.
  - Ipsilateral lung: <15% should receive 30% of the prescribe dose.
  - Contralateral lung: <15% should receive 5% of the prescribe dose.
  - Heart: for right-sided lesions, <5% should receive 5% of the prescribed dose, while for left-sided lesions, the volume of the heart receiving 5% of the prescribed dose should be less than 40%.
  - Thyroid: maximum point dose of 3% of the prescribe dose.
- *Prescribe treatment* to 38.5 Gy, given in twice daily fractions, separated by at least 6 hours.
- *Deliver treatment*. At a minimum, portal films or images of each beam and an orthogonal pair should be obtained prior to initiation of treatment. Orthogonal pair films must also be obtained prior to fraction number 5.

Our practice is similar to the NSABP B-39/RTOG 0413 technique with several notable exceptions. First, our preference is for two non-divergent mini-tangents delivering approximately 80% of the total dose with the rest of the dose provided by an en face electron beam. We have found that this three-field technique reduces dose to nontarget breast tissue (Fig. 55.3). In situations where the seroma is deep and would necessitate high-energy electrons (typically >20 MeV) leading to excessive dose to the lung and heart, we use the more commonly prescribed four-field noncoplanar technique. We also offer APBI over 1 week (4 Gy twice daily fractions to a total dose of 36 Gy) or 2 weeks (4 Gy once daily fractions to a total dose of 40 Gy) allowing patients to choose a schedule that is mostly convenience based. These dose fractionation regimens are based off of data obtained from a Phase I/II dose escalation study at Massachusetts General Hospital (MGH) described in Table 55.5. For treatment delivery, we use both X-ray imaging aligned to surgical clips and surface imaging with Vision RT [57] to account for more subtle changes in breast or arm positioning (Fig. 55.4).

There have been few published randomized series comparing whole breast irradiation to external beam APBI that have

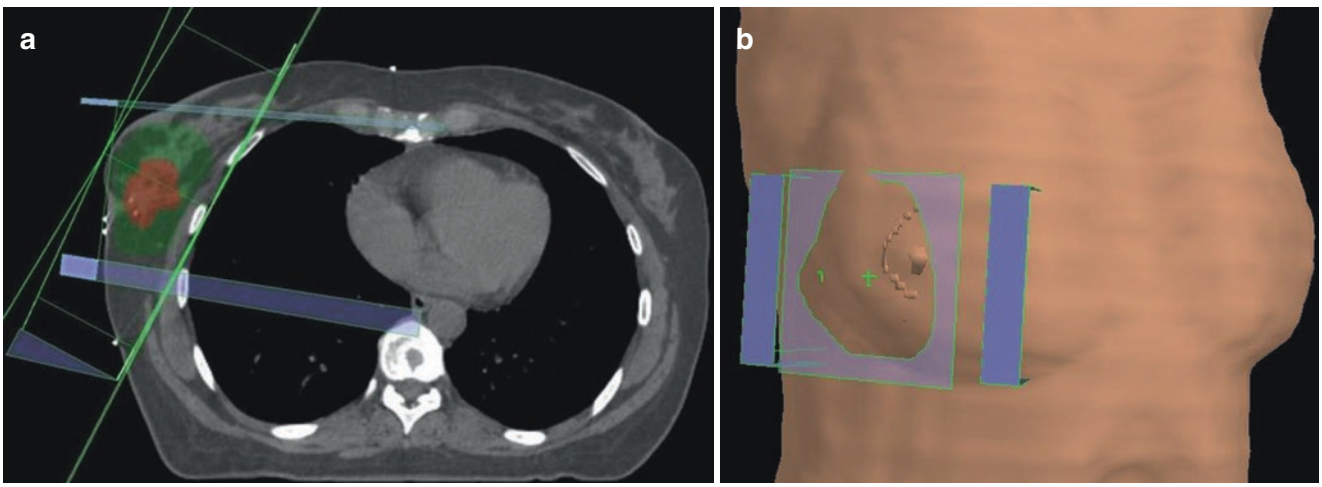

Fig. 55.3 (**a**) Axial CT image showing the use of two tangent fields with an en face electron field. A lateral wedge has been added to improve dose distribution. The seroma is shaded in *orange*, and the target volume is shaded in *green*. (**b**) Surface view of partial breast irradiation field showing en face electron field comprising 20% of the prescription dose. Two mini-tangents are also used delivery 80% of the total dose

reported local failure rates. The earliest study was conducted in the United Kingdom in the 1980s and, as described above in the introductory section, showed significantly higher local recurrence rates in the group receiving limited field treatment. Notably, no radiologic imaging was used to define the surgical cavity; thus, the target may have been missed in some patients in the APBI group. Since then, treatment planning has evolved significantly, and more rigorous patient selection criteria have been employed which has led to improved outcomes. Clinical results from select larger Phase I/II studies are summarized in Table 55.5.

As shown in Table 55.5, various dose fractionation schedules for 3D conformal APBI have been used, thus far, the majority of which have resulted in excellent local control. One dose escalation study from Massachusetts General Hospital including 323 patients treated to 32, 36, and 40 Gy in 4 Gy BID fractions showed that local failure rates were low at all three dose levels, but patients treated to 40 Gy had higher rates of fibrosis and fat necrosis [54]. Another dose escalation trial from the Institut Gustave Roussy in France comparing 40 Gy vs. 42 Gy, both in 10 BID fractions, showed both more severe early toxicities and higher rates of late toxicities with the higher dose [58]. At this time, the lowest dose needed to maintain excellent cancer-specific outcomes while optimizing cosmetic results remains unknown. The current national standard, as used in the NSABP B39/RTOG 0413 trial, is 38.5 Gy in 3.85 Gy BID fractions.

Due to the Bragg peak characteristic of proton beams allowing for preferential sparing of normal tissue proximal and distal to the target region, there has been interest in the use of proton radiotherapy for APBI. Dosimetric studies comparing proton versus photon APBI have consistently shown superior proton dose distributions [59–62]. The clinical data are more limited however and stem primarily from a few institutions including Massachusetts General Hospital,

Loma Linda, as well as MD Anderson, as shown in Table 55.5 [53, 54, 56]. Current proton protocols are actively accruing which may demonstrate a clinical advantage to protons [63].

55.5.4 Intraoperative Radiotherapy

Of all the APBI techniques, single-fraction intraoperative radiotherapy performed at the time of lumpectomy is felt by some clinicians to be the most convenient. Some clinicians have also hypothesized that immediate radiotherapy takes advantage of the well-vascularized postsurgical tumor microenvironment, thus maximizing the therapeutic effects of radiotherapy. The two most popular methods of accomplishing this is via photons (TARGIT: targeted intraoperative radiotherapy) or electrons (ELIOT: electron beam intraoperative radiation therapy) as described below.

55.5.5 ELIOT

Patients eligible for the ELIOT trial included women ages 48 and older with tumors 2.5 cm or smaller [64]. After tumor excision, intraoperative radiotherapy was delivered with a mobile LINAC with a 4–8 cm collimator using 6–9 MeV electrons. The total dose to the tumor bed was 21 Gy normalized to the 90% isodose line. The total "beam-on" time was 3–5 min. The chest wall and other normal tissues were protected with a lead/aluminum shield.

55.5.6 TARGIT

With TARGIT, radiotherapy is delivered over 20–45 min via 50 kV X-rays at the center of a spherical applicator that is temporarily sutured inside the surgical cavity [66]. The total dose is approximately 5 Gy at 1 cm (20 Gy at the surface) of the tumor bed. Patients eligible for the trial included women ≥45 years of age with unifocal invasive ductal carcinoma. Those randomized to TARGIT whose pathology revealed adverse features, including margin <1 mm, extensive DCIS, or with invasive lobular histology, were recommended to have supplemental external beam radiotherapy. Of note, to facilitate patient enrolment, the protocol was amended in 2004 to allow for post-lumpectomy randomization with the delivery of TARGIT accomplished via a second open procedure.

55.6 Phase III Clinical Trials

APBI is a promising technique yielding acceptable toxicity and potentially comparable local control to standard whole breast radiotherapy in an appropriately selected patient population. The results from the studies described above have helped to establish preliminary guidelines regarding patient eligibility for APBI. However, to fully understand the applicability of this treatment modality in early-stage breast cancer, large prospective studies are required. At the current time, results from ELIOT, TARGIT, RAPID, and GEC-ESTRO trials have been published as described below:

55.6.1 ELIOT

The ELIOT trial included 1305 women and compared intraoperative radiotherapy to standard whole breast external beam radiotherapy to 50 Gy followed by a 10 Gy boost over 6 weeks. At a median follow-up of 5.8 years, the 5-year recurrence rate for ELIOT met the prespecified threshold for non-inferiority, however was statistically significantly higher than that for whole breast radiotherapy (4.4% vs. 0.4%, $p < 0.0001$). On multivariable analysis, factors associated with local recurrence in the ELIOT group included tumor size >2 cm, presence of ≥4 positive lymph nodes, poorly differentiated tumor, and a triple-negative subtype. The authors concluded that intraoperative electron radiotherapy may be appropriate for women without these high-risk characteristics; however, given significantly increased recurrence rates compared to standard radiotherapy, further prospective validation is needed. Per the updated ASTRO 2017 guidelines, electron beam IORT should be restricted to women with invasive cancer considered "suitable" for APBI [15].

55.6.2 TARGIT

The TARGIT-A study was a randomized controlled trial comparing adjuvant external beam whole breast radiotherapy to risk-adapted intraoperative radiotherapy. The study was powered to assess non-inferiority of the TARGIT regimen of by a margin of 2.5% in local recurrence at 5 years. A total of 3451 patients were randomized and approximately 15% of patients randomized to TARGIT also received whole breast radiotherapy per criteria described above. The local recurrence in the TARGIT group was 3.3% versus 1.3% in the whole breast radiotherapy group ($p = 0.042$), meeting the prespecified threshold for non-inferiority. There were significantly fewer non-breast cancer deaths in the TARGIT group leading to a statistically nonsignificant decrease in overall mortality at 5 years, which the authors argued was due to a reduction in deaths from cardiac causes and non-breast cancers with TARGIT. Based on the results of this study, The National Institute for Health and Care Excellence (NICE) has given preliminary recommendation for the use of TARGIT in the United Kingdom. At the same time, noteworthy criticism has arisen regarding perceived flaws of the study's methodology and interpretation. These include

concerns regarding misuse of the non-inferiority criteria, lack of heterogeneity correction between the groups randomized before and after lumpectomy, and follow-up that is too short to enable conclusions on tumor control and toxicity, particularly in regard to rates of cardiac death and secondary malignancy [65]. Given these concerns, the most recently published ASTRO guidelines on APBI [15] recommend that the use of TARGIT be restricted to patients enrolled in a prospective registry or clinical trial; furthermore, these patients should meet the criteria for the ASTRO "suitable" risk category and have invasive disease only.

In addition, three large multi-institutional trials have completed accrual, and initial results from two of the studies have recently been released. To test the boundaries of patient selection, the inclusion criteria in all three studies are broader than those described in existing guidelines. Of note, none of these studies included intraoperative APBI as a treatment modality.

55.6.3 GEC-ESTRO

The European Brachytherapy Breast Cancer GEC-ESTRO Working Group randomized 1184 women aged 40 years and above to standard whole breast radiotherapy or APBI with HDR or pulse dose rate (PDR) MIB [67]. Core eligibility criteria are listed in the table below. After a median follow-up of 6.6 years, the 5-year local recurrence rates were similar between the two treatment arms (1.44% for APBI vs. 0.92% for whole breast radiotherapy, $p = 0.42$). There was also no significant difference in 5-year regional recurrence, breast cancer-related mortality, or overall survival, which was excellent for both arms at 95.55% for whole breast irradiation and 97.27% for APBI ($p = 0.11$).

55.6.4 RAPID

The Canadian RAPID trial compared whole breast irradiation delivered via a standard or hypofractionated schedule with optional boost to external beam APBI to 38.5 Gy in 3.85 Gy twice daily fractions [68]. The study accrued a total of 2135 women with characteristics described in Table 55.6. Rates of local recurrence have not yet been released; however, an interim analysis on cosmesis and toxicity was conducted after median follow-up of 36 months with results published in 2013. This analysis revealed that adverse cosmetic outcomes were increased in the APBI cohort when assessed by trained nurses (29% vs. 17%, $p < 0.001$), patients (26% vs. 18%, $p = 0.002$), and by physicians (35% vs. 17%, $p < 0.001$). In addition, although grade 3 toxicities were rare in both treatment groups (1.4% vs. 0%), a significantly higher proportion of patients randomized to APBI experienced grade 1 and 2 toxicities. The authors noted that the volume of breast receiving 95% of the prescribed dose was restricted to 35%, but this proportion may be too large in some breasts. We await the publication of mature study results on both efficacy and toxicity; however, these initial results emphasize the importance of establishing appropriate dose and volume parameters for APBI.

55.6.5 NSABP B39/RTOG 0413

The NSABP and RTOG jointly opened a US-based Phase III trial which is the largest randomized study comparing standard whole breast radiotherapy to APBI using 3DCRT, MIB, or MammoSite. The treatment modality will be determined based on physician recommendation, patient preference, and technical feasibility at each study center. This non-inferiority trial estimated a 6.1% 10-year recurrence rate for whole breast irradiation and was powered to detect a 3% higher local recurrence rate with APBI to exclude inferiority. In general, eligibility criteria for the NSABP/RTOG study are less restrictive than the GEC-ESTRO study. For example, there was no restriction on age, and patients with up to three lymph nodes involved were eligible. The original target size was 4300; however, the study was closed after a total of 4214 patients were randomized due to slow accrual. Seventy-one percent of patients were treated with 3DCRT, 23.3% with MammoSite, and 5.7% with MIB (F. Vicini, personal communication). Table 55.6 shows the eligibility criteria and results of the largest modern Phase III trials comparing APBI with whole breast irradiation.

Conclusion

Tremendous progress has been made in the field of APBI since its inception in the 1980s. Given its greater convenience, APBI has become an increasingly popular alternative to standard whole breast irradiation for women who choose breast-conserving therapy. While the earliest studies on APBI showed high local recurrence rates, with advancements in surgery, pathology, and with modern radiation techniques, both the efficacy and toxicity rates have improved significantly. Nevertheless, the majority of long-term published data on APBI are limited to single-arm prospective studies; thus, some clinicians express hesitancy in recommending APBI and the existing guidelines for off protocol eligibility remain stringent. We eagerly anticipate the near future publication of mature 620 results from multiple large randomized controlled trials including over 16,000 women [69] which will further define patient selection criteria, clarify details of treatment techniques including dosimetric parameters, and determine which APBI technique is appropriate for each clinical setting.

Table 55.6 Modern Phase III trials comparing APBI to WBI

Trial name	Location	Accrual dates	Patient inclusion criteria	Surgery	Control arm: WBI	Test arm: APBI	Median follow-up	Patient number	Local failure	Toxicity
National Institute of Oncology	Hungary	1998–2004	>40 years, invasive carcinoma, pT1, cN0, pN0-1mic, grade ≤2, unifocal, no EIC; after year 2001	Wide excision, negative margins	42–50 Gy/21–25 fx	MIB HDR 36.4 Gy/7 fx or electrons 42–50 Gy/21–25 fx	10 years	258	10-year IBTR: APBI 6% vs. 5% WBI ($p = 0.50$)	Excellent-good cosmesis: 81% APBI vs. 63% WBI ($p = 0.009$)
TARGIT-A	Multi-country	2000–2012	≥40 years, invasive carcinoma, T1 and small T2, N0/1, unifocal; no EIC, cN0	Wide local excision	40–56 Gy ± 10–16 Gy boost	50 kV X-rays: 5–7 Gy at 1 cm/1 fx	2 years	2232	4-year IBTR 1% APBI vs. 1% WBI ($p = 0.41$)	Skin breakdown or delayed wound healing: 3% APBI vs. 2% WBI ($p = 0.155$); RTOG grade 3/4 toxicity: 1% APBI vs. 2% WBI ($p = 0.002$); seroma requiring >3 aspirations: 2% APBI vs. 1% WBI ($p = 0.012$)
ELIOT	Italy	2000–2007	>45 years, invasive carcinoma tumor <2.5 cm	Quadrantectomy and ALND or SLNB	50 Gy/25 fx + 10 Gy boost	Intraoperative electrons: 21 Gy/1 fx	5.8 years	1305	5-year same quadrant failure: 3% APBI vs. 1% WBI; 5-year elsewhere failure: 2% APBI vs. 0% WBI	Overall toxicity less with APBI (skin erythema, dry skin, hyperpigmentation, breast edema, breast itching); WBI and APBI equivalent for skin atrophy, fibrosis, retraction, pain, burning; higher rates of fat necrosis and keloids seen with APBI
RAPID	Canada	2006–2011	≥40 years, DCIS or invasive carcinoma if tumor ≤3 cm, pN0	Breast-conserving surgery (BCS) with negative margins, negative ALND or SLNB	42.5Gy/16 fx or 50 Gy/25 fx (if large breast size) ±10 Gy boost	3DCRT 38.5 Gy/10 fx BID	Not reported	2135	Pending	3-year nurse-assessed poor-to-fair cosmesis: 29% APBI vs. 17% WBI ($p < 0.0001$); grade 1/2 late radiation toxicities increased with APBI vs. WBI; grade 3 toxicities rare in both groups (1.4% APBI vs. 0% WBI)

NSABP B39/ RTOG 0413	United States	2004–2013	All ages, DCIS or invasive carcinoma if ≤3 cm, pN0-N1, ECE negative	BCS with negative margins	50–50.4 Gy/25–28 fx ± boost to 60–66.6 Gy	3DCRT 38.5 Gy/10 fx BID, MIB 34 Gy/ 10 fx, MammoSite 34 Gy/10 fx	Pending	4216	Pending	Pending

Intraoperative Radiotherapy with Electrons (ELIOT)

56

Maria Cristina Leonardi

56.1 Introduction

Intraoperative radiotherapy (IORT) refers to the delivery of irradiation during a surgical procedure, immediately before or after the removal, radically or not, of the tumor mass. The IORT in single fraction can represent the whole treatment, or it can act as an anticipated boost to the most critical areas, followed by completion external radiotherapy.

The advantages of IORT are represented by:

- Direct visualization of the target area, allowing for maximum precision in delivering the treatment
- Sparing the surrounding structures and organs, by displacing or shielding them
- Delivering a single high dose in concomitance with surgery, possibly preventing repopulation from the neoplastic clones in the interval between surgery and subsequent adjuvant irradiation
- Better integration of radiotherapy with systemic treatment
- Shortening the whole radiation treatment, with significant impact on workload of radiotherapy (RT) centers, overall costs, and patient convenience
- Homogeneous dose distribution

These advantages can be applied to the treatment of early-stage breast cancer (BC). In the modern era, IORT is included among the accelerated partial breast irradiation (APBI) modalities, as sole treatment [1].

IORT can be performed by means of megavoltage electrons and kilovoltage photons. This section addresses IORT with intraoperative electrons (ELIOT).

M.C. Leonardi
Radiotherapy Division, European Institute of Oncology, Milan, Italy

56.2 Brief History

In 1906, the first intraoperative radiation treatment was performed on a pelvic tumor surgically exposed and submitted to dermopexy, by using low-energy X-rays, by Carl Beck [2]. It consisted actually in external roentgen treatment of internal structures and was carried out several times. The need of bringing tissues directly in contact with the radiation source came from the fact that deep-seated tumors challenged the delivery of high dosage while keeping the morbidity of treatment low, at that time when only low-energy photons were available. It was only several years later that the concept of IORT as a single fraction immediately after tumor removal emerged, but the technical difficulties of the procedures still restricted its widespread use [3]. The intraoperative techniques continued to be refined over the subsequent years, with the introduction of dedicated applicators and equipment. At the end of the 1940s, Fairchild and Shorter combined IORT with adjuvant external beam radiotherapy for inoperable gastric cancer [4], demonstrating the feasibility of integrating the two modalities. In the 1960s, Abe and collaborators at Kyoto University Hospital in Japan [5] started using IORT with electrons as the sole treatment, using doses of 20–40 Gy, which reduced the exit dose to normal tissues, introducing the advantage of megavoltage intraoperative irradiation over orthovoltage irradiation. Later on, in the 1970s in the USA, the role of IORT with electrons as a boost was investigated, followed by external beam doses. In the early 1980s, interest in IORT was also shown in Europe [6].

However, some logistical difficulties still limited the application of IORT. Patients with an open surgical wound and under anesthesia had to be moved from the surgical theater to the radiotherapy department, where the linear accelerator was located, with concerns related to sterility, anesthetic surveillance, and lengthening of the surgical time.

In the mid-1990s, the development of miniaturized mobile accelerators, which are placed directly in the operating theater with no need of special structural modifications for radioprotection, dramatically facilitated the procedure and

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_56

opened the way to a more extensive use of IORT. These dedicated linear accelerators of reduced weight and size produce electron beams with energies nominally comprised in a variable range from 3 to 12 MeV and are characterized by high-dose rates, which reduces the duration of the treatment to a few minutes.

The electron beam is collimated by means of applicators of cylindrical geometry, made of perspex or plastic material, whose sterile terminal part, during treatment, is placed in contact with the tissues to be irradiated. The components are made of materials which minimize the production of bremsstrahlung X-ray and scattered radiation in the surrounding environment, thus limiting the precautions linked to radioprotection.

The main fields of application of IORT consist of rectal, gastric, gynecologic cancers, and sarcomas. Reports on the use of IORT in breast cancer are less numerous. First experiences in Europe and the USA date back to the early 1980s, focusing on the use of IORT as a boost in combination with breast-conserving surgery. The feasibility of IORT was assessed on the basis of postoperative recovery, tolerance of the subsequent postoperative RT, cosmetic results, and local control. Highly positive results were reported in the first series of patients during the 1990s, showing a great potential for a larger application of IORT in breast cancer. In 1998 the International Society of Intraoperative Radiation Therapy (ISIORT) was set up to promote basic and clinical research programs and develop cooperative studies involving the use of IORT. Currently numerous centers worldwide are affiliated to the ISIORT [7]. In 2006 the European section of ISIORT (ISIORT-Europe) was established.

56.3 ELIOT in Breast Cancer

56.3.1 Intraoperative Procedures

After the excision of the breast tumor, the surgeon mobilizes part of the remaining breast around the tumor bed by separating the deep side from the fascia of the pectoralis major muscle and the superficial side from the subcutaneous tissue at the level of the anterior adipose lamina. To protect the chest wall and the deep-seated thoracic organs, a dedicated aluminum-lead shielding disk, available in various diameters, is placed between the gland and the pectoral muscle (Fig. 56.1). The breast anatomy is temporarily restored by bringing together the section areas of the excision with a line of sutures, in order to expose the most homogeneous surface to the radiation beam. The electron beam energy is selected in accordance with the thickness of the target tissue, which is measured with a needle and a ruler. The irradiation is delivered through Perspex cylindrical applicator with different diameters, from 3 to 12 cm, either flat or beveled (Fig. 56.2).

Fig. 56.1 After tumor removal, an aluminum-lead disk is placed over the pectoralis major fascia and under the gland, to shield the underlying chest wall structures

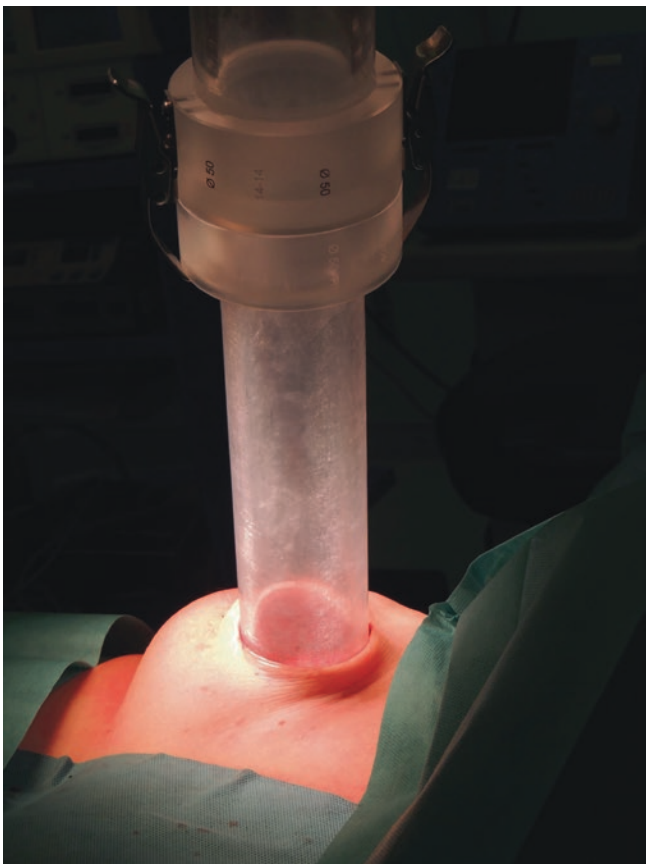

Fig. 56.2 The applicator is inserted through the surgical breech directly in contact with the breast tissue

The applicator is chosen in order to guarantee the proper coverage of the entire target volume, which is an area of 4–6 cm of diameter around the surgical sutured breech, depending on the tumor size and location. The applicator,

Fig. 56.3 The mobile linear accelerator in the operating theater, ready to deliver intraoperative radiotherapy

attached to the gantry, is placed directly in contact with the breast gland ("docked"), moving the linac by remote control (Fig. 56.3). If the operating theater walls are not structurally shielded, mobile barriers are positioned around (2-cm-thick lead shields, 100 cm long and 150 cm high) and beneath the operating table (primary beam stopper, a trolley-mounted 15-cm-thick lead shield) to provide a good shielding of X-rays scattered by the patient, the components of the linear accelerator, and the table itself. The whole irradiation lasts about 2 min. After delivery of the dose, the applicator is removed along with the shielding disk by undoing the temporary sutures, and the incision is closed again in the conventional fashion [8–10]. Some tumor locations are not suitable to be treated with ELIOT due to insufficient residual

breast parenchyma or the marginal localization, such as the axillary tail, the inframammary fold, or close proximity to the skin.

Among all the perioperative radiation techniques, namely, multicatheter brachytherapy, endocavitary brachytherapy, orthovoltage system, and ELIOT, the latter one ensures the best homogeneity of dose distribution within the planning target volume. In addition, the average dose delivered to the target volume by ELIOT was the closest to the prescribed dose, while the average dose outside the target was the smallest, obtaining the best dose sparing of the surrounding tissues. However, ELIOT, using a round central applicator, presents a strictly centric dose falloff, which makes it less adaptable to irregular-shaped target volume. This symmetric spatial dose delivery does not take into consideration the irregular spread of microscopic disease and the variability in surgical margin distance from the gross tumor, which only becomes available on the final histologic report [11].

ELIOT demands good multidisciplinary collaboration and quality assurance protocols, which define the organizational and operational aspects of the procedure [12, 13]. Continuous training for the personnel involved with a clear definition of roles and responsibilities, strict program of quality control for the equipment concerning all the physical and dosimetric characteristics of the electron beam, and guidelines to define patient selection, and prescription dose criteria must be established in each RT center [14].

In vivo dosimetry, which is routinely used in external RT, can be performed also for ELIOT, taking into account the particular conditions occurring in the operating room (need of sterility, field perturbation, etc.). By using radiochromic films to measure the entrance dose, although not giving an immediate redout of the dose, the agreement between measured and expected dose can be checked. Also a real-time procedure with micro-MOSFET detectors seems to be feasible and reliable, although with some technical limitations [15, 16].

56.3.2 Dosimetric Considerations

Biological equivalent dose (BED) is a measure for comparing the expected biological effect of different fractionations. The BED is given by

$$BED = \frac{nd\left[1+d\right]}{\alpha / \beta}$$

where n and d are the number of fractions and dose per fraction, respectively, and α/β ratio is the fractionation sensitivity.

When a tissue receives a higher dose than that prescribed, an increase in BED occurs with potential worsening of normal tissue toxicity. This effect is known as "double trouble" when conventional fractionation of 2 Gy is used, but it is even more problematic ("triple trouble") if larger dose/fraction is given, because a greater increase in BED results [17, 18].

The BED values of most APBI protocols resulted in tumor control BEDs lower than 60-Gy conventional schedule, being around 50 Gy given in 2 Gy/fraction. The critical organs' BED values were lower than the standard schedule with regard acute toxicity and roughly equivalent for late toxicity [19]. Conversely, when IORT was considered in comparison with the 60-Gy conventional fractionation, both the tumor and the normal tissue BEDs were higher. In particular, the normal tissue BED was as high as the double compared to 60 Gy standard fractionation (241 Gy vs. 120 Gy, using α/β ratio of 2 Gy). In theory, an excess in normal tissue damage by 21 Gy IORT would be expected due to a saturation of the repair mechanisms, but so far there is no evidence of severe side effects in the clinic.

The mathematical model used to derive the BED is based on the linear-quadratic (LQ) formalism: i.e., the effect of any single dose of RT depends on a weighted sum of the dose (with weighting coefficient α) and of the dose squared dose (with weighting coefficient β).

The LQ equation is the most used and the simplest model for calculating isoeffect doses for different fractionations. There are some concerns regarding whether LQ model can describe dose responses in the dose range of hypofractionated schedules. Based on experimental and empirical observations, LQ model is predictive of dose-response relations in the dose per fraction range of 2–10 Gy. Above 10 Gy, the model seems to become less accurate, but still acceptable for dose per fraction of 15–18 Gy. For ELIOT full dose of 21 Gy, LQ model should be not adequate for predicting fractionation effects. Moreover, the value of α/β ratios is not given once and for all, but must be fitted on clinical data and differ for different endpoints. Even for a single endpoint, wide confidence intervals of the α/β ratio are reported in literature.

In addition, most APBI schedules influence the biological mechanisms of cell response to radiation, represented by the 5Rs (repair, redistribution, reoxygenation, repopulation, radiosensitivity) [20, 21]. Although the tumor BED for IORT 21 Gy is higher than that of standard schedule (131 Gy vs. 90 Gy, using α/β ratio of 4 Gy), the single fraction delivered at a high-dose rate does not allow the reoxygenation effect and the redistribution of cells through the cell cycle. As a result, the less radiosensitivity might affect the local control [22]. On the other hand, the delivery of a high dose immediately after surgery might interfere with the tumor microenvironment and prevent repopulation from the neoplastic clones

in the interval between surgery and subsequent adjuvant irradiation [23].

Regarding ELIOT as the sole treatment, virtually all the clinical studies use 21 Gy as standard dose. The most common point of prescription is at the isodose of 90%, while some authors prefer at the depth of maximum dose (Dmax). The biological equivalent dose is felt to be 1.5–2.5 times higher than the dose delivered with external beam RT [24]. By applying the LQ model [25], using α/β ratio of 4 Gy for breast tumor, the single dose of 21 Gy appears to be equivalent to 65 Gy given with 2-Gy fractionation.

Regarding ELIOT as a boost, a wide variety of doses are described in the literature, mostly ranging from 6 Gy to 15 Gy. By applying the linear quadratic model, using α/β ratio of 4 Gy for breast tumor, the equivalence to the 2-Gy schedule for such a dose range falls in between 11 and 37.5 Gy.

From 2007 the ISIORT-Europe centers were asked to fill in an IORT registry available at the ISIORT website with clinical and technical data of patients affected by any type of cancer treated with IORT either with electrons or low-energy photons. Regarding breast cancer, data from 2395 patients were collected, providing an insight on the European clinical practice. Only one third of the patients entered clinical trials for the single dose, and even fewer in case of boost. IORT dose used as single treatment was in the range of 18 Gy (8%), 20 Gy (23.8%), and 21 Gy (71.1%), while IORT boost ranged between 8 and 12 Gy [26].

56.4 ELIOT as the Sole Treatment

The rationale of APBI is based on the fact that the majority of residual neoplastic cells are in the vicinity of the primary tumor, after breast-conserving surgery (BCS). Data from mastectomy studies showed a relationship between the index tumor and the occult multifocal and multicentric malignant disease. In the study performed by Holland [27] on tumors 4 cm or less in diameter, in 90% of cases, neoplastic foci were restricted within 3 cm from the edge of the index tumor. This pathological finding is supported by the clinical evidence that the majority of local relapses, after conservative treatment, arise in close proximity to the primary tumor [28, 29]. Therefore, in selected patients, limiting the radiation target volume to the area at higher risk should achieve local control equivalent to whole-breast radiotherapy (WBRT). Over the past 10–15 years, the partial breast radiation has been gaining ground in the treatment of early breast cancer. Among the various APBI modalities, ELIOT is an attractive approach and offers a number of advantages, but the real challenge now is to be able to select patients who would benefit most from this intraoperative modality.

The possibility of replacing the entire treatment of 5–7 weeks with a single session carries a positive impact on medical and social costs of treatments. Cost analysis studies demonstrated the cost-effectiveness of IORT as a single procedure over a long course of WBRT [30]. Even taking into account the capital investment for the equipment, IORT itself is a cost-saving procedure and provides greater quality of life. However, a warning comes from the higher risk of local relapse compared to whole-breast radiotherapy, which eventually leads to increased overall costs, jeopardizing its cost-effectiveness. A careful patient selection is advocated to maintain the economic advantage.

56.4.1 An Overview Across the Literature

In virtually all the clinical trials, ELIOT full dose was given in peri- or postmenopausal patients. Across the literature, the minimum age for APBI was 45 years, but most studies included patients aged 48 and over, while only one study considered eligible patients from the age of 40. At the study conducted at the University of Verona, Italy [31, 32], patients over 60 were enrolled, whereas Lemanski investigated the feasibility of IORT full dose in patients aged ≥65 in a small phase II trial conducted in Montpellier, France (the RADELEC trial) [33, 34]. The RADELEC trial was dedicated to very low-risk tumor profile: T1N0M0, unifocal, ductal invasive, positive estrogen status, and age ≥65 years old. Forty-five patients entered the study. The median age was 72 years. Four patients had local events (three in the same quadrant as the index tumor), with a median follow-up of 72 months, and underwent salvage standard mastectomy. Among patients treated off-protocol at the European Institute of Oncology (IEO), Milan, Italy [35], age under 50 emerged as a significant factor for local recurrence. Due to the limited flexibility of ELIOT field correlated with the surgical breech extension and the available collimators, ideally the maximum tumor size should be 2 cm. Tumor greater than 2 cm was found correlated with local relapse in the ELIOT randomized phase III trial carried out at IEO, Milan [36], but this study paid the price of having used too small collimator size (4 cm as median diameter). In the study from the University of Verona [31], tumors larger than 2 cm were included, but a median collimator size of 6 cm was used, and care was taken to ensure that the diameter was roughly 2 cm greater than the largest tumor dimension. The eligibility criteria included ≥50-year-old patients, with tumor size of ≤3 cm, any grade, any estrogen receptor status, unifocal ductal carcinoma, and radically excised. At a median follow-up of 62 months, 4/226 patients developed local recurrences. Mussari and colleagues from Trento, Italy [37], reported on 47 patients treated with three different dose levels: 20 Gy (at 90% and 100% isodose), 22 Gy (at 100% isodose), and 24 Gy (at 100% isodose). The eligibility criteria included age >45 years, T1N0 up to 2 cm,

clinically negative axillary nodes, G1-G2, positive hormonal status, and no intraductal component at preliminary biopsy. After median follow-up of 48 months, no local relapse was found. The collimator diameter was 5–6 cm. The most common applicator used in the study from Brussels, Belgium [38], was of 5 mm in diameter. The investigators tried to adapt the intraoperative planning target volume to the tumor size, by applying the rule of increasing the field diameter by 4 cm compared to the tumor diameter. Therefore, for pT1a tumor, the field size was at least 36 mm, while for pT1c tumor, the field size was 46 mm. One local recurrence occurred in a quadrant of the breast not originally involved. The actuarial rates for disease-free survival and overall survival and disease-specific survival were 97.6%, 98.9%, and 98.9%, respectively. Five-millimeter diameter was also used by Osti and colleagues from Rome, Italy [39], who evaluated the effectiveness and the tolerance of 21-Gy full dose (prescribed at 90% or 100% isodose curves) in 110 patients, with the same inclusion criteria as ELIOT trial (tumor size <2–5 cm, age >48 years, postmenopausal status). Three local recurrences (2.7%) occurred with actuarial local control rate at 2 and 3 years of 98.4% and 94.5%, respectively. Out of three local relapses, two were true recurrence (1.8%) and one was suggestive of new ipsilateral tumor.

Beyond the width of the intraoperative radiation field, another critical issue regards arranging the cylindrical applicator so that the central axis coincides with the center of the original tumor site. Not always surgical excision has the lump perfectly at the center of the breech, and, once the breast is temporary reconstructed, the collimator cannot ensure equidistant margin from the former tumor site [40].

To address the problem of the correct identification of the tumor bed once the tumor has been excised, the group from University of North Carolina adopted the approach of delivering ELIOT before tumor removal [41, 42]. In this series of 53 patients, aged ≥48, with invasive ductal carcinoma, ≤3 cm, nodal negative, a single dose of 15 Gy was given to the intact tumor, before excision. Median FU was 69 months. A total of eight local recurrences (five of them were true recurrences) for a crude rate of 15.1% were observed. By applying the ASTRO Accelerated Partial Breast Irradiation Consensus Statement Criteria [43], the local event rates were 5% in the suitable, 27% in the cautionary, and 0% in the unsuitable group, without statistically significant difference. The overall survival was 94.45 and the breast cancer-specific survival was 100%.

Few studies did not consider poorly differentiated tumors (grade 3) as eligible for ELIOT [37]. In the ELIOT phase III randomized trial [36], grade 3 tumors were predictors for local recurrence. In the University of Verona study [31], which included any grade, two out of the four locally relapsed tumors were of grade 3.

Estrogen receptor status was predictor of local failure in the ELIOT phase III trial [36], but it was not a uniform criterion of exclusion in all the studies.

Histology other than ductal carcinoma was excluded in some studies [31, 34, 44] and included in others, without detecting significant differences [37–39]. In the ELIOT phase III study [36], the extensive intraductal component (EIC) did not result in increased risk of local relapse. Other trials [31, 34, 39] did not consider EIC among the eligibility criteria for ELIOT.

The eligibility criteria of majority of the studies included clinically negative axillary nodes. The study carried out by Cedolini and colleagues from Udine [44], Italy, on 77 patients included among the inclusion criteria N0 or N1mi along with ductal histology, size <3 cm, free margin of >5 mm, and age ≥48 years. At 6 years of follow-up, 2% of local recurrences were described, distant from the index tumor site. However, although clinically negative, some patients turned out to be nodal positive on the final histologic analysis. In the ELIOT randomized phase III trial [36], more than three positive nodes was correlated to an increased risk of local failure. This correlation seemed to disappear in case of limited nodal involvement. In fact, the patient group from the University of Verona study [31], patients having 1–2 positive nodes (22.1%), and the patient group from Udine [44] with minimal nodal involvement (4.1% N1mi and 1.4% pN0i+) did not present any increase in risk of local failure.

56.4.2 The IEO Experience

The IEO extensively developed and implemented this modality of APBI, going through a number of phases aimed at clinical validation of the procedure.

Phase I/II dose escalation. The study began in July 1999 and was closed in April 2000. The primary endpoint was the assessment of tolerance of progressively increasing doses of ELIOT. The first ten patients received an intraoperative boost dose of 10 Gy followed by external beam RT to the whole breast up to 44 Gy in 22 fractions. In seven patients, the boost dose was increased to 15 Gy, while the whole breast received 40 Gy in 20 fraction with external RT. The remaining patients were treated with ELIOT alone, with three different dose levels, 17 Gy (8 patients), 19 Gy (6 patients), and 21 Gy (24 patients), prescribed at Dmax in all the cases. No major acute and intermediate toxicity was observed during a relatively short follow-up. One patient treated with 21 Gy developed an infection, while one patient treated with 10 Gy boost suffered from severe fibrosis. One local relapse was observed after 17-Gy full dose, and one patient in the boost group had bone metastases.

Phase II study. From May to November 2000, 50 additional patients were treated with the single dose which was

prescribed at the 90% isodose. This change in dose prescription increased the Dmax dose from 21 to 23.2 Gy, because it was observed that a small percentage of patients with large breasts had a slight underdosage of the deep part of the target tissue. The aim was to assess the acute and intermediate toxicity. Acute toxicity was low: 15 cases had signs of moderate mammary fibrosis and 4 cases had liponecrosis, in line with the relevant literature. Five cases developed local relapse, two of them in the same quadrant as the primary tumor [29].

Phase III study. The results of the phase I–II studies laid the foundation for the prospective, randomized phase III study (ELIOT trial) designed to assess the equivalence in efficacy between the postoperative conventional radiotherapy and ELIOT full dose (21 Gy).

The randomized phase III trial started in 2000 after being designed in 1999 [36]. The eligibility criteria were very simple and were based mainly on clinical, radiological criteria and on cytology. The trial randomized 1305 patients aged over 48 with tumors smaller than 2.5 cm between WBRT (50 Gy + 10 Gy boost) and a single fraction of 21 Gy directed to the tumor bed using intraoperative electrons. Available for the analysis were 601 and 585 patients in each arm. The two arms were well balanced with each other; only an excess of grade 1 tumors was seen in the IORT arm.

The primary endpoint was local recurrences, which was defined as a sum of local recurrences at the lumpectomy site ("true") and second ipsilateral tumors ("elsewhere") occurring in any breast quadrant. This was an equivalence trial, and the prespecified equivalence margin was a 7.5% rate of local recurrence in the ELIOT arm, assuming a 3% rate of local recurrence in the WBRT arm. After medium follow-up of 5.8 years, ELIOT patients had a higher 5-year recurrence rate than WBRT patients (4.4% vs. 0.4%, $p < 0.0001$). As 60% of local relapses in the ELIOT trial occurred near the primary tumor site, this observation called for a comment on radiation field size. Median applicator size of 4 cm may have been too small to adequately cover larger tumors. Tissues at the periphery of these smaller applicators may have been inadequately irradiated.

In addition, regional lymph node relapse was significantly greater in the ELIOT group, probably due to the lack of tangent field contribution. In contrast, there was no significant difference in the 5-year rates of contralateral breast cancer, distant metastases, breast cancer-specific mortality, and overall survival between the two groups.

For patients in the intraoperative radiotherapy group, the characteristics associated with local relapse were analyzed, to allow identification of patients who might benefit from subsequent whole-breast irradiation.

In multivariable analysis, tumor size greater than 2 cm, the presence of four or more positive lymph nodes, a poorly differentiated tumor, and triple-negative subtype roughly doubled the risk of local recurrence. In fact, the presence of one or more of these risk factors brought up the 5-year local recurrence rate to 11.3%. It is important to note that the ELIOT protocol did not account for adverse final pathology findings, so that no additional treatment was delivered in case of disappointing final histologic report.

All the patients who wished to undergo IORT but did not fulfill the eligibility criteria to enter the phase III randomized trial were treated apart and formed the so-called out-trial population that provided very interesting results. A total of 1822 patients treated off-protocol was analyzed [35]. In this group, the rate of nodal positivity was relevant. At median follow-up of 4 years, cumulative incidence of local recurrence was 3.6%, and dividing it into true and elsewhere recurrence, the rate was 2.3% near or at the original tumor bed and 1.3% elsewhere, very similar to the rate of contralateral breast cancer. The 5-year and 10-year survival was 97% and 90%, respectively. At the multivariate analysis, predictors of local events were young age, namely <50, tumor size of >2 cm, and unfavorable subtypes. To help physicians to select the proper patients for APBI, the American and European radiation oncologists provided some guidelines which stratify patients into three subgroups defined as suitable, to be treated with caution or unsuitable for APBI [43, 45]. These guidelines are based on clinical and histopathologic factors known to be predictive for local recurrence, although some other important features, as Ki-67 or HER2, were not included. Although it is challenging to apply the ASTRO guidelines in the case of ELIOT, because the comprehensive pathologic view is not yet available while delivering intraoperative irradiation, any efforts must be made in collecting as much information as possible in the preoperative setting. It is of utmost importance that core needle biopsy and intraoperative frozen section assessment can detect the most pertinent pathologic information either before or at the time of surgery.

Categorizing out-trial patients into the ASTRO and ESTRO groups [46, 47], ASTRO recommendations well defined the risk groups with statistical differences in the rate of local failure among the three groups. The 5-year rate of ipsilateral breast recurrence for suitable, cautionary, and unsuitable groups was 1.5%, 4.4%, and 8.8%, respectively ($p = 0.0003$). Conversely, ESTRO recommendations, that are less strict than ASTRO, failed to do so. ESTRO criteria identified the good candidates, who experienced 1.9% rate of local relapse, but did not differentiate the intermediate ("possible candidates") and the high-risk ("contraindications") patients, who experienced 7.4% and 7.7% rates of local relapse, respectively. Breaking down the cumulative rate of local failure, in the low-risk group, the rate of true and elsewhere failure was very low (1.6% and 0.6%, respectively), and this category can be safely treated with ELIOT, while the intermediate- and high-risk groups showed a high incidence of both true and elsewhere recurrences (4% and 3.3% and

4.7% and 3%, respectively) that probably only WBRT can optimally handle.

A post hoc analysis conducted among in-trial patients [36] confirmed the effectiveness of ELIOT in the suitable category according to ASTRO criteria 2010. Less than 25% of the analyzed patients fell into ASTRO's suitable category for APBI [43]. In fact, categorizing the patients enrolled in the randomized trial into the three ASTRO groups, the suitable ones fared well, irrespective of the radiation modality. In the study from the University of Verona [32], three out of four failures reported did not meet ASTRO suitable guidelines for APBI. It proves that a proper selection can bring positive results. The strict selection can bring to a drastic reduction in the number of patients fully suitable for ELIOT. The group from Genoa, Italy, applied two-step decision-making procedure: the first decisional step was made after diagnosis and staging and the second one during the surgical procedure on the basis of intraoperative tumor information. In their experience, the ultimate rate of patients deemed good candidate for IORT was 43% [48].

56.4.3 Cosmesis and Side Effects

So far, reports across the literature have shown that ELIOT presents low acute toxicity and acceptable late toxicity. Cosmesis has been scored as good to excellent in the majority of patients. In fact, all the studies describing aesthetic outcome, cosmesis was judged good or excellent in 92–95.5% of the cases [37–39, 49]. The most common side effect reported was breast fibrosis. The severity of fibrosis was described using different scales. Among 1822 out-trial patients, breast fibrosis was scored by using four-point scale (none, light, moderate, and severe). Breast fibrosis was detected in 34 (1.9%) and was scored as severe in 2 of them, while moderate skin retraction was observed in 14 (0.6%), after median follow-up of 36 months [35]. In a small group of 119 patients treated at IEO off-protocol, with a longer follow-up of 71 months, fibrosis was scored according to LENT-SOMA scale [49]. Fibrosis was grade 2 in 32% and grade 3 in 6%. Light persistent or mild intermittent pain was reported in 3.3% of the cases. By applying the LENT-SOMA scale, Philippson and colleagues from Brussels observed late toxicity in 17.1% of the patients who were given ELIOT 21 Gy (90% isodose). Fibrosis was grade 1 in 8.3% and grade 2 in 3.4%. Grade 1 atrophy was described in 5.4% [38].

In the French study by Lemanski [34], side effects were scored using the CTV v.3.0 scale. The study population included elderly patients, who are known to be susceptible to experience worse cosmetic results due to the increased amount of fatty tissue replacing glandular parenchyma [50]. Fat necrosis was frequent: it was observed in 71% of patients, corresponding to a palpable fibrosis in the ELIOT area in 40% of the cases. Ten patients suffered from late grade 1 breast pain and one experienced a rib fracture. Other studies reported lower incidence of radiological liponecrosis [37, 51].

Using the RTOG/EORTC scale for late toxicity, in the study from Trento [37], fibrosis was reported of grade 2 in 30% and of grade 3 in 2% of the cases. A minority of patients complained breast pain (2.1%). In the study from Rome [39], fibrosis was defined as mild in 4.5% of patients, and 5.5% had moderate skin retraction. The authors noticed that over time there was a tendency of gradual attenuation in the severity of fibrosis.

The most common postoperative complications reported in the studies included edema (1.5%), hematoma (1.5–12%), seroma (8%), light to moderate pain (1.3–14%), wound complications like dehiscence, delayed cicatrization (1–7%), and infection (0.4–2.3%) [31, 36, 38, 49]. Clinical liponecrosis, which was a localized collection of brown fluid with skin erythema, was observed in 2–15.5% [36, 37, 39].

In the study from the University of Verona, at 6 months after IORT, 31.4% presented breast asymmetry involving ≤1/3 of the gland, while in 8.4% of the patients asymmetry was greater than one third of the breast volume.

Pulmonary fibrosis was uncommon among IORT patients, because of the aluminum-lead shielding disk beneath the reconstructed gland [52].

56.5 ELIOT as a Boost

56.5.1 An Overview Across the Literature

The role of the boost in reducing the incidence of local recurrence has been widely confirmed by the final data of the EORTC trial, which showed a significant increase in local control in the group receiving 16 Gy boost compared to that receiving WBRT alone [53]. This benefit was particularly significant for younger patients. In the era of oncoplastic surgery, where the mammary gland is reshaped after conservative surgery to obtain the best cosmetic outcome, the delivery of the boost dose with an intraoperative technique is quite relevant, as the original tumor bed can no longer be radiologically or anatomically evident. ELIOT boost prevents missing the target or enlarging the boost area, which might lead to more extensive fibrosis and impaired aesthetic result. Moreover, the partial sparing of skin and subcutaneous tissues could limit dyschromias and telangiectasia. In addition, the intraoperative boost reduces the overall treatment time with external whole-breast irradiation by 1–2 weeks. Feasibility studies carried out in Montpellier, France [54], and at the Medical College of Ohio, Toledo, USA [55, 56], on small groups of patients (51 and 21, respectively) affected by stage I or II breast cancer were published in the late 1990s

and were satisfactory in terms of efficacy and toxicity. In the French study by Dubois and colleagues, 51 patients were treated with IORT at a dose of 10 Gy and, after an interval of 10–15 days, with external RT on the entire breast to 45 Gy. With a minimum follow-up of 2 years, there was no local recurrence and the aesthetic result was acceptable, reporting only three cases of subcutaneous sclerosis with negative aesthetic impact. The study was updated in 2006 by Lemanski [57], who reported, after a median follow-up of 9.1 years (range 5–15 years), two local recurrences within the primary tumor bed. Six patients complained grade 2 subcutaneous fibrosis in the boost area, and other two patients experienced grade 1 telangiectasia. No grade 3 side effects were detected, and cosmesis was good to excellent in all the patients. The clinical experience in the USA, performed at the Medical College of Ohio, Toledo [55, 56], regarded 21 patients who were treated in the period 1984–1996 with 10 Gy (18 patients) and 15 Gy (three patients) intraoperative boost and subsequently with 45–50 Gy with external beam radiotherapy to the entire breast. Cosmesis was excellent (only two cases of palpable fibrosis), and after a median follow-up of 71 months, there was no local recurrence. These studies favored the boost dose of 10 Gy as the most tolerable in combination with external WBRT. The boost dose 10 Gy was adopted by other American institutions. St Joseph Hospital, in California [58], reported low acute toxicity on 50 patients with median follow-up of 10 months, treated with subsequent WBRT with different dose (40–50.4 Gy). A similar number of patients were irradiated at the Mayo Clinic in Arizona [59] with the same approach (10 Gy ELIOT boost and 48 Gy external WBRT). At a median follow-up of 79 months, two patients had local recurrences. At univariate analysis, HER2 overexpression and the presence of extensive intraductal component were significantly associated with local failure. Most toxicities improved with time. At last follow-up cosmesis was judged good to excellent in 86% of cases and poor in two patients (4%). One patient developed severe fibrosis and breast deformation after aspiration of a symptomatic seroma. The 6-year actuarial overall survival and distant control rate were 89% and 96%, respectively.

In the Austrian retrospective comparative study, the boost dose delivered with ELIOT seems to be even more effective than that given immediately after the completion of WBRT [60, 61]. Three hundred and seventy-eight women affected by stage I and II breast cancer were operated on conservatively and received postoperative breast irradiation (51–56.1 Gy) with two different kinds of boost. One hundred and eighty-eight patients received 12 Gy boost dose with external electron beams after whole-breast irradiation, while 190 patients received 9 Gy boost with intraoperative electrons before whole-breast irradiation. Although not randomized, both groups of treatment were well balanced. After a minimum median follow-up of 50 months, the 5-year actuarial rate of in-breast recurrence was 4.3% (95% CI, 1.9–8.3%) and 0% (95% CI, 0-1.9%), respectively ($p=0.0018$). The ELIOT boost was proved to be not only time-saving but also strongly effective. The same Austrian group from Salzburg did a similar study on patients with locally advanced tumor treated with primary anthracycline-based chemotherapy [62]. Eighty-three patients were given 9 Gy ELIOT boost and 26 patients received postoperative external boost radiotherapy (median dose 12 Gy, range 6–16 Gy) following WBRT. After a minimum median follow-up of 59 months, two recurrences in each groups, all in the original tumor bed, were detected. No statistical difference was found in the actuarial rates for local control, locoregional control, metastasis-free survival, disease-specific survival, and overall survival. Higher local control using the ELIOT boost, although not statistically significant, was also found in the study from Udine [44]. In the population aged <48 years treated with IORT boost and external radiotherapy to the whole breast, no recurrence was seen at 6 years of follow-up, while the group treated with external WBRT presented a cumulative local recurrence rate of 8.3% (95% CI, 0–22.7). At IEO, Milan, the ELIOT boost was implemented for premenopausal patients with early disease and undergoing conservative surgery. Young age is proved to be an independent risk factor for local recurrence, and limiting the irradiated area to the tumor bed only is not considered adequate. With the aim of shortening the duration of treatment without changing the philosophy of the adjuvant approach to treat both the breast and the tumor bed, a hypofractionated scheme was designed at IEO. It consists of 13 fractions over 2.5 weeks (total dose of 37.05 Gy) following the 12 Gy intraoperative boost, and it starts very close to surgery, usually during the third week from the tumor removal, as soon as the wound heals. This short WBRT allows patients to undergo systemic treatment with no interaction with radiotherapy, because the whole treatment is completed 1 month and a half after surgery. The preliminary results on 211 patients were published in 2008 [63]. Acute toxicity was low. Intermediate toxicity was evaluated in 108 patients, with a medium follow-up of 9 months. Only one grade 4 skin toxicity was observed, in an obese woman, who underwent breast remodeling during the chemotherapy course, and one grade 3 skin side effect. For postmenopausal women who present high aggressive tumor features, a shorter hypofractionated scheme, consisting in eight fractions of 4 Gy each delivered over 1 week and a half, using intensity-modulated radiotherapy (IMRT) is currently being investigated at IEO.

56.5.2 The ISIORT-Europe Experience

A joint analysis was carried out by seven RT centers across Europe with the aim of evaluating the effectiveness of

ELIOT boost with the support of ISIORT-Europe. A total of 1109 patients treated with the ELIOT (median dose of 10 Gy) followed by external WBRT with 50–54 Gy entered the joint analysis [64, 65]. At a median follow-up of 72.4 months (0.9–239 months), only 16 local recurrences, equally distributed between true and elsewhere local relapses, were observed, and the local tumor control rate was as high as 99.2%. Analyzing the age as predictor for local failure, the crude annual local relapse rates were 0.64%, 0.34%, 0.21%, and 0.16% in the age groups <40, 41–49, 50–59, and ≥60 years, respectively. This trend toward less local relapse as the age increased was observed for both true and elsewhere recurrences. On multivariate analysis, grade 3 was a significant factor only for true local relapses. At univariate analysis, negative hormonal receptor status and age under 40 proved to be significant factors for local failure. When the time gap between ELIOT boost and WBRT was considered, starting WBRT within 70 days or at more than 140 days after ELIOT had no influence on local control.

On the basis of the positive experiences on ELIOT boost, the HIOB trial, a multicenter prospective one-armed study of hypofractionated whole-breast irradiation following intraoperative electron boost (http://www.clinicaltrials.gov/ct2/show/NCT01343459?term=hiob&rank=1), started in January 2001 on behalf of the ISIORT-Europe [66]. The eligibility criteria included women aged ≥35, with early-stage breast cancer (T1-2, N0-1), any grade, any hormonal receptor status and HER2 status, unifocal or limited multifocal lesion, or free surgical margins. The primary endpoint is to prove the superiority of the experimental scheme in terms of local tumor control by benchmarking with best published results after "gold standard" RT. The HIOB schedule consists of 10 Gy ELIOT boost followed by 40.5 Gy to the whole breast in 15 fractions/3 weeks. The trial is currently open and recruiting patients. As of November 2013, 426 patients from seven radiotherapy centers entered the trial. No major complications were recorded. At a median FU of 13 months, distant metastases in two cases and local relapse in none were observed [67].

56.6 Nipple-Sparing Mastectomy

Nipple-sparing mastectomy (NSM) combines a skin-sparing mastectomy with the preservation of the nipple-areola complex (NAC). In the past, a number of historical publications advised against the use NSM in the invasive setting because of the high rate of nipple involvement reported. Specifically addressed studies in the literature reported NAC involvement ranging from 8% to 33%, with the majority at 25%, but some studies showed nipple involvement rates as high as 58% [68, 69]. Recently, the indications for NSM have been expanded [70].

The approach of combining the surgical technique with ELIOT to the nipple/areola complex was set up at IEO, Milan, in order to kill the potential neoplastic cells in the retroareolar tissue intentionally left by the surgeon behind the areola to preserve the blood supply. The ELIOT schedule consisted of one fraction of 16 Gy at the 90% isodose, which was calculated to be equivalent to 42 Gy given on conventional fractionation [71, 72]. This approach has never met large consensus, and some concerns have arisen about the real effectiveness of this procedure. A report on 1001 NSMs receiving ELIOT to the NAC, in the period 2002–2007 at IEO, Milan, with a median follow-up of 20 months showed promising results and encouraged the experience [73]. NAC necrosis occurred completely in 3.5% and partially in 5.5% of the cases, leading to 5% NAC removal. In 2% of patients infections complicated the postoperative course, and the implant was removed in 4.3% of the cases. No recurrences were observed in the NAC, but 1.4% of the patients experienced local failure on the mastectomy site. In hindsight of a more detailed report on 934 patients, treated at IEO with a median follow-up of 50 months [74], the role of ELIOT on the NAC became uncertain. The proportion of stage II and III disease was as high as 42% and 15%, respectively, and 38% of patients had 1–3 positive lymph nodes. Among 772 invasive cancer patients, the incidence of local recurrence was 3.6% in the mastectomy site and 0.8% on the NAC. Among 162 patients with intraepithelial neoplasia, local recurrence accounts for 4.9% in mastectomy site and 2.9% on the NAC. Considering the histology of the local recurrences on the NAC, seven Paget disease and ductal carcinoma in situ in the underlying ducts and four invasive cancers were detected. All the recurrences were excised. Interestingly in 70 patients with negative frozen section who underwent ELIOT to the NAC, the final definitive histology was positive. Even if the frozen section examination shows high accuracy in predicting the presence of tumor cells in the retroareolar tissue, 8% of false-negative results were observed. In agreement with the patients, the NAC was preserved despite the lack of free margin, and no local relapse was observed with a median follow-up of 50 months. In the IEO series the factors involved in local recurrence on the NAC after invasive cancer were tumor size, receptor status, HER2/neu, grade, and Ki-67 (looking specifically at the NAC relapses, the risk factors were EIC, hormonal receptor, and biomarkers). After ductal carcinoma in situ, prognostic factors for the NAC recurrence were also the young age and retroareolar margins.

The role of ELIOT on the NAC should be demonstrated in controlled clinical trials. The current surgical technique removes almost the entire retroareolar breast tissue and creates thin nipple areolar flap to preserve the subdermal vessels. Besides, most recurrences occur mainly in the mastectomy site rather than from major ducts left behind the nipple. These

observations questioned the use of ELIOT on the NAC, and this approach is being abandoned in favor of more careful clinical and radiological selection of patients.

56.7 Special Conditions

56.7.1 Breast Augmentation

In selected patients having breast augmentation surgery, ELIOT full dose allows avoiding the well-known complications related to external RT, such as capsular contracture, cutaneous fibrosis, and progressive asymmetry, leading to unfavorable aesthetic results [75].

ELIOT full dose can be performed after quadrantectomy with concomitant immediate augmentation mammoplasty only to the tumor bed. By sparing skin and pectoralis major muscle, ELIOT does not cause fibrosis in pectoralis muscle and in the implant/tissue interface or inadequate healing of the skin [76].

56.7.2 Previous Thoracic Radiotherapy

Survivors of Hodgkin's lymphoma carry an increased risk of treatment-related subsequent malignant neoplasms. Breast cancer accounts for more than 40% of the excess risk of a second cancer [77]. When breast RT is indicated as part of breast cancer adjuvant strategy, previous chest irradiation poses serious concerns regarding the risk of overlapping doses to critical organs, such as the heart, lungs, and breasts. In some cases, modified radiation techniques such as the lateral decubitus isocentric position [78] are necessary to protect the underlying heart and lung. ELIOT could represent an option for selected cases, taking advantage of limited radiation fields and of the capability to spare the adjacent organs. Forty-three patients affected by early breast cancer, previously treated with mantle radiation for malignant lymphoma, underwent breast conservative surgery and ELIOT. Median interval between lymphoma and breast cancer occurrence was 19 years. A total dose of 21 Gy (prescribed at 90% isodose) in 39 patients (91%), of 17 Gy (prescribed at Dmax) in 1 patient, and of 18 Gy (prescribed at 90% isodose) was delivered. Good tolerance was observed in all patients. After a median follow-up of 52 months, local recurrence occurred in 9% of the patients and metastases in 7% of the patients [79–81].

56.7.3 Concomitant Systemic Diseases

Patients with severe cardiovascular diseases, respiratory syndromes, skin disorders such as vitiligo, and large pigmented hypertrophic thoracic scars due to skin burns from hot water in childhood might benefit from excluding the skin, heart, and lung from the radiation fields [81]. A dosimetric study evaluating the dose absorbed in the subclavicular region, where cardiac implantable electronical devices (CIED) are usually placed, was performed in healthy patients undergoing BCS and ELIOT [82]. The dose measured with thermoluminescent dosimeters seems to be safe for patients using cardiac devices, since it does not exceed the recommended dose threshold of 2 Gy. Therefore, when clinically indicated, ELIOT might be a valid alternative to external irradiation.

56.7.4 Pregnancy

In vivo dosimetry study was performed at IEO, Milan, Italy, with thermoluminescence radiation detectors (TLDs) placed in three different positions across the abdomen and into the uterus in nonpregnant patients receiving ELIOT with the aim to assess the safety of such treatment in pregnant patients [83]. The embryo/fetus must be deemed sensitive to radiation at all stages of gestation, but most biological effects of radiation have a dose-response relationship. For deterministic effects, such as malformation or mental retardation, a threshold value is approximately 0.1–0.2 Gy [84].

With external breast adjuvant irradiation, the estimated dose to the fetus ranges between 0.14 and 0.18 Gy, doses for which the safety of the embryo/fetus is uncertain [85]. The dosimetry results showed a mean dose of 1.7 mGy in the utero, of 3.7 mGy on subdiaphragm area, and of 0.9 mGy on the pubic region. These findings indicate that ELIOT would be safe for the fetus as doses of a few mGy are not associated with measurable increased risk of fetal damage.

Conclusion

ELIOT represents an attractive option, both for physicians and patients. By reducing the entire radiation treatment of 5–6 weeks from a few fractions up to a single session during surgery, ELIOT has a favorable impact on treatment costs and patients' convenience. One of its strengths is that of potentially decreasing normal tissue toxicity, since the skin, the subcutaneous tissue, and the thoracic wall along with the underlying structures are not irradiated. However, ELIOT suffers from some limitations which must be overcome to improve the efficacy and the cost-effectiveness. The proper identification of the ideal candidates is challenging because at the time of the intraoperative irradiation, the complete tumor profile is not available. Efforts must be made in order to obtain the biologic and histologic tumor characterization through preoperative (true cut or core biopsy) and intraoperative (frozen sections) pathologic assessment. Subgroup analysis showed that ELIOT is effective in selected patients for whom external whole-breast radiotherapy would not be more

beneficial. Other issues address the proper width of the intraoperative radiation field to uniformly cover all the area at risk of microscopic disease. Besides, the appropriateness of 21 Gy full dose is a matter of debate. The linear-quadratic model used to derive the biological equivalent dose seems not adequate in the range of high dose/fraction. The ELIOT boost dose can be successfully integrated in the schedules of adjuvant breast radiotherapy.

Radiotherapy for Metastatic Lesions

57

Per Karlsson and Dan Lundstedt

57.1 Introduction

Radiotherapy of metastatic lesions is generally of palliative intent. In these situations it is important to weigh the symptom-relieving effects against potential side effects of the radiotherapy. Metastatic breast cancer includes a wide range of clinical situations, all the way from situations in which the patient with modern treatment can be expected to live for many years to symptom-relieving situations in the end of life. The radiotherapy must be adjusted to the overall situation for the patient. The term oligometastatic disease, first described by Hellman and Weichselbaum [1], means a limited spread of the disease with just a few metastases but not a fully disseminated disease.

In patients with oligometastatic disease, the modern systemic treatments and the possibilities with the new techniques in the radiotherapy to deliver high doses with sharp dose margins have actualized the question if not some of these patients may have a curative potential [2]. At least, there are some long-term survivors in series with patients treated with radiotherapy with oligometastatic disease [3]. When it comes to radiotherapy in patients with metastatic lesions, it is important to include the total situation for the patient in a multidisciplinary dialogue. For some patients late in life, it may be wise to refrain from radiotherapy or just give a single pain-relieving fraction, and for others the decision may be to choose an extensive stereotactic radiotherapy if a potential for long-term survival exists.

57.2 Bone Metastases

In 2012 Chow et al. published meta-analyses of 25 randomized radiotherapy trials which compared a single fraction with multiple fractions for pain relief in patients with bone metastases [4]. The overall response rate after a single dose was 60% and after multiple fractions 61%. Complete pain response was found in 23% after a single fraction and 24% after multiple fractions [4]. However, the re-treatment rate was higher after single fraction (20%) than after multiple fractions (8%). This review confirms the results from previous reviews that a single dose is as effective as multiple fractions [5, 6]. Hartsell et al. published a randomized phase 3 study in patients with bone metastases specifically from breast and prostate cancer and compared a single dose of 8 Gy versus multiple fractionations of 3–30 Gy [7]. A single dose of 8 Gy was as effective as multiple fractionations. There was less acute toxicity after 8 Gy, 10% compared to 17% after 30 Gy. The frequency of pathologic fractures within the treatment field was similar between the groups, 4% and 5%, respectively. However, the re-treatment rate was higher after 8 Gy, 18% compared to 9% after 30 Gy. Also the guidelines for palliative radiotherapy for bone metastases from the American Society for Radiation Oncology (ASTRO) state that a single fraction is as effective in pain relief as multiple fractions and that a single fraction generally is more convenient for the patients and caregivers [8].

Dennis et al. reviewed various doses of single fractions for the treatment of painful bone metastases and found that 8 Gy probably is close to an optimal dose [9]. Wong et al. made a systemic review of re-irradiation for painful bone metastases and found that the overall and complete response rate was 68% and 20%, respectively, which is comparable to the response frequencies seen after the initial radiation for bone metastases [10]. To reduce the acute pain flare seen in some patients after palliative irradiation of bone metastases, Chow et al. showed in a randomized study that taking 8 mg dexamethasone at the day of the radiotherapy and during the following 4 days reduced the frequency of patients having the pain flare from 36% to 26% [11] (Fig. 57.1).

57.3 Malignant Spinal Cord Compression

Malignant spinal cord compression (MSCC) is a feared complication to metastatic cancer. A population-based study from Ontario reported that about 2.5% of all metastatic

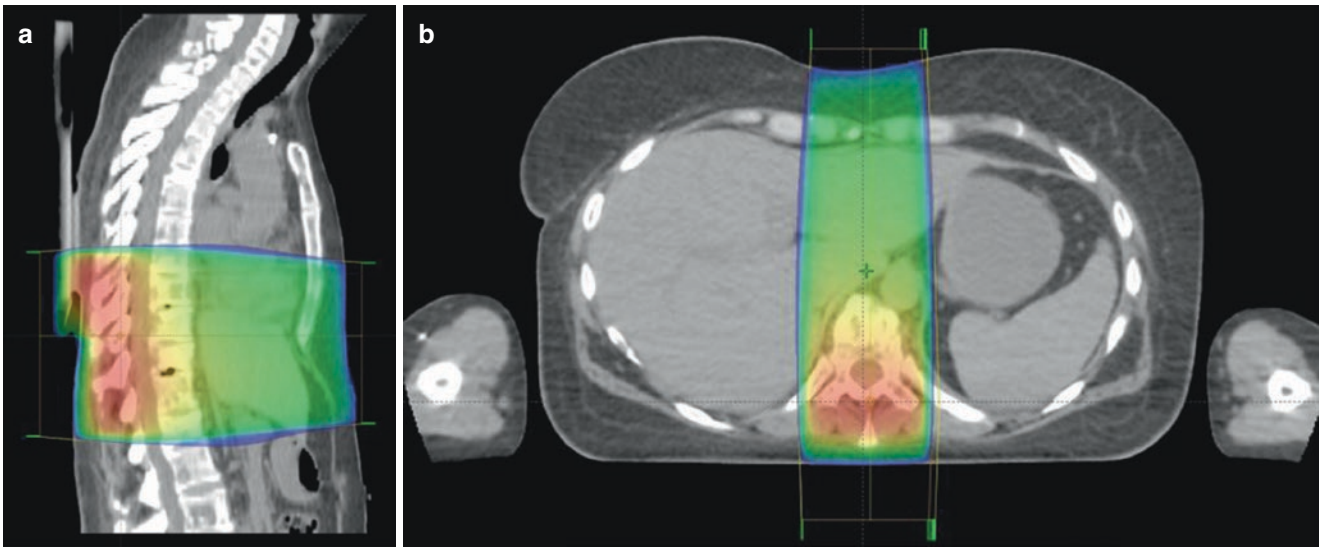

Fig. 57.1 Palliative radiotherapy for part of the thoracic spine. Sagittal (**a**) and transversal (**b**) views of a treatment plan with a dose prescription of 8.0 Gy in a single fraction. The *blue color* corresponds to the 50% dose level. Eclipse™ Treatment Planning System

patients dying from cancer had at least one admission to a hospital with MSCC [12]. Patchell et al. studied the effect of decompressive surgery in addition to radiotherapy in a randomized study in which the patients had either decompressive surgery followed by radiotherapy (n = 50) or radiotherapy alone (n = 51) [13]. The radiotherapy was given with ten 3 Gy fractions, and dexamethasone was given in both arms. The primary endpoint was ability to walk after treatment. For patients having surgery plus radiotherapy, 84% were able to walk after treatment in comparison to 54% of the patients having radiotherapy alone. A later publication from the same group indicated that the additional benefit of the decompressive surgery only was seen in the age group younger than 65 years [14]. In patients fit for surgery and a single-level MSCC decompressive surgery followed by radiotherapy is recommended.

For older patients and patients not fit for surgery, radiotherapy alone is recommended [15]. Two randomized Italian trials comparing different fractionation schedules in patients with short life expectancy could not find any significant difference in outcome [16, 17]. In the first trial, two 8 Gy fractions were compared with a split course of three fractions of 5 Gy followed by five fractions of 3 Gy [16], and 68 and 71% of the patients were able to walk after the two radiotherapy regimens, respectively. In the second trial, 8 Gy as a single fraction was compared to two 8 Gy fractions, with 62% and 69% of the patients were keeping or improving their walking function in the two fractionation arms, respectively [17]. This difference was not statistically significant. Thus in patients with short life expectancy, 8 Gy as a single fraction is recommended. Patients with MSCC are generally recommended steroids, if not medically contraindicated [15].

57.4 Brain Metastases

In early breast cancer patient randomized in different clinical studies (n = 9524) within the International Breast Cancer Study Group (IBCSG), the 10-year incidence of brain metastases was 5.2% [18]. Among patients with metastatic breast cancer, approximately 10–16% will develop brain metastases [19]. The choice of treatment depends on various factors, e.g., number of metastases and the overall prognosis. The Radiation Therapy Oncology Group (RTOG) has from their trials established three prognostic groups using the recursive partitioning analysis (RPA) [20, 21]. The RPA classes were based on Karnofsky performance status, age, primary tumor status, and presence of extracranial metastases. The RPA has been challenged by the graded prognostic assessment (GPA) index, which also includes number of brain metastases [22], and further prognostic information have been derived in the diagnosis-specific GPA which also included information of the primary tumor [23]. For breast cancer patients with brain metastases, the breast-GPA has been established which takes breast cancer subtype, age, and Karnofsky performance index into consideration [24]. The breast-GPA score is the sum of the score for these three factors (Table 57.1). Sperduto et al. have shown in a retrospective multi-institutional database study of 400 breast cancer patient with brain metastases that total scores of 0–1, 1.5–2, 2.5–3, and 3.5–4 correspond to median survival times of 3.4, 7.7, 15.1, and 25.3 months, respectively [24].

Looking at different subtypes of the breast cancer only, the mean survival time after diagnoses of brain metastases was 7.3, 10.0, 17.9, and 22.9 months for women with triple negative, hormone receptor positive/HER2 negative, hormone receptor negative/HER2 positive, and hormone receptor positive/HER2 positive, respectively [25].

57.4.1 Whole-Brain Radiotherapy (WBRT)

The purpose of WBRT is to irradiate both visual tumors and microscopic disease (Fig. 57.2). Whole-brain radiotherapy is generally recommended in patients with multiple brain metastases or patients with poor life expectancy. If life expectancy is very short, less than 3 months, supportive care alone with dexamethasone may be recommended [26]. One old randomized trial included 48 patients with brain metastases and compared the effect of WBRT + prednisone with prednisone alone and found an increase in survival from 10 to 14 weeks in favor of the group receiving the combination [27]. In a newly presented abstract from ASCO, 538 non-small cell lung cancer patients with brain metastases were randomized to 20 Gy in five fractions or optimal supportive care only [28]. No significant difference in overall survival (65 days vs. 57 days) or quality-adjusted survival was seen in this patient group. The standard fractionation schedules are ten times 3 Gy in 2 weeks or 20 Gy in four or five daily fractions. Davey et al. compared a higher total dose of 40 Gy (20 × 2 Gy) with 20 Gy (5 × 4 Gy), but the median survival time was 19.1 weeks in both arms [29]. Also Graham compared a higher total dose 20 × 2 Gy, twice daily, to 4 × 5 Gy, which resulted in similar median survival, 6.1 and 6.6 months, respectively [30]. In a Cohrane report from 2012, the authors concluded no other dose fractionation schemes thus far compared to 30 Gy in ten fractions or 20 Gy in 4–5 fractions resulted in any benefit in overall survival, neurologic function, or symptom control [31]. When interpreting the length of the survival time in the abovementioned studies, one has to remember that these studies contained mainly lung cancer patients and only a smaller fraction had breast cancer as the primary tumor. Thus the breast cancer-graded prognostic assessment index (breast-GPA) must be considered while estimating life expectancy after WBRT in breast cancer patient with brain metastases [24]. WBRT can cause chronic neurocognitive side effects as affected memory function [32] which becomes especially important among long-time survivors.

Table 57.1 The graded prognostic assessment for breast cancer (breast-GPA) [24]

Score					
Factor	0.0	0.5	1.0	1.5	2.0
Age (years)	≥60	<60	–	–	–
KPS	≤50	60	70–80	90–100	–
Genetic subtype	Her2 neg and ER/PR neg	–	Her2 neg and ER/PR pos	HER2 pos and ER/PR neg	HER2 pos and ER/PR pos

KPS Karnofsky performance status

57.4.2 Stereotactic Radiotherapy for Brain Metastasis

Stereotactic radiosurgery (SRS), stereotactic radiotherapy (SRT), and Gamma Knife all refer to treatment techniques where a group of convergent beams is used to target an exactly defined lesion. This technique makes it possible to treat local brain metastases with a very high dose and at the same time spare the normal brain tissue. Single doses of at least 20 Gy seem to result in better local control rates [33], but the maximum tolerated dose is dependent on the maximum diameter of the lesion [34] (Fig. 57.3).

Stereotactic radiotherapy can be used alone or in combination with WBRT. In the RTOG 9508 trial, 333 patients with 1–3 brain metastases were randomized to WBRT with or without stereotactic radiotherapy [35]. For patients with one brain metastasis, stereotactic radiotherapy improved the median survival from 4.9 months to 6.5 months, $p = 0.01$ [35]. No survival benefit was seen for those with two or three metastases [35].

The addition of WBRT to SRS or surgery does not affect survival, but it increases the total intracranial tumor control by reducing the number of new brain metastases and by improving the local control [36]. The EORTC 22952-26001 study of SRS or surgery with or without WBRT for patients with 1–3 metastases found that WBRT reduced the 2-year relapse rate both at the initial sites (radiosurgery, 31–19%; surgery, 59–27%) and at new sites (radiosurgery, 48–33%; surgery, 42–23%). However, the median overall survival time was similar in the both arms, 10.9 months with WBRT and 10.7 without ($p = 0.89$). The median time to impaired functional status, WHO performance status more than two, was 10.0 months without WBRT and 9.5 months with WBRT ($p = 0.71$), indicating that WBRT did not prolong the duration of functional independence [36]. According to a Cochrane review 2014 including five randomized controlled trials, adding WBRT to SRS or surgery among patients with 1–4 metastases decreased the relative risk of any intracranial disease progression at 1 year by 53% (RR 0.47, 95% CI 0.34–0.66), but there was no clear evidence of a difference in OS (HR 1.11, 95% CI 0.83–1.48) or in PFS (HR 0.76, 95% CI 0.53–1.10) [37].

Chang et al. studied the effect on neurocognitive function in patients with 1–3 brain metastases randomized to stereotactic radiotherapy with or without WBRT [32]. The study was stopped by the data monitoring committee, already after 58 included patients, since the probability of decline in memory function at 4 months was much higher in the group having WBRT, 52% versus 24% [32]. To avoid the side effect

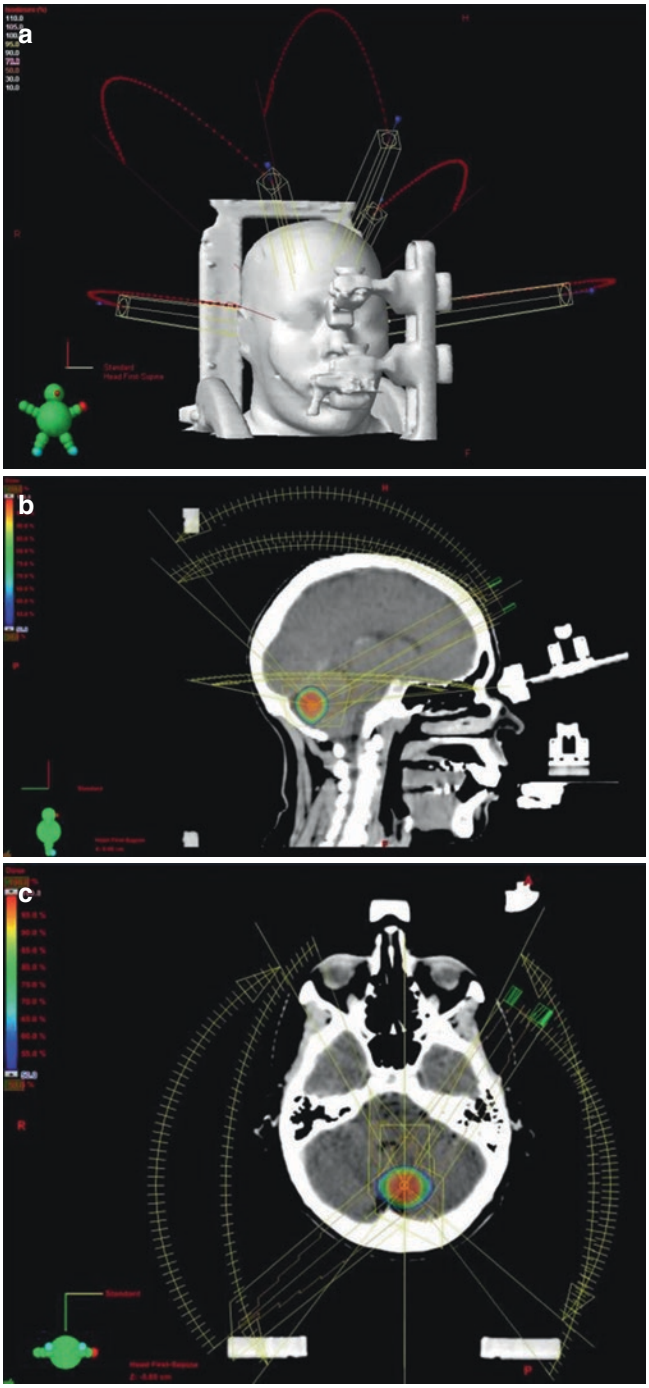

Fig. 57.3 Stereotactic radiotherapy plan of a single metastasis in the cerebellum with a dose prescription of 20.0 Gy in one fraction. The DRR (**a**) with the immobilization system (trUpoint ARCH™ SRS/SRT System: head support, bite tray, mask, and nasion cushion) as well as the treatment archs (Varian TrueBeam™ STx). Sagittal (**b**) and transversal (**c**) views. The *blue color* corresponds to the 50% dose level. Eclipse™ Treatment Planning System

related to WBRT, the authors recommend initial treatment with SRS followed by close monitoring [32], which has also been supported by the American College of Radiology [38].

In the NCCTG N0574 (Alliance) study, 213 patients with 1–3 brain metastases were randomized to receive or not to receive WBRT in addition to SRS with cognitive progression as primary endpoint [39]. The study was presented at ASCO in 2015. They showed that cognitive progression at 3 months was more frequent after WBRT + SRS vs. SRS alone (91.7% vs. 63.5%, respectively, $p = 0.007$) and at 6 months there was still a significant difference (97.9% vs. 77.8%). The difference in cognitive progression seen was mainly due to impairment in immediate and delayed recall as well as impairment in verbal fluency. To avoid the early side effects related to WBRT in combination with SRS, the author recommended initial treatment with SRS alone followed by close monitoring [39].

57.4.3 New Techniques to Spare Cognitive Functions

The radiation-induced cognitive impairment seems to be associated with exposure to the hippocampus region [40] and especially the neural stem cells located in the hippocampal dentate gyrus [41]. Therefore, radiotherapy technique to minimize the dose to the hippocampal region has been developed [42]. In the RTOG 0933 trial, which was a phase II single-arm study, 113 patients with brain metastases were treated with IMRT (intensity-modulated radiotherapy) to the whole brain but avoiding the hippocampal region [43]. The primary endpoint was decline in delayed recall at 4 months. The relative decline seen among 48 evaluable patients was 7%, which was lower than 30% seen in historical controls of WBRT [43]. Further neuroprotective drugs have been tested. Memantine, an N-methyl-D-aspartate (NMDA) receptor agonist, has been tested during WBRT with some positive indications on delayed recall, however not statistically significant [44].

57.5 Extracranial Oligometastases

Oligometastatic disease is a clinical situation with a few metastases, but not yet with disseminated spread, first described by Hellman and Weichselbaum [1]. In the same manner as surgical removal of liver metastases in colonic cancer [45] or removal of lung metastases in a sarcoma patients [46] has resulted in long-term survivors, one may expect some long-term survivors after SBRT in patients with oligometastatic disease. The question about possibilities of stereotactic body radiation therapy (SBRT) in metastatic breast cancer has been more actualized with the improvement of the systemic therapies in controlling the spread of the disease. Several prospective series with stereotactic body radiation therapy have proven high local control rates in the treated metastases (~80%) and a progression-free survival of about 20–30% [47].

57.5.1 Stereotactic Body Radiation Therapy (SBRT)

The techniques to exactly deliver the dose to the target volumes have developed remarkably during later years. American Society for Therapeutic Radiology and Oncology (ASTRO) describes stereotactic body radiation therapy (SBRT) in the following way: “Stereotactic body radiation therapy (SBRT) is an external beam radiation therapy method used to very precisely deliver a high dose of radiation to an extracranial target within the body, using either a single dose or a small number of fractions” [48]. SBRT is suitable for small lesions with a largest dimension of about 4–5 cm. For larger lesions the radiation volumes increase rapidly since the volume of a sphere multiplies by a factor three times the radius (Fig. 57.4).

SBRT is of special interest in patients with oligometastatic disease. One of the larger series has been published by Milano and colleagues [3, 49]. They present a follow-up of 121 patients with five or fewer metastases treated with SBRT. The median number of treated lesions was 2, and the median sum of the gross target volume (GTV) was 28 cm^3. For liver and lung metastases, the most common used fractionation was 5 Gy times ten fractions. The 2-, 4-, and 6-year overall survival (OS) rates were 50%, 28%, and 20%, and the 2-, 4-, and 6-year freedom from widespread distant metastasis (FFDM) rates were 35%, 26%, and 21%. For the 39 patients with breast cancer as their primary tumor, the outcome was better, 74%, 54%, and 47% for 2-, 4-, and 6-year OS and 52%, 43%, and 36% for FFDM at 2, 4, and 6 years. For the breast cancer patients responding to the systemic treatment before the SBRT, the 2-year OS was 81% in comparison to 55% for those not responding to systemic therapy before SBRT.

Andratschke et al. found that the size of the gross target volume (GTV) was correlated to inferior OS and the biologic equivalent dose was correlated to local control in a series of 74 patients with one to four liver metastases treated with SBRT in three to five fractions of 5–12.5 Gy per fraction [50].

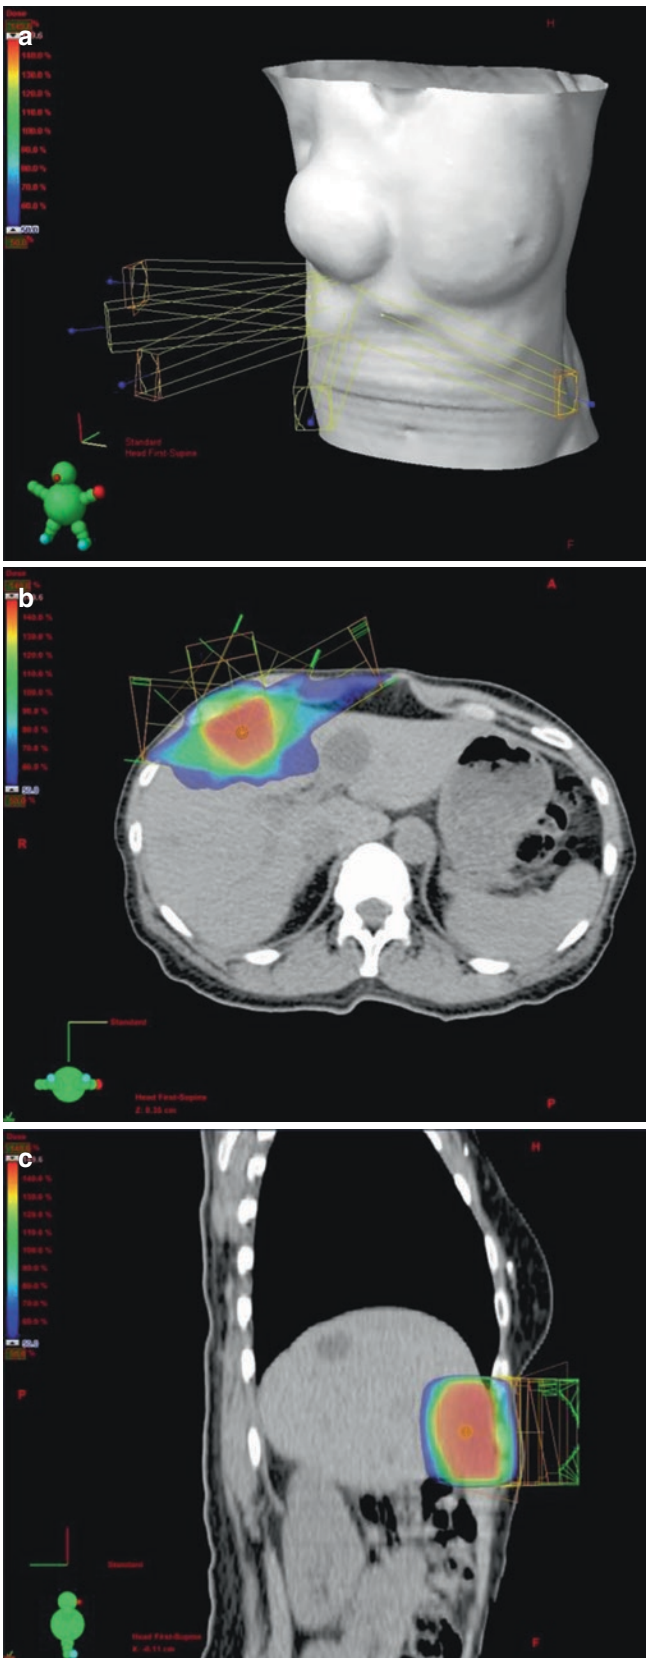

Fig. 57.4 Stereotactic body radiotherapy plan of a liver metastasis with a dose prescription of 40.0 Gy in four fractions. The target definition is based on the movements captured with a 4D CT. The DRR (**a**) with the treatment fields. Transversal (**b**) and sagittal (**c**) views. The *blue color* corresponds to the 50% dose level. Eclipse™ Treatment Planning System

To conclude, SBRT gives possibilities to long-term survival in some patients with oligometastatic disease. For breast cancer patients previously responding to systemic therapy and with controlled disease outside the oligometastatic lesions, SBRT is a reasonable option after discussion in a multidisciplinary team. Unfortunately we lack evidence from randomized controlled trials, and to exactly know the indication for SBRT, randomized controlled trials are warranted.

57.6 Locally Advanced and Recurrent Breast Cancer

The role of radiotherapy in locally recurrent breast cancer depends on the extent of the recurrence, the sensitivity to systemic therapies, the symptoms of the patient, and previous radiation within the area. In patients refractory to systemic therapies, the aim of the radiotherapy is to achieve local control and to diminish symptoms. Bedwinek and colleagues found that the dose needed for local control was dependent on the size of the recurrence [51]. Their study indicated the need of 50 Gy in 2 Gy fractions if the recurrence was completely excised, 55 Gy if remaining tumor was <1 cm, and 60 Gy if remaining tumor was 1–3 cm. If remaining tumor was more than 3 cm, 65 Gy was not sufficient. Another nonrandomized series with primary radiotherapy in 192 patients with advanced breast cancer have shown better 5-year local control rates with doses greater than 60 Gy [52].

For patients not previously irradiated and with longer expected survival, a radiotherapy series with smaller fractions to 50–60 Gy may be indicated. For patient with shorter life expectancy and local symptoms, a short course of 20–30 Gy in 5–10 fractions may be more appropriate [53].

Recurrence in a previously irradiated volume is a complex clinical situation, and the potential benefits and harms of reirradiation must be weighed carefully in a multidisciplinary conference. The risk of fibrosis, necrosis, brachial plexopathy, and rib fractures depends on the combined dose and the volume exposed [54, 55]. There are small series of reirradiation with total combined doses up to 100 Gy with local control rates at 1 year of about 60–80% and with limited short-term toxicity [56, 57]. Hyperthermia seems to potentiate the effect of the reirradiation [56, 58]. Electrochemotherapy (ECT) may be an alternative and complementary local treatment for cutaneous metastases [59].

57.7 Integration with Systemic Therapy

Regarding bisphosphonates and palliative radiotherapy, there are some indications of possible additive effects when these treatments are given during the same period of time [60–62], even if no formal randomized studies of sequential and concurrent use have been performed.

For endocrine therapy it is reasonable to continue with the endocrine treatment during the palliative radiation. At least in early breast cancer, no significant difference was seen in studies with concurrent or sequential use of tamoxifen and radiotherapy [63, 64]. Regarding chemotherapy the palliative radiotherapy is often given in between the chemo courses and not concurrently. Some studies in locally advanced breast cancer have studied the potential benefit of concurrent radiochemotherapy but not much data exist [65–67]. There are also some indications of increased toxicity in these trials which must be weighed against potential benefits in a palliative situation.

57.7.1 Radiation Recall

First to describe radiation recall was D'Angio [68], who already in 1959 described reactivation of latent radiation effects in the skin when actinomycin D was given weeks after radiotherapy. The reaction was sharply restricted to the area of the previous radiation.

Many case reports of radiation recall exist but systematic series are rarely reported. Kodym et al. followed 142 patients having palliative radiotherapy, and of these 91 received subsequent palliative chemotherapy within 6 months [69]. Of these 91, 8 patients (8.8%) did show a reactivation of the skin reaction within the former radiation field (radiation recall) [69]. The skin reactions ranged from dermatitis, WHO grade I, to exfoliative dermatitis, WHO grade III. The reaction was seen after several types of chemo, taxanes, alkylating agents, antimetabolites, and antitumor antibiotics. During later years radiation recall has been actualized when introducing modern targeted therapies, for instance, after treatment in melanoma with the BRAF inhibitor vemurafenib [70]. When introducing new targeted therapies, some awareness among doctors of these types of reactions should be warranted.

Conclusions

Radiotherapy for metastatic lesions includes a wide variety of clinical situations from symptom control late in life to potentially curative advanced stereotactic radiotherapy in oligometastatic disease. The combination of the modern imaging techniques and the extremely high precision of dose delivery has made it possible to increase the doses to the metastatic lesion but still spare the surrounding normal tissues. With new possibilities in radiotherapy, it is even more important to discuss what is appropriate with the patient and in a multidisciplinary team. Late in life it is important with symptom control and not to overtreat the patient with advanced technology; however with long life expectancy and with appropriate systemic treatment, it is also important to really use the advanced radiotherapy techniques if considered right for the patient after a multidisciplinary dialogue.

Special Conditions Requiring Multidisciplinary Approaches

Emergencies in Breast Cancer

58

Lorenzo Gianni, Maria Vittoria Stefania Nicoletti, and Valentina Arcangeli

58.1 Introduction

The increasing number of cancer survivors [1] and of patients living with a "chronic" form of advanced disease, often managed as outpatients, explains their growing request for clinical evaluation at the Emergency Department [2]. Cancer patients may be admitted either for the first symptoms of the disease, for a tumor or treatment-related complication, and for other comorbidities or symptoms near the end of life, sometimes with the characteristics of an oncological emergency (OE) [3]. These are serious and potentially life-threatening complications of cancer that may occur in any phase of the disease. Proper management requires adequate training, integration between different specialists, and timely access to diagnostic and treatment resources. Two major principal groups of OEs are identified: mechanical and metabolic OEs (Table 58.1); other two categories such as hematologic emergencies and treatment-related emergencies are occasionally added [4].

Table 58.1 List of the principal oncological emergencies

Obstructive/structural emergencies	Increased intracranial pressure
	Malignant pericardial effusion
	Malignant spinal cord compression
	Superior vena cava syndrome (SVCS)
Metabolic emergencies	Hypercalcemia
	Hyponatremia and SIADH
	Tumor lysis syndrome
Hematologic emergencies	Disseminated intravascular coagulation (DIC)
Treatment related	Febrile neutropenia

58.2 Mechanical Emergencies

58.2.1 Increased Intracranial Pressure

Increased intracranial pressure (ICP) is defined as a sustained ICP of more than 20 mmHg (normal values 0–10 mmHg) and is originated by several causes such as space-occupying lesions, edema, and hydrocephalus [5]. Intracranial neoplasm, more often of metastatic origin from lung cancer (20%), renal cancer (10%), melanoma (7%), breast cancer (BC) (5%), and colorectal cancer (1%), is an important cause of ICP [4].

Pathophysiology. Brain metastases (BM) grow after hematogenous spread with predilection for the cerebral hemispheres, cerebellum, and brainstem [6]. The tumor mass effect and the cerebral edema related to blood barrier disruption contribute to the elevation of ICP [7]. The brain, together with cerebrospinal fluid and blood, is contained within a rigid skull, with limited capabilities of compensation for increases in ICP. Large volume changes may result in cerebral herniation or displacement, compression of brain structures, and blood flow impairment with neurological impairment and severe symptoms [5].

Clinical Feature. The most frequent clinical manifestations are headache, nausea, vomiting, and focal neurological signs depending on lesion site or complication. As ICP increases, seizures, altered mental status, and coma may appear; hypertension, bradycardia, and irregular breathing (Cushing triad), diplopia, and pupillary changes may suggest impending herniation [5].

Diagnosis. Contrast-enhanced computed tomography (CT) is the screening test of choice when BM are suspected; non-contrast CT scan may be preferred in more acute clinical condition, when hemorrhage or hydrocephalus is suspected. Contrast-enhanced magnetic resonance imaging (MRI) is the more sensitive diagnostic tool, particularly for metastasis in the posterior fossa [4].

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_58

Management. Nursing considerations include 30° elevation of the head of bed and maintenance of normal body temperature and of blood pressure above 90 mmHg [5]. Hypotonic saline should be avoided. Corticosteroids may reduce capillary permeability. Dexamethasone, the preferred agent, is administered intravenously (IV) or orally, at the dose of 4 mg every 6 h (often after a loading dose of 10–24 mg), even if no general consensus about dose exists [4, 7]. Subsequent dose tapering to the minimum effective amount is indicated. *Pneumocystis jirovecii* prophylaxis should be considered when extended treatment is planned [8]. Mannitol may temporarily be used to reduce ICP, but rebound increase of ICP may occur [9]. The routine prophylactic use of antiepileptic drugs for adult with BM who have not experienced seizures is not recommended [10]. The presence of BM is not viewed as an absolute contraindication to the use of low molecular weight heparin for venous thromboembolic complications [11, 12] that can occur in approximately 20% of patients [13].

Local and systemic treatment of brain metastases may be indicated: in general whole-brain radiation therapy, most commonly used in patients with multiple brain lesions, may prolong median survival from 1 to 2 months to 3–6 months [7].

58.2.2 Malignant Pericardial Effusion

Cancer explains about 10–25% of incidentally discovered pericardial effusion (PE) in asymptomatic patients [14] and even more in symptomatic patients [15, 16]. Pericardial infiltration or metastases from lung cancer (34.4%), BC (16.7%), leukemia (9.4%), and other cancers are the main causes [15]. Inner quadrant-located BC has a fourfold increased risk [17]. Despite a reported poor prognosis for malignant PE [15], no difference in survival was observed in BC patients compared to those with metastatic disease in general [17].

Pathophysiology. Increase of intrapericardial pressure may lead to impaired filling of one or both ventricles and decreased cardiac output resulting in cardiac tamponade, depending on the amount of pericardial fluid and the speed of its accumulation [18].

Clinical Features. Pericardial effusion can be initially asymptomatic; symptoms include dyspnea, chest pain, and/or fullness, cough, weakness, fatigue, anorexia, and palpitations, nausea, dysphagia, hoarseness, and hiccups. Clinical findings include hypotension, increased jugular venous pressure with neck vein distention, and small and distant heart sounds on cardiac auscultation (Beck triad), tachycardia, and pulsus paradoxus [14].

Diagnosis. Routine blood tests, including markers of inflammation and troponins, are recommended in all cases of suspected pericarditis. Low electric voltage or electrical alternans may be evident on electrocardiography registration. Chest x-rays may show cardiomegaly, but transthoracic echocardiography is the imaging test of choice: it detects pericardial effusion and cardiac tamponade and gives important information about ventricular function [14, 18]. A small PE is an echo-free space of <10 mm generally located posteriorly, adjacent to the right atrium; moderate (10–20 mm) and large (>20 mm) PEs tend to become circumferential [19]. Chest CT and MRI allow an accurate study of the chest and pericardium. Cytological or histological diagnosis confirmation may rule out nonmalignant complication [14].

Management. Most of evidence relies on retrospective case series with mixed types of cancer. In case of cardiac tamponade, fluid infusion may be indicated in hypovolemic patients, but elective treatment is ultrasound (US)-guided pericardiocentesis and indwelling catheter placement [6]. Intrapericardial (IP) instillation of sclerosing or cytotoxic agents may be used to prevent PE reappearance. Cisplatin and thiotepa are the agents of choice for IP treatment (CHT), respectively, in case of pericardial involvement by lung cancer and BC [14], with PE control in 83–100% of cases [20–25]. Possible effective alternatives are mitoxantrone, mitomycin-C, bleomycin, and ^{32}P-colloid [26–29]. Surgical approach with pericardial window and pericardiodesis or percutaneous balloon pericardiotomy are alternatives for severe, recurrent, life-threatening PE [30]. Control of the underlying neoplasm is the only significant factor influencing survival [31].

58.2.3 Malignant Spinal Cord Compression

Malignant spinal cord compression (MSCC) is one of the most serious complications of cancer [32]. About 2.5% of patients with advanced cancer develop MSCC [33]. Up to 20% of cases occurs at cancer diagnosis (12% in BC) [34]. Between 5% and 20% of patients with spinal metastases (SM) develop MSCC during the course of their disease [35]. In BC patients with SM, neurological deficit leading to the diagnosis of SM was reported in 1.4% of patients, while 2.8% developed MSCC during follow-up [36].

Pathophysiology. Spinal epidural metastases or locally advanced cancer may compress, displace, or encase the thecal sac that surrounds the spinal cord or cauda equina. Compression may originate by posterior extension of a vertebral body mass or vertebral body collapse and retropulsion of bony fragments into the epidural space, by anterior expansion of a mass arising from the dorsal elements, or by tumoral invasion of the vertebral foramen [32]. About 60–80% of spinal extradural metastasis occurs in the thoracic spine, 15–30% occurs in the lumbosacral region, and less than 10% involves the cervical spine. Up to 50% of patients have involvement of more than one area of the spine [34]. The

damage to the spinal cord is the result of many factors including vasogenic edema, ischemia, venous congestion, and demyelination.

Clinical Features. Back pain is the most frequent symptom of presentation. In a prospective study, 94% of patients reported pain that had been present for approximately 3 months. Most patients (85%) had noticed weakness (median duration of 20 days), difficulty walking, or falls [37]; however, motor symptoms may appear suddenly. Paresthesia, decreased sensation, and numbness are also common. Symptoms related to autonomic dysfunction with urinary retention, incontinence or constipation, and impotence are a later consequence [32].

Compression of cauda equina may be suggested by low back pain; motor symptoms; saddle anesthesia or numbness in the buttocks, thighs, and perineum; urinary retention; overflow incontinence, occasionally with loss of anal sphincter tone; or constipation [38].

Diagnosis. Patients with recent onset of back pain, symmetric weakness, or paresthesia must be quickly evaluated, to prevent significant morbidity and permanent disability. The entire spine should be evaluated to rule out multiple epidural lesions [4]. Plain radiographs may be falsely negative [32]; MRI is the gold standard imaging approach, while CT may be useful when MRI is contraindicated and for surgery and radiotherapy planning [32, 39].

Management. Corticosteroids are indicated to reduce edema, to limit neurological impairment, and to improve pain control [40]. Patients receiving radiotherapy (RT) for MSCC have better outcome if they receive high dose of dexamethasone [41], though controversy exists regarding the optimal dose [39].

Surgery is the treatment of choice for selected patients with good prognosis, unstable spine, compression due to bony fragments, and impending neurologic deterioration, who are unlikely to respond to RT or at risk of spinal damage due to previous radiotherapy [32]. Surgery followed by RT is better than RT alone in preserving walking function [42]. Timing of the procedure is a critical point to attain neurological function preservation. Complete paraplegia, poor prognosis, or frailty contraindicates surgery.

Radiotherapy is indicated for patients not eligible for surgery or as a completion of operation [40, 43]. Hypofractionated RT schedules are effective with acceptable toxicity [44]. A single RT fraction of 8 Gy is recommended for patients with poor prognosis, otherwise a radiation dose of 30 Gy in ten fractions may be considered [44]. Timing of RT and cancer radiosensitivity are critical factors. Spinal stereotactic radiosurgery and intensity-modulated RT may allow more accurate RT delivery to the target [45].

When surgery is not indicated, vertebroplasty and kyphoplasty are options for intractable pain due to pathologic vertebral body fractures [45].

58.2.4 Superior Vena Cava Syndrome

Malignancy represents the main cause of superior vena cava syndrome (SVCS) (60–85%), followed by iatrogenic complication, related to intravascular devices and other benign diseases [44, 45]. Non-small cell lung cancer (50%), small cell lung cancer (22%), lymphoma (12%), metastatic lesions (9%, mainly from BC), germ cell cancer (3%), thymoma (2%), and mesothelioma (1%) are the most frequent causes [46].

Pathophysiology. Obstruction of the superior vena cava (SVC) can be caused by compression or infiltration by an adjacent pathologic process involving the middle or anterior mediastinum and/or by thrombosis within the SVC [6]. The azygos venous system represents the most important collateral pathways, but in case of obstruction at the level of this vein, collateral veins on the chest and abdominal walls may drain the blood toward the inferior vena cava [47].

Clinical Features. Clinical manifestation includes dyspnea; cough; swelling of the face, neck, and arms; cyanosis; and distended neck and chest veins [46, 48]. Pleural effusion may be present in 60% of patients [49]. Edema may compromise the function of the larynx or pharynx, causing stridor, cough, hoarseness, and dysphagia. Neurologic symptoms related to cerebral edema, with headaches, confusion, and significant respiratory impairment, may portend a more serious clinical picture [47]. An SVCS grading system based on clinical findings has been proposed to evaluate the severity of symptoms and the urgency of intervention [49].

Diagnosis. Chest radiography can reveal a mediastinal enlargement, but multi-detector CT with multiplanar reconstructions is the preferred imaging modality [6, 50]. It may provide important information about SVC obstruction, its underlying cause, and collateral circulation [51]. Venography, once the gold standard [52], is performed only when stent placement or surgery is planned [46]; MRI has high sensitivity and specificity and is preferred in case of allergy to radiographic contrast media [52]. ^{18}Fluorodeoxyglucose positron emission tomography may add some details and information useful for prognosis and treatment response evaluation [53, 54]. Tissue biopsy is warranted before cancer treatment when malignancy is suspected [55]: SVCS often develops gradually and may allow treatment delay for definitive diagnosis [4, 46].

Management. Nursing management includes bed rest with a Fowler or semi-Fowler position to elevate the patient's head to facilitate venous drainage and oxygen therapy. Systemic corticosteroids (and diuretics) are frequently used (particularly during radiotherapy), even if their efficacy is largely unproven except in lymphomas [46, 55]. Therapeutic choice may be different according to the clinical severity of SVCS and underlying disease. For highly chemo-responsive disease such as lymphoma, germ cell cancer, small cell lung

cancer [4, 46], and possibly BC [56], CHT may be the preferred treatment. Targeted therapy may be indicated according to pathological evaluation. Radiotherapy induces a rapid symptomatic improvement in 74–95% of patients within 3–14 days [57] and may be part of multimodal treatment in metastatic BC. Intravascular stent placing is reserved to cases with severe clinical presentation and limited efficacy or recurrence after medical treatment [46]. Heparin is generally administered around the procedure, but the need for long-term anticoagulation remains controversial [52]. Complications of stent placing are rare, but possibly severe with 2% of mortality rate [58]. Surgery, although effective, requires careful patient selection in view of morbidity and 5% mortality rate [59].

58.3 Metabolic Emergencies

58.3.1 Hypercalcemia

Hypercalcemia of malignancy (HCM) is the most frequent cause of hypercalcemia in the hospital setting [60–62]. It affects 3–30% of cancer patients, particularly with advanced disease. Improved recording may explain increasing prevalence [62], while the widespread adoption of bisphosphonates (BPs) may limit its occurrence [61]. Lung cancer, BC, and multiple myeloma (MM) are the most frequent causes of HCM, followed by cancers of the head and neck, kidney, and ovary [63].

Pathophysiology. The total serum calcium, normally ranging from 8.9 to 10.3 mg/dL, is the sum of the free ionized calcium (47%), the sole component with biological activity, and the non-ionized calcium, mainly bound to albumin and to a lesser extent to serum anions [63]. Accordingly, calcium values should be more conveniently reported as a function of the patient's albumin or "corrected serum calcium" [61, 63].

Four types of HCM have been identified [61]. The most frequent is humoral HCM (about 80% of cases), often with minimal or absent bone involvement and caused by secretion of parathyroid hormone (PTH)-related protein (PTHrP) by malignant tumors (mainly squamous cell cancer, renal cancer, ovarian cancer, endometrial cancer, HTLV-associated lymphoma, BC). The second most common type of HCM, "local osteolytic hypercalcemia" (about 20% of all cases, mainly BC, MM, or lymphoma), affects patients with high bone metastatic tumor burden. Less frequent forms of HCM may be related to excess vitamin D activation (absorptive hypercalcemia) or to ectopic secretion of PTH [61, 63].

The PTHrP protein binds to the same PTH receptor (PTH1R) and stimulates bone resorption with calcium and phosphate release through increased osteoblast receptor activator of nuclear factor kB (RANK) ligand expression, leading to activation of RANK located on osteoclast precursors. It is worth remembering flare hypercalcemia in metastatic BC treated with tamoxifen [64, 65] and less frequently described after treatment with aromatase inhibitors [66–68].

Clinical Features. Clinical manifestations, not precisely related to the severity of hypercalcemia but also to the rate of calcium increase and to albumin level, may be initially nonspecific with possible diagnosis delay [61]. Classic symptoms comprise gastrointestinal manifestation with anorexia, nausea, vomiting, weight loss, abdominal pain, constipation, pancreatitis [63], bone pain revealing skeletal disease involvement, polyuria, fatigue, and weakness. Higher calcium level can lead to renal failure, progressive neurological impairment culminating in coma, and death. Patients with HCM may have short survival, but poor prognosis could reflect advanced cancer stage [63]. Median survival after diagnosis of HCM in BC was 4.5 months and decreased to only 3 months after exclusion of patients with flare HCM. The interval between the first relapse and HCM, sites of metastases, primary treatment, and the level of serum alkaline phosphatase were independent prognostic factors. In a palliative setting, patients not receiving anticancer treatment calcium response to BPs had a significantly positive effect on survival [69].

Diagnosis. The evidence of advanced cancer disease at the time of clinical onset often suggests diagnosis. Laboratory investigation includes measurement of calcium, of albumin, and of intact PTH which should be suppressed. Serum and urine electrophoresis with serum and urine immunofixation are indicated if MM is suspected.

Management. Fluid rehydration is almost universally prescribed. Diuretics, though used, have no proven benefit. Intravenous BPs are treatment of choice, but patients may have incomplete response in 21% or relapse after treatment in 24% of cases [70]. Denosumab may be better than zoledronic acid in preventing skeletal-related events or HCM in advanced malignancies involving bone [71] with 52% lower incidence of HCM in BC [72, 73]. Intensive denosumab schedules may allow calcium control in patients with BP-refractory HCM; however, adverse events were reported [74] and caution was suggested, particularly in patients with renal dysfunction, for the risk of fatal hypocalcemic episodes [75].

58.4 Hyponatremia and SIADH

Hyponatremia (HN) is the most common electrolyte disorder in patients with cancer and possibly associated with decreased survival. Approximately 14% of HN in medical inpatients is related to cancer [76, 77].

Pathophysiology. Hyponatremia is defined as a serum sodium level <135 mmol/L [78]. In most cases, HN in cancer

is induced by syndrome of inappropriate antidiuretic hormone (SIADH), firstly described by Schwartz in 1957 [79], where antidiuretic hormone (ADH) increased release by the pituitary gland or from ectopic production occurs independently from effective serum osmolality or circulating volume [80]. Cancer types most frequently associated with SIADH are small cell lung cancer (10–15%) and head and neck cancer (3%), but it has been identified in a wide variety of other solid and hematological malignancies, including BC [80].

Antineoplastic drugs, especially vincristine, vinblastine, cyclophosphamide, and cisplatin, may cause SIADH [77, 81].

Clinical Features. Hyponatremia can be asymptomatic, or neurological symptoms can appear related to brain edema and increased intracranial pressure.

Milder symptoms, more frequent in patients with chronic hyponatremia, are nausea, headache, confusion, attention deficit, gait disturbances, and risk for falls. Large or rapid declines in serum sodium may cause seizures, coma, and cardiorespiratory arrest [77, 78].

Diagnosis. Evaluation of plasma osmolality is the first step for differential diagnosis. It will be within the normal range in pseudo-HN, a laboratory artifact that is related to high blood concentrations of lipids or proteins interfering with measurement of sodium.

A high plasma osmolality (> 280 mOsm/kg, hypertonic HN) can be due to the presence of osmotically active substances, such as glucose or mannitol, inducing HN by dilution.

In most cases of hyponatremia, plasma osmolality will be low (<280 mOsm/kg, hypotonic HN). In these cases, the next step is to assess urine osmolality. If urine osmolality is <100 mOsm/kg, renal diluting mechanism is intact, and this suggests excessive water intake as a cause of HN. If urine osmolality is >100 mOsm/kg, an inappropriate renal dilution and impaired water excretion are likely.

Evaluation of volume status of the patient can help to distinguish between:

- Hypovolemic hyponatremia: decrease in both total body water volume and sodium, but with the decrease in sodium exceeds the water volume, a condition due to renal sodium loss (e.g., use of thiazide diuretics, gastrointestinal loss).
- Euvolemic hyponatremia: increase in total body water while sodium is near normal, a condition due to SIADH with water retention and urine sodium elimination.
- Hypervolemic hyponatremia: increase in both the total body water volume and sodium, but the increase of water volume exceeds sodium, a condition due to inappropriately elevated amounts of ADH (renal failure, heart failure, cirrhosis). The patient has volume overload or edema. [77, 82, 83].

Management. Medications that may cause hyponatremia should be discontinued.

Hypovolemic patients should be treated with 0.9% saline.

Hypervolemic patients need therapy of the underlying pathology, but usually can be treated safely with loop diuretics.

For euvolemic, mild, or moderate HN that is chronic and minimally symptomatic, there is consensus against a treatment. Fluid restriction is the cornerstone of therapy. In case of acute, symptomatic, moderate, or profound HN, 3% of hypertonic saline is indicated to gradually correct the HN. Correction of sodium should not be too rapid for the risk of neurological "sequelae" due to osmotic demyelination.

If a diagnosis of SIADH is made and HN is refractory to fluid restriction and saline infusion, guidelines recommend increasing intake of osmotic solutes (oral urea). Demeclocycline and vasopressin receptor antagonists (vaptan drugs) can increase serum sodium, but they have limited clinical experience and concerns on safety [78–80, 84].

58.4.1 Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is a cancer complication generated by tumor cell damage and release into the bloodstream of cellular components with complex metabolic and electrolytic perturbation [4]. It is a common complication in patients with hematological malignancies and less frequent in solid tumors [85]. Sporadic cases have been reported also in BC, sometimes after single doses of CHT [86–88].

Pathophysiology. Tumor cell lysis causes rapid release in the bloodstream of intracellular potassium, phosphate, and nucleic acids (purines). Purines are catabolized to hypoxanthine, then to xanthine, and finally to uric acid by the enzyme xanthine oxidase. Uric acid (UA) can crystalize and obstruct the flow in the renal tubules [89, 90]; plasma phosphate and calcium phosphate crystalize in soft tissue, including the renal tract. Renal injury causes hyperkaliemia and acidosis, thus promoting further UA crystallization.

Clinical Features. Cairo classification [89] distinguishes a clinically silent, laboratory-detected TLS and a TLS with clinical manifestations.

Clinical manifestations may include nausea, vomiting, lethargy, edema, fluid overload, congestive heart failure, cardiac dysrhythmias, seizures, muscle cramps, tetany, syncope, and possibly sudden death. The clinical onset may start prior to, or more commonly within 12–72 h after, administration of cytotoxic therapy.

A grading of TLS severity on the basis of clinical complications is also defined [90].

Diagnosis. Diagnostic criteria for TLS have been indicated by Cairo-Bishop in 2004. Laboratory TLS is defined as the presence of two or more of the following abnormalities in a cancer patient within 3 days prior to and up to 7 days after initiation of treatment: plasma levels of UA ≥8 mg/dL,

potassium ≥6 mEq/L, phosphorus ≥4,5 mg/dL, and/or calcium ≤7 mg/dL. Clinical TLS is diagnosed in a patient with laboratory TLS and at least one of these: creatinine serum level ≥1.5 ULN, cardiac arrhythmia, seizure, and sudden death [89].

High morbidity and mortality associated to TLS require identification of patients at risk [90]. Patient-related predictors are older age and low glomerular filtration rate, volume depletion, nephrotoxic medications, and high baseline serum UA, phosphorus, potassium, and lactate dehydrogenase. Tumor-related risk factors include type and burden of disease, high proliferation rate, and high sensitivity to anticancer therapy [86, 91]. These factors allow for patients stratification into three main risk groups [92].

Management. Prevention of TLS is the appropriate strategy. Hydration with intravenous fluid infusion is recommended in intermediate- and high-risk patients to ensure urine output of at least 2 mL/kg/h to minimize risk of kidney injury, before initiation of CHT [90, 93]. Prophylactic oral xanthine oxidase inhibitor, allopurinol, which is highly effective to reduce the conversion of xanthine and hypoxanthine to UA, should be used at the dose of 200–400 mg/m^2/day in one to three doses, up to a maximum of 800 mg a day, given for up to 7 days after CHT is started. Allopurinol's therapeutic effect is delayed by 24–72 h [90], while rasburicase, a recombinant form of the enzyme urate oxidase, reduces plasma UA metabolizing it to allantoin, a much more soluble product. In patients with high risk of developing TLS, rasburicase should be offered along with hydration, as a single dose of 0.1–0.2 mg/kg or as a fixed dose of 3 mg, and repeated only if clinically necessary [90, 92]. Urinary alkalinization increases uric acid solubility but decreases calcium phosphate solubility and should be avoided if rasburicase is available [94].

Once TLS has developed, frequent clinical monitoring and intensive care physicians are indicated. The first step is to maintain a high urine output with hydration with careful fluid balance monitoring. The use of diuretics is controversial because hypovolemia may further compromise kidney function. Rasburicase is the drug of choice for TLS at the dose of 0.2 mg/kg daily, continued for 3–7 days, on the basis of clinical response. Correction of hyperkalemia and hypocalcemia may be needed. Hemodialysis should be considered in patients who are anuric with fluid overload and who have refractory hyperkalemia, hyperuricemia, hyperphosphoremia, and/or symptomatic hypocalcemia [90, 91].

58.5 Hematologic Emergencies

58.5.1 Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a rare hemostatic disorder characterized by activation of clotting and fibrinolytic systems and possible occurrence of bleeding and/or thrombosis. It may be associated with cancer or other diseases, sometimes as the first clinical manifestation [95, 96].

It is reported in approximately 15% of patients with acute leukemia [97] and 6.8% of patients with solid tumors [98] with older age, male gender, advanced malignancies, BC, and tumor necrosis being risk factors. Acute DIC was reported in 1.1% of patients with advanced BC [99].

Pathophysiology. Cancer-related DIC can be due to cancer itself, cancer treatment, or infections [100]. Activation of the blood coagulation pathways is triggered by tissue factor generated by the tumor cells or by host monocytes-macrophages with excessive production of thrombin within the intravascular space. An increased expression of tissue factor can also be observed on endothelial cells, strictly involved in the regulation of blood coagulation by protein C activation, the tissue factor pathway inhibition, or thrombomodulin, and in the same way pro-inflammatory cytokines or tumor necrosis factor can trigger procoagulant pathways, even exacerbating a possible role of CHT or any other treatment [101].

The consumption of platelets and hemostatic factors, the deposition of fibrin in the microcirculation, and the activation of the fibrinolytic system are the main following pathogenetic events and often result in an increased risk of bleeding. Vascular fibrin deposition may cause micro- or macrothrombosis, organ dysfunction, or microangiopathic hemolytic anemia [100].

Clinical Features. The clinical expression of DIC in cancer patients can be widely variable. A clinical distinction can be made between thrombotic, hemorrhagic, or silent forms suggested by laboratory tests. Likewise acute, subacute, or silent forms can be distinguished [101]. Limited data are available about clinical presentation of DIC in BC; although neither acute nor thrombotic/hemorrhagic forms can be excluded, subacute or silent forms seem a more frequent expression in BC (Table 58.2).

Diagnosis. Evidence of hemorrhage and/or thrombotic manifestations together with laboratory findings, including thrombocytopenia, prolonged prothrombin time or activated partial thromboplastin time, decreased serum fibrinogen levels, elevated D-dimer levels, and microangiopathic anemia with schistocytes in the peripheral blood smear, may suggest DIC [102]. Bone marrow metastases can be present [96, 103]. A diagnostic algorithm and score system are useful to assess the probability of DIC (Table 58.3) [101].

Treatment. Treatment of the underlying cause is the primary objective for an effective control of any form of DIC. As most patients have a disseminated cancer at the time of DIC presentation, systemic treatment is the only possible therapy. The choice of an appropriate CHT regimen can be difficult. The risk of serious myelosuppression, also in view

Table 58.2 Clinical manifestations and clinical approach in cancer-related DIC

	Procoagulant	Hyperfibrinolytic	Subclinical
Predominant kinds of cancer	Pancreatic cancer, adenocarcinoma	Acute promyelocytic leukemia, prostate cancer	The most part of solid tumors (breast cancer)
Predominant clinical symptoms	Thrombosis	Bleeding	No symptoms
Clinical presentations	Signs or symptoms of arterial ischemia, cerebrovascular manifestations, venous thrombosis or pulmonary embolism, noninfectious endocarditis	Abnormal hemorrhagic symptoms	Only laboratory abnormalities, without any sign or symptoms of thrombotic or hemorrhagic syndrome
Treatment	Underlying cancer Anticoagulation with heparin	Underlying cancer Supportive care with blood products	Underlying cancer Anticoagulation with heparin

Table 58.3 ISTH score for DIC diagnosis [101]

Laboratory result	Score
Platelet count	
>100,000/mm^3	0
50,000–100,000/mm^3	1
<50,000/mm^3	2
Fibrinogen level	
>100 mg/dL	0
<100 mg/dL	1
Prothrombin time (PT)	
Prolonged <3 s	0
Prolonged 3–5 s	1
Prolonged ≥6 s	2
D-Dimer or fibrin degradation products	
No increase	0
Moderate increase	2
High increase	3
Diagnosis of DIC can be made when a score of ≥ 5 is associated with clinical signs or symptoms of thrombotic and/or hemorrhagic syndrome	

of the frequent bone marrow involvement and preexisting thrombocytopenia, can precipitate bleeding; patient often has large tumor burden with liver involvement and reduced performance status. Interestingly a weekly CHT regimen with high dose of 5-fluorouracil and leucovorin infused over 24 h showed low marrow toxicity and efficacy in patients with gastric cancer and DIC [104] and safety in patients with organ dysfunction [105]. Unfortunately it was not very successful in patients with BC and DIC, even if efficacy was apparently improved when vinorelbine was added [99].

Supportive care may be important even if it can place the dilemma of balancing between the risk of thrombotic and hemorrhagic manifestations.

Prophylactic heparin anticoagulation may be suggested in patients with cancer-related DIC, with the exception of hyperfibrinolytic DIC or other contraindications. Heparin is indicated in patients with predominating thrombotic manifestations with regular clinical and laboratory surveillance [106]. Recombinant human soluble thrombomodulin (TM-α) could become a possible alternative to heparin [107].

In patients with active bleeding, platelet transfusion to maintain the platelet count above 50,000/mm^3 is suggested. Patients at high risk of bleeding (e.g., surgery or invasive procedures) should receive prophylactic transfusions when platelet count is less than 20,000/mm^3.

Fresh frozen plasma (15–30 mL/kg) is suggested in case of active bleeding. Prothrombin complex concentrates can be preferred in case of concerns over volume overload. When low fibrinogen values (below 1.5 g/L) persist despite these supportive measures, transfusion of cryoprecipitate (whenever available) or fibrinogen concentrate is an option [106].

58.6 Treatment Related

58.6.1 Febrile Neutropenia (FN)

Neutropenia is a common effect of anticancer CHT and often goes asymptomatic until hematological recovery; however, infection and febrile neutropenia (FN) may arise, with possible complications, hospitalization, increased costs, treatment delays or discontinuations, dose reductions, and death [108, 109].

The Infectious Diseases Society of America defines FN as a disorder characterized by an absolute neutrophil count (ANC) <1000/mm^3 and a single temperature of >38.3 °C (101 °F) or a sustained temperature of ≥38 °C (100.4 °F) for more than 1 h [110]; other definitions are quite similar [110–117]. In a recent survey, FN occurred in 15.1–21.5% of patients undergoing CHT for metastatic BC, with a 2.1–6.2% rate after the first cycle [110].

Pathophysiology. Incidence and severity of infection are inversely proportional to the ANC, with increasing risk as the ANC falls below 500/mmc and especially under 100/mmc; however, also the ANC fall rate, neutropenia duration, and other predisposing factors are important. The damages of mucosal membranes induced by CHT, any interruption to the integument integrity (e.g., venipuncture and indwelling vascular catheter), the damage of the ciliary function of the trachea and bronchi, any form of obstructive

phenomenon, and alteration of microbial flora may allow bacteria and/or fungi, already colonizing the patient, to permeate the host tissues through his/her mucosal barriers [108]. Neutropenic fever syndromes may fall in three categories: microbiologically documented infection, clinical documented infection, and unexplained fever. Common sites of infections are the oropharynges, the lungs, the perianal area, and the skin.

The most frequently isolated microorganisms from blood culture in patients with FN are Gram-positive cocci, including *Staphylococcus aureus*, *Staphylococcus epidermidis* (especially in patients with indwelling devices), *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Viridans streptococci*, and *Enterococcus faecalis* and *Enterococcus faecium*. Gram-negative bacilli include *Escherichia coli*, *Klebsiella* species, and *Pseudomonas aeruginosa*. *Candida* is the most common fungal infection [118].

Clinical Features. As inflammatory response may be decreased in neutropenic patients, cutaneous, soft tissue, and pulmonary infections may not be obviously clinically or radiologically recognizable; fever can be the sole sign of an initially localized infection [108]. Glucocorticoids may be a confounding factor, limiting the febrile response to bacteria on pyrogens [119]. Accordingly attention should be paid in case of tachycardia, tachypnea, or hypotension in afebrile neutropenic patients as signs of incipient septic shock.

Diagnosis. The initial evaluation should include [110–113]:

- A detailed history with particular attention to new site-specific symptoms, antimicrobial prophylaxis, infection exposures, prior documented infections or pathogen colonization, and underlying comorbid disease.
- A careful clinical examination of the patients with cardiovascular and respiratory assessment and evaluation of the skin, oropharynx, perineum, maxillary and frontal sinuses, abdomen, as well as vascular access site.
- Laboratory tests comprising a complete blood count and measurement of serum levels of creatinine and blood urea nitrogen, electrolytes, liver enzymes, and bilirubin and blood cultures. Chest radiograph, particularly for patients with respiratory signs or symptoms, should be considered.
- Assessment of risk factors for complications of FN [112]. A validated tool is the Multinational Association for Supportive Care in Cancer (MASCC), a simple scoring system with a maximum theoretical score of 26. Patients with a score < 21 are considered as high risk (Table 58.4) [120].

Table 58.4 MASCC scoring index [120]

Characteristic	Score
Burden of illness: no or mild symptoms	5
Burden of illness: moderate symptoms	3
Burden of illness: severe symptoms	0
No hypotension (systolic BP >90 mmHg)	5
No chronic obstructive pulmonary disease	4
Solid tumor/lymphoma with no previous fungal infection	4
No dehydration	3
Outpatient status (at onset of fever)	3
Age <60 years	2

Management. Therapy of FN must be prompt, empiric, bactericidal, and broad spectrum [108]. High-risk patients require hospitalization and IV empirical antibiotic monotherapy with an antipseudomonal beta-lactam agent, such as piperacillin-tazobactam, cefepime, or carbapenem. Vancomycin should be added only in case of suspected catheter-related infection, skin or soft tissue infection, pneumonia, or hemodynamic instability. Modification of treatment should be considered on the basis of clinical and microbiologic information [110].

Low-risk, hemodynamically stable patients may receive oral and/or outpatient treatment, with ciprofloxacin plus amoxicillin-clavulanate, levofloxacin, or ciprofloxacin monotherapy, with hospital admission in case of worsening conditions [121]. For high-risk patients, with persistent fever after 4–7 days of antibiotic treatment without identified fever source, empirical antifungal treatment should be considered. Antibiotic treatment should be continued at least until ANC recovery of ≥500/mmc in patients being afebrile for 48 h with negative blood cultures.

Prophylactic treatment with fluoroquinolone and antifungal agents is generally considered for high-risk patients with expected, prolonged, and profound neutropenia (ANC to ≤100/mmc for ≥7 days).

Routine use of granulocyte colony-stimulating factors (G-CSF), for treatment of uncomplicated FN, is not recommended, except for patients at higher risk of complications, not responding to adequate antibiotic treatment, and with life-threatening infectious complications [113–116].

Primary G-CSF prophylaxis is recommended when FN risk exceeds a threshold of 20% [113, 115, 122]. When FN risk is 10–20%, patient-related risk factors, such as age ≥65 and comorbidities, should guide the decision [113–116]. Secondary prophylaxis with CSFs is indicated after a previous FN episode. An expanded list of CHT regimens at high (≥20%) or intermediate (10–20%) risk of FN is available [113, 116]. However, it must be remembered that FN rates could be higher in the real-world nonselected patients [118]. Several FN predictive tools have been developed, even if few have been prospectively validated [120, 123, 124]. Finally education of outpatients with detailed and clear instruction regarding symptoms and referral contacts should be provided [111].

59 Breast Cancer (Diagnosed) During Pregnancy: Adapting Recent Advances in Breast Cancer Care for Pregnant Patients

Sibylle Loibl, André Schmidt, Oreste D. Gentilini, Bella Kaufman, Christine Kuhl, Carsten Denkert, Gunter von Minckwitz, Anastasia Parokonnaya, Hanne Stensheim, Christoph Thomssen, Kristel van Calsteren, Philip Poortmans, Paul Berveiller, Udo Markert, and Frederic Amant

59.1 Introduction

Breast cancer diagnosed during pregnancy (BCP) is rare, but an increased awareness of treatment options has led to more intensive breast cancer treatment during pregnancy in recent years. The recommendations for diagnosis and treatment of BCP, first published in 2006 and updated in 2010, aimed to increase awareness that treatment during pregnancy is the first option [1, 2], adhering as closely as possible to the general recommendations for young non-pregnant women.

This article aims to provide guidance on BCP with a focus on novel data on BCP and recent advances in breast cancer therapy, including the use of carboplatin, dose-dense chemotherapy, trastuzumab, neoadjuvant therapy and sentinel lymph node biopsy (SLNB) as sole treatment, and how these can be adapted to the needs of pregnant patients (Table 59.1).

59.2 Methods

Members of the breast cancer guideline consortium of the German Cancer Society (DKG) (AGO Kommission Mamma; SL, GvM, CT); the International Network on Cancer, Infertility and Pregnancy (INCIP) of the European Society of Gynaecological Oncology (ESGO; FA, SL, PB, KVC); and other internationally renowned experts in the fields of breast cancer and placenta research (AP, BK, CK, CD, HS, AS, OG, PP, UM) reviewed the literature on BCP, with a focus on 'when the general recommendation to treat as closely as

Table 59.1 Updated recommendations for breast cancer diagnosis and treatment in pregnant and non-pregnant women incorporating recent advances

	Non-pregnant women	Remarks for pregnant women
Diagnostic		
Ultrasound		The preferred technique
Mammography	Techniques with lower exposure	Bilateral mammography recommended in case of BC
MRI and PET	Not generally recommended	Not recommended during pregnancy
Targeted treatment		
Endocrine treatment	GnRH + aromatase inhibitors or tamoxifen	Not indicated
Trastuzumab and pertuzumab	Pertuzumab in addition to trastuzumab for neoadjuvant-treated patients	Risk/benefit analysis needs to be discussed, as early start of trastuzumab improves survival. However, foetal toxicity and oligo-/anhydramnios need to be considered. No data for pertuzumab
Chemotherapy		
Anthracyclines		Transplacental transport, while low, is higher vs taxanes. PK unchanged vs non-pregnant women
Taxanes	Paclitaxel and docetaxel are used mainly in sequential regimen. Weekly paclitaxel is the preferred taxane	Transplacental transport is very low. Small series PK seems to be lower in pregnant vs non-pregnant women, *but dose according to actual body weight and use dose for non-pregnant women*. *Prefer paclitaxel to docetaxel*
Nab-paclitaxel	Higher pCR rate in one study vs. paclitaxel but no long-term data	No data during pregnancy, not indicated
Carboplatin	May be considered for neoadjuvant therapy in TNBC ± g*BRCA* mutation carriers	May be considered for neoadjuvant therapy in TNBC ± g*BRCA* mutation carriers
5-FU	Does not demonstrate added value in non-pregnant women	5-FU-containing regimen not indicated during pregnancy
Preferred regimen		
Standard *EC/AC q3w/Pac q1w*	Taxane based: EC every 3 weeks followed by paclitaxel weekly is one of the most widely used regimens; long-term follow-up recently confirmed activity (reverse sequence is possible)	Taxane based: EC every 3 weeks followed by paclitaxel weekly (reverse sequence is possible—decision might be based on gestational age)
EC/AC q3w/Doc q3w	An almost equally effective regimen—higher myelotoxicity, less sensory neuropathy	An option decision based on side effects and experience
DAC	As effective as AC-Doc, less frequently used because of higher toxicity	Not recommended during pregnancy, because better evaluated and less toxic regimen available
Dose-dense regimen *EC/AC q2w/Pac q1w*	One of the standard[a/b]regimen and an alternative to *EC/AC q3w/Pac q1w*	Can be considered as an option in higher risk BCP patients –G-CSF obligatory
EC/AC q3w/Pac q2w	See above[a]	No data in BCP
ACPac/AC-Pac q2w	See above[a/b]	AC q2w/Pac q2w seems to be an alternative in BCP patients [3]
Dose-dense and intensified dose-dense CT E-Pac-C q2w	Dose-dense and intensified dose-dense CT can be considered in certain high-risk patients	Intensified dose-dense CT is not recommended: high risk for febrile neutropenia and anaemia with need for transfusion
Surgery		
BCS/mastectomy		Indication as in non-pregnant women
Sentinel lymph node biopsy	SNLB is one standard procedure for a certain group of women It is a standard diagnostic procedure for cN0 women	Higher evidence to support use during pregnancy—use to be discussed in pregnant women. Radioactive tracer preferred. Use adapted 1-day protocol

Table 59.1 (continued)

	Non-pregnant women	Remarks for pregnant women
Immediate breast reconstruction		One series during pregnancy reported insertion of an expander as an option. Further, breast reconstruction, e.g. a flap, is not a standard option during pregnancy—breast size differs between pregnant and non-pregnant status

BC breast cancer, *MRI* magnetic resonance imaging, *PET* positron emission tomography, *GnRH* gonadotropin-releasing hormone, *CT* chemotherapy, *PK* pharmacokinetics, *EC* epirubicin/cyclophosphamide, *pCR* pathological complete response, g*BRCA* germ line BRCA, *TNBC* triple-negative breast cancer, *5-FU* 5-fluorouracil, *BCS* breast-conserving surgery, *SLNB* sentinel lymph node biopsy, *cN0* baseline node negative
[a]According to www.ago-online.de; Commission Mamma Version 14.1.0 (March 2015)
[b]According to NCCN Clinical Practice Guidelines in Oncology: Breast Cancer. Version 2.2015

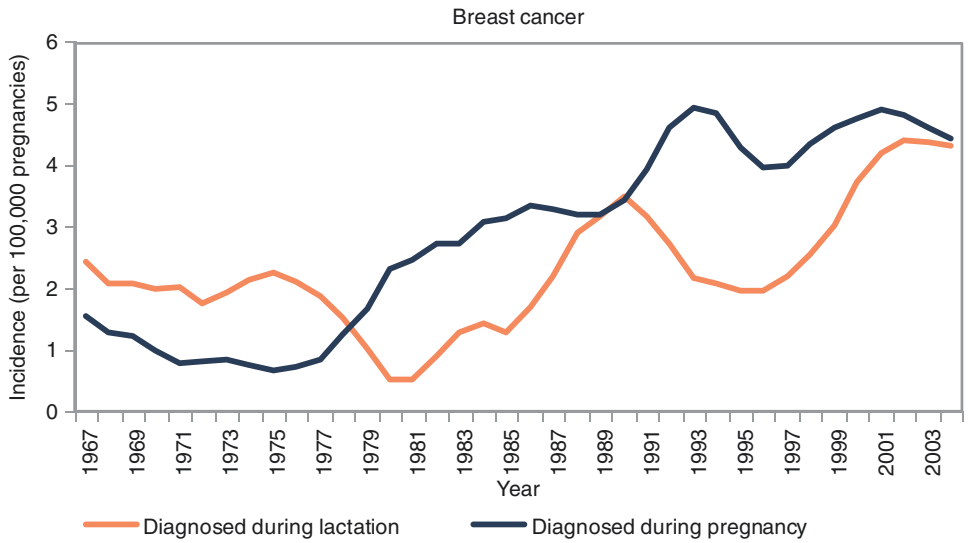

Fig. 59.1 Incidence of breast cancer during pregnancy and lactation (up to 6 months after delivery) based on data extracted from the Cancer Registry and the Medical Birth Registry of Norway. The figure shows annual incidence of BC during pregnancy, *blue line*, for the period 1967–2004, using 5 years of moving averages, showed as proportions per year per 100,000 pregnancies. The mean annual incidence during lactation is about 1.7/100,000 and during pregnancy 3.3/100,000. For the period 1990–2004, the incidence of BC during pregnancy was 4.6/100,000, which is about 1/20,000. For the pregnancy-associated breast cancer (PABC) period, about 1% of all pregnancies are affected. The data are extracted from the material used in the publication by Stensheim et al. [5]

possible to non-pregnant women cannot be followed'. The aim was to provide a narrative review on this special patient cohort providing an update on current understanding of the disease, as well as diagnostic and treatment considerations. A meeting under the umbrella of the DKG and the Union Internationale Contre le Cancer (UICC), supported by DKG and the German Breast Group (GBG) Foundation, was held to discuss the draft recommendations.

59.3 Epidemiology

Breast cancer is one of the most common malignancies during pregnancy [4, 5]. Overall, the incidence of BCP has been increasing during the last few decades (Fig. 59.1). Maternal age has been on the rise in developed countries since the 1970s and subsequently also in several developing countries [6, 7]. The upward trend of breast cancer incidence and the postponing of childbearing have increased the numbers of BCP cases [4, 5, 8, 9]. Approximately one in five breast cancers diagnosed in the age group 25–29 years are associated with a pregnancy, either diagnosed during pregnancy or during the first postpartum year. The reported occurrence of breast cancer diagnosed during pregnancy ranges from 2.4 to 7.3 per 100,000 pregnancies in population-based investigations [4, 5, 8, 9].

A Danish study found that 81% of pregnancies affected with breast cancer were terminated during the first trimester, while others report that only 19% of all BCP was diagnosed in the first trimester [9, 10]. Delayed diagnosis is a likely explanation for the lower number of observed versus expected breast cancer cases.

59.4 Prognosis

Breast cancer during pregnancy generally presents in more advanced stages when compared to that in non-pregnant women, potentially resulting in an overall worse outcome [11]. Several previous studies have addressed this issue, but due to small numbers, results were inconsistent [12, 13]. The largest cohort study included 313 patients controlling for stage, prognostic factors and adjuvant treatment; survival was similar for patients with BCP versus non-pregnant breast cancer patients [14]. In contrast to breast cancer diagnosed during the first year after delivery, the diagnosis of breast cancer during pregnancy does not seem to be an independent poor prognostic factor, provided that standard treatment is administered. Despite possible pharmacokinetic changes, survival rates did not differ between patients who received chemotherapy during pregnancy versus after delivery [10].

59.5 Diagnosis

59.5.1 Imaging Diagnostics

The general recommendations have not changed since 2010. Breast imaging and staging require separate consideration. Breast ultrasound and mammography can be safely and effectively performed during pregnancy [15, 16]. Bilateral mammography is recommended in all women with a confirmed or highly suspicious malignant lesion. The radiation dose is less than 3 mGy, which corresponds to approximately 7 weeks of background radiation [17]. The estimated dose to the uterus/foetus is less than 0.03 μGy [18]. Nevertheless, many patients and physicians are concerned about radiation safety, and this should be discussed with the patient. 'In general, maternal and fetal radiation exposure and dose are affected by gestational age, anatomic site, modality, and technique [16]'. The threshold for negative effects of radiation on the foetus is around 100 mGy, with uncertainty at doses between 50 and 100 mGy [19]. Contrast-enhanced MRI is not recommended during pregnancy. The use of iodinated and gadolinium-based contrast agents during pregnancy is insufficiently explored. The imaging/staging procedures should be conducted only in advanced stages where they might alter the treatment. Unnecessary and less accurate staging procedures should be avoided, as in non-pregnant breast cancer patients. Whole-body MRI has not been studied sufficiently in breast cancer in general. Although pharmacologic agents used for diagnostic nuclear medicine and PET probably do not result in radiation exposure exceeding 50 mGy, they are not recommended during pregnancy [20]. All palpable masses require imaging and imaging-guided biopsy without delay.

59.5.2 Pathology

Histopathologic diagnosis based on core biopsy of the suspicious lesion is the gold standard for BCP. The pathologist needs to be informed about the pregnancy. Overall, the histological features of BCP tumours do not differ from those in young non-pregnant women with breast cancer [10]. The vast majority are ductal invasive, mainly hormone-receptor negative and undifferentiated. In general, tumour mutations do not differ between pregnant and non-pregnant young women, although small series showed significant differences in gene expression analyses [21]. No definite conclusions for general practice can be drawn so far from these analyses. The main challenge for future research is the selection of an appropriate control cohort. Matching cohorts by treatment and/or histology, as well as by age, is required.

59.5.3 BRCA Testing

Family history-taking is a prerequisite, and genetic counselling should be offered according to national guidelines, which differ significantly between countries. BRCA testing will become treatment relevant. The majority of BCP are triple-negative (TNBC); in young TNBC patients, the probability of detecting a germ line *BRCA* mutation is around 20% [22].

59.6 Local Treatment

59.6.1 Surgical Treatment

In general the surgical approach is the same as for non-pregnant patients. Mastectomy is not recommended solely on the basis of pregnancy and possible consequent delay of the radiotherapy. The general recommendations are detailed in a recent publication [23]. Immediate breast reconstruction after mastectomy is an essential component in managing breast cancer patients, particularly those diagnosed at a young age. Based on a single published experience, tissue expander insertion appears to ensure a short operation time and does not seem to be associated with considerable morbidity to the patient or the foetus. Hence, this surgical technique could be considered in the multidisciplinary management of women diagnosed with breast cancer during pregnancy [24].

59.6.2 SLNB

Recommendations from ASCO still state that pregnant patients should not undergo SLNB, based on cohort studies and/or informal consensus [25]. However, it has been shown

that this procedure can be safely performed during pregnancy [26, 27]. SLNB involves locoregional administration of relatively low injected radioactivity doses, with rapid clearance of the negligible radioactivity in the body, as well as substantial and stable uptake at the injection site—which is shortly thereafter removed by surgery. Considering the radiopharmaceuticals and the amounts of activity typically used for SLNB in optimised protocols, the doses absorbed by the foetus are mostly below 20 μGy for 10–20 MBq (about 1 μGy/MBq), as assessed by experimental results and Medical Internal Radiation Dose (MIRD) Committee models [28, 29].

From a maternal oncologic point of view, SLNB appears to be accurate and safe, with only one unsuccessful mapping and one recurrence among 97 patients with BCP [30, 31]. Pregnant breast cancer patients should be offered SLNB rather than axillary clearance whenever it is indicated according to general practice in non-pregnant patients. It is advisable to inject colloid in the morning (1-day protocol) in order to minimise radiation exposure. Blue dye as a sole procedure is not recommended outside pregnancy and is therefore not an option in BCP, because of the low (1%) but potentially harmful underlying risk of an anaphylactic maternal reaction [32, 33]. In a small series of 25 women with SLNB during pregnancy, 7 received blue dye for mapping [31].

59.6.3 Radiation Therapy (RT)

RT during pregnancy is rarely indicated in BCP. In general it is recommended to postpone RT until after delivery [34]. The available information on long-term consequences of in utero exposure to RT is limited [35]. The two factors that have to be considered when RT during pregnancy is indicated are the dose to the foetus and the risk that radiation causes side effects to the foetus. It is important to relate the latter to the magnitude of spontaneously occurring abnormalities. Deterministic (teratogenic) effects must be discriminated from stochastic (carcinogenic) effects. The former are dose dependent and occur only above a certain threshold, while the severity of the latter is independent of the dose, although the probability is dose dependent and without a threshold.

In early pregnancy (when it may not have been diagnosed), irradiation will generally lead to spontaneous abortion, while from the third week onwards, malformations can occur. Radiation may influence the development of the central nervous system, possibly inducing neuropsychological and behavioural dysfunction. The main stochastic effect is the induction of childhood cancer and leukaemia. At low doses the incidence of childhood cancer and leukaemia (0.2–0.3% for ages 0–15 years) does not seem to be increased. Following a dose of 10 mGy, the relative risk increases to 1.4, still resulting in a low absolute excess risk [36]. Another stochastic effect is the induction of germ line mutations to the oocytes; however, there is no evidence of negative effects in humans (Table 59.2).

Table 59.2 Overview of risks and threshold doses following radiation to the foetus

Stage of pregnancy (weeks)	Risk	Threshold dose
<2	Spontaneous abortion	None
3–8	Malformations	100–200 mGy
8–25	Disturbed CNS development	50 mGy
0–40	Childhood cancer/ leukaemia	None

The radiation dose received by the foetus depends on the distance between the RT field and the position of the foetus, so is dependent on gestational age, as well as the amount of leakage of irradiation outside the radiation field and the use of effective shielding, which can reduce the dose by 50–75%. During the first months of pregnancy, the uterus does not extend outside the true pelvis, and, provided that appropriate techniques and shielding are used, the dose to the foetus will be only 0.1–0.3% of the prescribed dose to the breast, resulting in a very low risk of inducing malformations [35]. Several cases with RT administered for BCP are reported, with low foetal doses and resulting in the delivery of healthy babies [37]. Therefore, RT might be considered in the first or early second trimester, if the risk of delaying or omitting RT is felt to outweigh that of harming the foetus.

59.7 Systemic Therapy

59.7.1 Chemotherapy

Chemotherapy is contraindicated during the first trimester of pregnancy because of a higher risk of inducing foetal malformations. The (US) National Toxicology Program (NTP) monograph reports a prevalence of malformations of 14% if chemotherapy is given in the first trimester, declining to 3% if chemotherapy is applied later in gestation [38]. In comparison, the reported rate of major malformations in the general population is approximately 3% in the US and 6.7% in a German registry [39, 40]. Postponing chemotherapy treatment until after delivery might seem to be an option. However, data in non-pregnant young women indicate that delaying/postponing chemotherapy might increase the risk of relapse [41]. Therefore, it is recommended to treat women with BCP during the second and third trimester, following guidelines for non-pregnant young patients as closely as possible [1, 2]. Some anticancer agents, such as trastuzumab, tamoxifen and endocrine agents, should in general be avoided during pregnancy, given their potential foetal toxicity [1, 2]. Individual decisions may be taken.

Anthracyclines, cyclophosphamide and taxanes, the standard adjuvant or neoadjuvant combination recommended for non-pregnant patients, are recommended for treatment of BCP, after the first trimester [42–44]. One of the most widely used regimens, which is also used during pregnancy, is epirubicin/cyclophosphamide (EC) followed by weekly paclitaxel (EC-Pw). The reverse sequence, starting with a taxane, is also possible [45]. Currently, the data do not support the use of anthracycline- or taxane-free regimens, as these are not considered to be standard in non-pregnant women. It was found that 5-fluorouracil does not add any benefit to an anthracycline-taxane-based regimen [46] and is therefore no longer indicated for breast cancer therapy.

Platinum derivatives may have a role in triple-negative breast cancer patients [47]. Neoadjuvant trials demonstrated significantly higher pathological complete response rates by adding carboplatin, but data are immature for survival analyses. Therefore, carboplatin may be considered during the second and third trimesters of pregnancy [48, 49]. It is unclear which platinum molecule is most effective, but carboplatin may have less overall toxicity than cisplatin [38].

Several studies have shown that dose-dense (same dose administered over a shorter interval) or intensified dose-dense (IDD; higher dose over a shorter interval) treatment leads to better survival than conventionally dosed chemotherapy regimens, especially in high-risk patients [50, 51]. While dose-dense chemotherapy seems to be an acceptable option during pregnancy, IDD chemotherapy has not been studied systematically, and only a small number of reports are available [3]. The high rate of grade 2–4 anaemia (59%), with a need for transfusion in 28% of patients, and the high risk of febrile neutropenia (7% despite primary granulocyte colony-stimulating factor (G-CSF) prophylaxis) mandate a very strict risk/benefit analysis, and IDD treatment can therefore not generally be recommended in BCP.

59.7.1.1 Special Considerations in Pregnancy

General rules for administering chemotherapy to a pregnant breast cancer patient are summarised in Table 59.3.

The physiological variations in drug pharmacokinetics during pregnancy raise important concerns regarding optimal drug dosing in pregnant patients [52]. Physiologic alterations associated with pregnancy result in lower maximal concentrations of chemotherapy and a lower area under the concentration-time curve [53]. Most anticancer agents are empirically prescribed according to body surface area (BSA), resulting in large inter-patient variability, even outside the pregnancy setting.

An increased activity of major enzymes involved in the metabolism of taxanes and anthracyclines (including cytochrome p450 isoforms such as CYP3A4 or CYP2C8) has been observed during the late trimesters of pregnancy, potentially resulting in decreased drug exposure [54]. Moreover, since albumin concentrations vary significantly during pregnancy and taxanes are highly protein bound, this may lead to significant changes in taxane pharmacokinetics [52]. Pharmacokinetic data comparing the use of anthracyclines and taxanes in pregnant versus non-pregnant patients demonstrated that taxane serum levels were significantly decreased during pregnancy, especially for paclitaxel [55]. Conversely, exposure to anthracyclines was not significantly modified by pregnancy [52, 53].

Table 59.3 General rules for safe application of chemotherapy during pregnancy

Rule	Comment
Maintain dose intensity	Important to discuss timing of the chemotherapy start in relation to delivery
Use published standard protocols	Neither decrease nor increase the dose Do not increase treatment intervals
Dose according to actual bodyweight	Important to avoid underdosing, which is a risk factor during pregnancy, due to physiologic variation in drug pharmacokinetics. We do not recommend dose adaptation in overweight non-pregnant women
Do not increase the dose	Some data show a lower AUC and C_{max} in women with taxanes treated during pregnancy vs non-pregnant women. Based on 11 cases without outcome data, dose increase cannot be recommended
Recommended to stop chemotherapy around 35th to 37th week of gestation	To allow the bone marrow to recover and prevent hematologic toxicity to the mother and child

AUC area under the concentration-time curve, C_{max} maximum serum concentration

Whether doses should be increased in pregnancy remains uncertain, given that such increases could result in severe toxicities, with potential harm for mother and neonate. Secondly, in overweight women, who also have altered pharmacokinetics, the dose will not be increased [56]. Thirdly, it was shown that the chemotherapy is as active in pregnant as in non-pregnant women [57]. Thus, dosing based on BSA, using the current patient weight (prior to every course), remains a standard, as well as using the same dose for pregnant as non-pregnant women.

While maternal drug exposure is a concern in terms of treatment efficacy, the transplacental transfer of anticancer agents is a critical issue for foetal safety. The placenta is the central organ for foetal-maternal exchange, in addition to its functions such as the protection of the foetus and preparing the maternal body for pregnancy and subsequent lactation [58]. While the transplacental transfer of pharmaceuticals can be well analysed using the perfused human ex vivo placenta, toxic effects of cancer therapy on the human placenta are poorly understood, and data are limited [59]. One reason for this might be that most animal models fail to represent central features of human placentation, with even closely related species such as rhesus monkeys show diverging invasion patterns [60].

Data on transplacental transfer rates indicate similar and reassuring data on anthracyclines and taxanes, although with marked inter-patient variability, particularly with docetaxel [11]. As a consequence, from the foetal safety point of view,

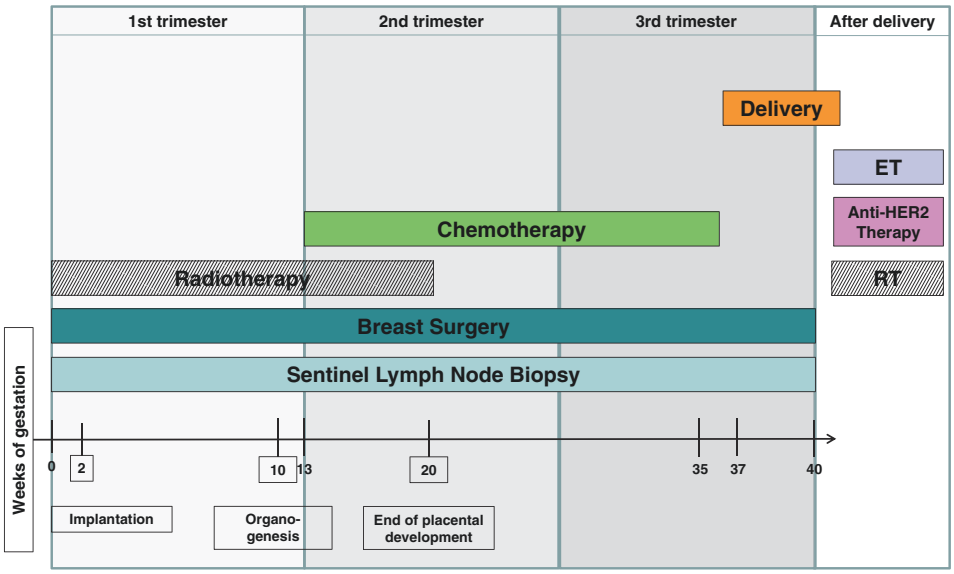

Fig. 59.2 Overview of therapeutic options during pregnancy. Crucial phases: implantation (0–2 w), organogenesis (2–10 w), foetal phase (>10 w). Starting chemotherapy from week 13 to 14 instead of week 10 allows a 'safety period'. Radiotherapy if indicated and decided not to be postponed after delivery can be applied during the first until early second trimester. Preferred option if possible to apply after delivery. Endocrine therapy and anti-HER2 treatment to be given after delivery

paclitaxel should probably be preferred to docetaxel in the setting of pregnancy [61]. Significant transplacental transfer of carboplatin was demonstrated, but long-term data from children remain limited [38, 62].

A significantly higher incidence of small-for-gestational-age babies is observed when chemotherapy is given during pregnancy, indicating a potentially toxic influence on placental development leading to placental malfunction, e.g. via incomplete trophoblast invasion into the uterus, resulting in a decreased transfer of nutrients to the foetus [10, 63]. Organogenesis is completed around the tenth week of gestation (and this is the reason why chemotherapy can be considered from that time point onwards); trophoblast invasion of the placenta is not completed until around week 20 [64]. These observations explain why starting chemotherapy at week 14 might interfere with late stages of placental development (Fig. 59.2).

59.8 Anti-HER2 Treatment

Trastuzumab is indicated as an integral part of primary treatment in women with HER2+ breast cancer. Initiating trastuzumab as early as possible, and in combination with the cytotoxic agents rather than in sequence, is associated with a better long-term outcome in non-pregnant patients [65]. In a recent review, the authors identified 18 reports in the literature of using trastuzumab during pregnancy and 19 newborns [43]. They described oligo- and anhydramnios as the most frequent side effect (33.3%) that was in general self-limiting when trastuzumab was stopped. However, most of the pregnancies ended prematurely, and four of the newborns died due to complications of prematurity (mainly respiratory failure). Although it is generally not recommended to use trastuzumab during pregnancy, it may be discussed in special high-risk situations [43]. Foetal and maternal risks and benefits need to be weighed, and informed decision-making is absolutely crucial, if trastuzumab is considered for use during pregnancy. However, inadvertent foetal exposure of 1–2 cycles of trastuzumab is no reason for termination of pregnancy. Pertuzumab in addition to trastuzumab and chemotherapy increases the pathological complete response rate in patients with HER2+ breast cancer, but currently there are no data on the use of pertuzumab during pregnancy.

59.9 Supportive Treatment

The overall aim is to offer the best supportive therapy without adding further risk. In general the majority of supportive regimens can be given safely during pregnancy (Table 59.4). According to international guidelines, women receiving an anthracycline/cyclophosphamide combination are at particularly high risk of nausea and vomiting. A 3-drug regimen including a 5-HT3 receptor antagonist, dexamethasone and a neurokinin1 (NK1) inhibitor is recommended in non-pregnant patients [66]. 5-HT3 antagonists have been extensively studied for pregnancy-induced and spinal anaesthesia-induced nausea and vomiting and were shown to be safe [67]. The use of NK1 inhibitors, without adverse effects, has been reported only in single cases of a BCP registry (GBG data on file), but these agents cannot be recommended until more safety data become available. The recommendation on dexamethasone remains unchanged (Table 59.4) [68–70].

Although granulocyte colony-stimulating factor (G-CSF) support can reduce the occurrence of febrile neutropenia, its effectiveness and safety profile during pregnancy are not clearly confirmed. One retrospective analysis reported that the use of daily or long-acting G-CSF did not affect outcome in the newborn [71]. As dose-dense chemotherapy absolutely requires the use of primary prophylaxis with G-CSF, this supportive treatment should not be withheld if a careful risk/benefit assessment indicates that this more aggressive form of chemotherapy is required.

Table 59.4 Supportive therapy for chemotherapy during pregnancy

Drug class	Examples	Recommendation
Antiemetics		
5-HT3 antagonists	*Ondansetron* Palonosetron Granisetron Tropisetron Dolasetron	Ondansetron during pregnancy not associated with significantly increased risk of adverse foetal outcomes. Other 5-HT3 antagonists are less well investigated. Granisetron does not appear to cross the placenta
Neurokinin 1 inhibitors	*Aprepitant* Fosaprepitant	No data available; single reports with no adverse outcome can be given if necessary
Corticosteroids	Dexamethasone Betamethasone *Methylprednisolone*	Dexamethasone contraindicated in the first trimester (risk of cleft palate). Attention deficit disorder reported with dexa- and betamethasone use. Methylprednisolone is the preferred option
H1 antagonists		Seem to be safe
H2 antagonists	*Ranitidine* *Cimetidine*	No increased incidence of malformations with H2 blocker. Can be used to prevent allergic reaction
Proton pump inhibitors	Omeprazole Pantoprazole	Seems to have muscle-relaxant effects in vitro
Colony-stimulating factors		
Granulocyte-stimulating colony factor	*Daily use* (*filgrastim*, lenograstim) or *long acting* (pegfilgrastim, lipegfilgrastim)	Information about the use of G-CSF during pregnancy is limited. In a series of 34 children exposed to daily G-CSF, no splenomegaly and no increased rate of opportunistic infections were reported

5-HT3 5-hydroxytryptamine, *H1* histamine H1 receptor, *H2* histamine H2 receptor, *G-CSF* granulocyte-stimulating colony factor

59.10 Obstetrical Care

In utero exposure to chemotherapy has also been associated with a small increase in risk of preterm rupture of membranes (3% vs. 0%) and preterm labour (6% vs. 2%) [10]. The largest and most recent studies report a mean gestational age at delivery of 36–37 weeks, indicating that a significant proportion of patients deliver (iatrogenically) preterm [10, 63]. Reassuring data from older studies investigating long-term outcome of children antenatally exposed to chemotherapy were recently confirmed using a standardised age-appropriate assessment to examine neurocognitive functioning, as well as in a subsequent case-control study [72, 73]. Since prematurity has an important impact on neuropsychological outcome, this should be avoided whenever possible. Treatment during pregnancy may help to achieve a full-term pregnancy. Also, the cardiac outcome of children who received anthracyclines antenatally appears to be reassuring [74].

The obstetrician should see the patient at least once every 3 weeks with an ultrasound assessment of the foetus, the amniotic fluid and the flow in the umbilical artery, in addition to standard prenatal care. Prior to start of treatment, the status quo of the pregnancy should be documented and the estimated date of delivery confirmed. If the pregnancy is complicated, for example, by gestational diabetes or hypertension, additional measures need to be implemented, and shorter intervals might be necessary.

It is recommended to deliver as closely as possible to term, after close observation of the mother and child. A 2–3-week interval between the last chemotherapy cycle and delivery is recommended, in order to allow the bone marrow to recover and prevent hematologic toxicity to the mother and child.

Conclusion

Breast cancer should be treated during pregnancy following the general guidelines for young non-pregnant patients as closely as possible. The complex medical situation of breast cancer in pregnancy requires a multidisciplinary discussion. Major concerns are congenital malformations, effects on foetal growth, preterm delivery and long-term toxicity in children [10]. An individual risk/benefit analysis, taking into account the mother and foetus, is crucial. Staging and treatment procedures need to be discussed, aiming to reduce the foetal toxicity from (accumulated) radiation. A close collaboration with the obstetrician and perinatologist is warranted.

Evidence for current and future recommendations for BCP, taking into account treatment evolvement for the care of our patients, can be generated only by large prospective cohort studies. BCP cases should be registered through the German Breast Group (www.germanbreastgroup.de) or through the registry of the INCIP (www.cancerinpregnancy.org). These international collaborations started 10 years ago and have provided the basis of current knowledge on BCP.

Chest Wall Disease: The Clinical Continuum Between Inflammatory and Lymphangitic Breast Cancer

60

Giuseppe Curigliano

60.1 Introduction

Inflammatory breast cancer (IBC) is an uncommon entity that affects about 2.0–2.5% of women diagnosed with breast cancer [1]. The clinical presentation consists of diffuse erythema, rapid enlargement of the breast, skin ridging, and a characteristic "peau d'orange" appearance of the skin secondary to dermal lymphatic involvement [2, 3]. Overall survival is shorter than with non-IBC [4, 5]. Many patients relapse and progress locally to a lymphangitic spread to chest wall and to metastatic disease. Lymphangitic breast cancer (LBC) is pathologically characterized by high vascularity, skin lymphatic vessel infiltration, and increased microvessel density because of high expression of angiogenic factors [3]. Vascular endothelial growth factor (VEGF) is a key mediator of angiogenesis and is involved in endothelial and tumor cell growth and motility and blood vessel permeability [6]. Extensive vascular involvement of LBC makes this tumor especially amenable to antiangiogenic treatment. The use of bevacizumab, a VEGF-targeting monoclonal antibody, resulted in improved progression-free survival and response in patients with advanced breast cancer in several randomized phase III trials [7–12].

60.2 Management of Inflammatory Breast Cancer

The diagnosis of IBC should remain a clinical one with essential pathological confirmation of invasive carcinoma, while dermal lymphovascular tumor emboli, when a skin punch biopsy is carried out, is pathogneumonic but not required for a diagnosis. Although routine breast radiological investigations are recommended as part of staging workup, the data are currently not sufficient to define any radiological signs specific for IBC and are therefore not part of the diagnostic criteria. A multidisciplinary approach for women with IBC is recommended. Primary systemic chemotherapy, surgery, and radiation therapy should all be included in the treatment plan. Due to the fact that most women with IBC will have locoregional disease at presentation and the presence of extensive skin involvement, surgery should not be considered the first approach. If surgery is attempted upfront, the probability of residual disease being left behind is high, and therefore, it is strongly recommended that patients with clinical diagnosed IBC be referred to a medical oncologist. All women with IBC should be offered primary systemic chemotherapy as the first line of treatment with the goal of downstaging the tumor to allow for definitive surgery. There are no data from large randomized clinical trials looking at the optimal chemotherapeutic regimen specifically for women with IBC. Thus, recommendations made are based primarily on retrospective studies, small prospective studies, and extrapolation of data available from prospective trials evaluating women with non-IBC tumors. Systemic treatment should be defined according to biological features of disease. The monitoring of response to primary systemic chemotherapy should be a combination of physical examination and radiological assessment. Physical examination of the breast for response may be conducted at every course of systemic therapy. Radiological assessment should be carried out at the end of treatment and compared with baseline results. Due to clinical presentation, the physical examination and imaging techniques can underestimate the extent of residual disease. Despite a clinical response to treatment is observed, residual disease may still be present in the affected skin of the involved breast. The surgical approach to IBC following preoperative systemic treatment is a modified radical mastectomy. A skin-sparing mastectomy approach is contraindicated, and breast-conserving approaches may only be attempted within the context of a clinical trial. All women with IBC who undergo a modified radical mastectomy are recommended to receive postmastectomy radiation therapy. Since a

high probability exists of involvement of locoregional lymph nodes, which would predict for a high likelihood of locoregional recurrence, is highly recommended radiation therapy on the supraclavicular regions and internal mammary lymph nodes. It is also recommended that the cumulative radiation dose be escalated to 66 Gy in the subset of women who are <45 years of age, who have close or positive surgical margins, who have four or more positive lymph nodes following preoperative systemic treatment, or who have demonstrated a poor response preoperative systemic treatment. Skin dose should be modulated to ensure moderate acute erythema in response to radiation.

60.3 Clinical and Pathological Characteristics of Inflammatory Breast Cancer

A differentiation between primary and secondary inflammatory breast cancer has to be made. By primary inflammatory breast cancer, we refer to the development of breast carcinoma in a previously normal breast. The term secondary inflammatory breast carcinoma is given to the development of inflammatory skin changes associated with invasive breast carcinoma in a breast that already had cancer, or there was carcinoma in the chest wall that developed after a mastectomy for noninflammatory breast carcinoma. Several conditions can mimic the clinical presentation of IBC. Non-puerperal bacterial mastitis may be confused with IBC, leading to potentially preventable delays in diagnosis and treatment. The skin changes in IBC are caused by tumor emboli within the dermal lymphatics and—contrary to the suggestion evoked by the nomenclature—not by infiltration of inflammatory cells. Although microscopical detection of tumor emboli in dermal lymphatic vessels is supportive of the diagnosis, it is not required. Furthermore, dermal lymphatic invasion without typical clinical findings is not sufficient for a diagnosis of IBC.

60.4 Epidemiologic Features

Inflammatory breast cancer is the most aggressive entity of breast cancer and comprises 2.5% of all breast cancers [1]. The median overall survival among women with IBC is less than 4 years even with multimodality treatment options. However, an increasing survival in recent years has been noted with improvement of chemotherapeutical management [2]. The incidence of IBC appears to be increasing, particularly among Caucasian women. Women with IBC typically present at a younger age than non-IBC [2]. Four large population-based studies have reported a higher incidence in young African-American women, and they had a worse survival compared to Caucasian women. The cause of racial disparities has not yet been elucidated [2–5]. It has been noted that Hispanic women had the youngest mean age of onset (50.5 years) compared with 55.2 years for African-American women and 58.1 years for Caucasian women [2]. Data on risk factors is limited: a high body mass index (BMI) is positively associated with a diagnosis of IBC compared to non-IBC [2]. Several other risk factors have shown some indication of being associated with the diagnosis of IBC (e.g., younger age at live first birth), but further studies are warranted [2]. In contrast, higher level of education was associated with reduced risk of ER-positive IBC, more so than for noninflammatory breast cancer. Advanced age at first birth was associated with reduced risk of ER-negative IBC. Several studies have reported that IBC constitutes a larger proportion of breast cancers in low-income countries than Western countries [13, 14]. Managing IBC in low-income countries poses a different set of challenges including access to screening, stage at presentation, adequacy of multidisciplinary management, and availability of therapeutic interventions [15].

60.5 Biological Features of Disease

IBC is characterized by less hormone receptor expression compared to noninflammatory breast cancer (NIBC), which has been associated with a more aggressive clinical course and decreased survival [16, 17]. Up to 83% of IBC tumors lack estrogen receptor (ER) expression compared with other forms of locally advanced breast cancers which are mostly ER positive [18, 19]. Analysis of 2000 patients with IBC from the California Cancer Registry has shown that expression of ER and PR was lower among IBC patient cases compared to both non-T4 carcinomas (56% ER, 45% PR versus 80% ER, 68% PR) and in patients with locally advanced breast cancer (67% ER, 54% PR) [19]. Despite a decreased estrogen receptor expression in IBC, hormone production might still play a role. GPR30 expression (a seven-transmembrane receptor belonging to the G protein-coupled receptor family and regulates cellular and physiological responsiveness to estrogen) was found in 69% of patients with IBC which was not interdependently expressed with ER. Therefore, estrogen signaling may be active in ER-negative IBC patients [20]. Subsequently, it may be possible to exploit new potential therapies through nonclassical estrogen-dependent pathways despite the lack of detectable ER. Specific GPR30 antagonists (G15 and G36) have shown to inhibit estrogen-stimulated proliferation of uterine epithelial cells in vivo. Further assessment of the effects and mechanisms of action of both agents in IBC cell lines and tumor xenografts is yet to be conducted [21, 22].

60.6 Epidermal Growth Factor Receptors

The epidermal growth factor receptor family plays an important role in cell proliferation, survival, migration, and differentiation and consists of four members: epidermal growth factor receptor (EGFR) and human epidermal growth factor receptor 2, 3, and 4 (HER2, HER3, and HER4) [23]. EGFR overexpression was detected in 30% of patients with IBC and found to be associated with a significantly worse 5-year overall survival rate compared to EGFR-negative IBC. Furthermore, EGFR expression was associated with increased risk of IBC recurrence [23]. In an IBC xenograft model, erlotinib (an EGFR tyrosine kinase inhibitor) inhibited IBC tumor growth and inhibited spontaneous lung metastasis. These results suggest that the EGFR pathway is involved in tumor growth and metastasis of IBC and thereby potentially represents an effective therapeutic target [24]. Human epidermal growth factor receptor 2 (HER2) is a transmembrane receptor tyrosine kinase and is involved in signal transduction pathways leading to cell growth and differentiation [25]. Overexpression of HER2 in breast cancer is associated with increased aggressiveness and higher recurrence rates and higher mortality [26]. IBC patient cases were noted to have a higher proportion of HER2-positive patient cases compared with non-T4 patients and compared with LABC [27]. Despite the association with advanced tumor stage, HER2-positive status is not an independent adverse prognostic factor for survival among IBC patient cases [27]. The NOAH trial aimed to assess event-free survival in patients with HER2-positive locally advanced or inflammatory breast cancer, respectively, 144 and 77 patients, receiving neoadjuvant chemotherapy with or without 1 year of trastuzumab. The addition of neoadjuvant and adjuvant trastuzumab to neoadjuvant chemotherapy showed a significantly improved event-free survival in patients with HER2-positive breast cancer (3-year event-free survival of 71% study) and a significantly improved pathological response in both breast tissue and axillary lymph nodes [22]. When trastuzumab is administered in the neoadjuvant setting only, with an average of 20 weeks preoperative administration, patients with IBC continue to have a high risk of locoregional recurrence and relatively early recurrence in the brain even when pathological complete response is reached [27]. However, it should be noted that no comparison with NIBC was made and that current standard is 1-year duration of trastuzumab treatment, rather than 20 weeks only. Lapatinib is a dual inhibitor of the EGFR and HER2 receptor tyrosine kinases. Lapatinib induces tumor delayed cell growth or apoptosis in EGFR- or HER2-dependent tumor cell lines or xenografts [49]. A phase II trial was performed to investigate the neoadjuvant administration of lapatinib in combination with paclitaxel [28]. Patients were assigned to cohorts A (HER2-overexpressing [HER2+] ± EGFR) or B (HER2−/EGFR+). The primary end point was pathologic response, which was evaluated at the time of surgical resection at the completion of 12 weeks of lapatinib/paclitaxel combination therapy and was defined according to evidence of residual invasive tumor, including residual tumor in the axillary lymph nodes. The HER2-negative/EGFR-positive cohort had been terminated because of lack of efficacy observed in another trial with IBC patients with HER2-negative/EGFR-positive tumors. Secondary endpoints included safety and tolerability of lapatinib and paclitaxel combination [27]. A neoadjuvant treatment regimen of daily lapatinib monotherapy for 14 days, followed by combination therapy with daily oral lapatinib and weekly paclitaxel for 12 weeks, had a combined clinical response rate of 78.1% in IBC patients with HER2-overexpressing tumors without unexpected toxicity [29]. The impact on DFS and OS of neoadjuvant administration of lapatinib has to be evaluated in future clinical trials. Remarkably, HER3 has been identified as a potential marker of drug sensitivity in lapatinib therapy [30]. Phosphorylated HER3 predicted response to lapatinib and tumors coexpressing phosphorylated HER2 and HER3 were more likely to respond [30]. As a prognostic marker, expression of HER3 has been associated with reduced breast cancer-specific survival [31]. A more complete picture of the role of HER3 as a therapeutic target or potential marker in IBC is yet to emerge. HER3 lacks a tyrosine kinase domain; therefore other potential targets than the tyrosine kinase domain have to be addressed. Several ligands, such as the neuregulins and heregulin, bind HER3 [32, 33]. Blocking heregulin expression inhibits tumorigenicity and metastasis of breast cancer cells [34]. HER3 ligands could thereby be potential therapeutic targets in IBC.

60.7 Tumor Suppressor Genes and Oncogenes

Tumor suppressor p53 is a transcription factor that regulates the cell cycle. Alteration or inactivation of p53 by mutation can lead to cancer development [34]. Higher levels of dysregulated p53 expression have been detected in IBC compared with other locally advanced breast cancers, however not statistically significant: 53% versus 36% ($p = 0.19$) [35]. In a study of 24 patients, it was shown that patients with IBC with a p53 gene mutation and nuclear overexpression of p53 protein have an 8.6-fold higher risk of death compared with patients that had neither mutation nor protein overexpression. Moreover, an important prognostic interaction with ER expression was observed. Patients who were both ER negative and had nuclear p53 overexpression had a 17.9-fold higher risk of death, compared to 2.8-fold for women with tumors that had p53 nuclear overexpression alone [36]. Analysis of 95 patients with IBC has shown that patients with IBC who do not have dysfunctional p53 protein

expression (p53 negative) have a better prognosis compared to p53-positive IBC when treated with optimal systemic and locoregional treatments. All recurrences and deaths in this study, 28 and 26, respectively, occurred in the group of nuclear p53-positive tumors [37]. As p53 status seems to have an important influence on outcome, the results of the INGN-201-bioengineer construct are eagerly awaited. INGN-201 is an adenoviral vector that carries the normal p53 gene under the control of the cytomegalovirus (CMV) promoter. INGN-201-mediated p53 expression induces apoptosis and/or inhibition of proliferation in vitro in cancer cell lines from numerous tumor types, with almost no effects on normal cells [38]. INGN-201 was investigated in combination with docetaxel and doxorubicin in locally advanced breast cancer [38]. Unfortunately, no results are known and patients with IBC were excluded. However, the higher levels of expression of p53 IBC cancer may justify the use of INGN-201 in future IBC trials. Another potential target might be anaplastic lymphoma kinase (ALK) genetic abnormalities. ALK is a receptor tyrosine kinase (RTK) within the insulin receptor superfamily, and there has been evidence for the activation of ALK pathway activation in preclinical models of IBC [39]. Crizotinib, a small molecule ALK inhibitor, showed promising results in non-small cell lung cancer patients with ALK genetic abnormalities compared with standard second-line chemotherapy [40]. Crizotinib arrested growth of IBC cells in culture and activated the cell death pathway [39]. Based on these results, IBC patients are being screened for ALK genetic abnormalities and, if eligible, included in clinical trials with ALK inhibitors [41].

60.8 (Lymph) Angiogenic Factors

The dependence of solid tumors on blood supply for their ability to grow and metastasize is nowadays an established concept in tumor biology. Tumor angiogenesis, the sprouting of new capillaries from existing vessels, is the result of a complex and precise balance between proangiogenic and antiangiogenic factors and is essential to the growth of primary and metastatic tumors beyond the diameter of 1–2 mm^3. A variety of endogenous factors associated with angiogenesis induction have been studied extensively, including vascular endothelial growth factors (VEGF) and basic fibroblast growth factors (bFGF). Recently, endogenous inhibitors of angiogenesis gained more attention. At time of diagnosis, most patients with IBC have axillary lymph node involvement [63]. Lymphatic metastases can occur by invasion of pre-existing lymph vessels and by tumor-induced lymph angiogenesis in which VEGF also plays an important role [42]. Therefore, it might be an interesting molecular mechanism to target in the prevention of axillary involvement. Molecular and histomorphometric studies of human IBC samples have provided evidence of increased angiogenesis and lymphangiogenesis in IBC. Significant increased intratumoral microvessel density was observed in IBC patients compared to NIBC, thereby indicating IBC as a highly vascular disease with an enlarged intratumoral vascular area [43]. Furthermore, a positive correlation between the expression of carbonic anhydrase IX (an endogenous hypoxia marker) and endothelial cell proliferation was found. However, expression of CA IX was significantly less frequent in IBC than in NIBC with early metastasis. There was a significant positive correlation between the expression of CA IX and endothelial cell proliferation in IBC, implying that the angiogenesis is partly hypoxia driven. However, the higher endothelial cell proliferation in IBC and the less frequent expression of CA IX in IBC versus NIBC points at a role for other factors than hypoxia in stimulating angiogenesis [44]. Molecular evidence of increased angiogenesis was provided by elevated mRNA expression of angiogenic factors and their receptors which were quantified by real-time reverse transcriptase polymerase chain reaction (RT-PCR). Among others, expressions of TIE-1 and TIE-2 (cell surface proteins of endothelial cells), which have been described in angiogenesis, are elevated [45]. Histomorphometric evidence of lymphangiogenesis appeared from a study comparing samples from 29 patients with IBC with 56 samples from patients with NIBC. A higher lymphatic endothelial cell proliferation in IBC was demonstrated and a larger relative tumor area occupied by lymph vessels compared to NIBC [46]. As previously noted, VEGF is involved in both angiogenesis and lymphangiogenesis, and elevated levels of VEGF are found to be highly expressed in IBC [2, 47]. It was observed that intratumoral VEGF-C and VEGF-D mRNA were significantly more expressed in IBC than in patients with noninflammatory disease [47]. VEGF-C has shown to be associated with increased lymph vessel density and lymph node involvement in invasive breast cancer [48]. VEGF-D can induce both tumor angiogenesis and lymphangiogenesis and promotes the lymphatic spread of tumors [45]. By real-time quantitative reverse transcriptase-PCR, levels of mRNA of tumor angiogenesis and lymphangiogenesis-related factors (e.g., VEGF) were measured in 16 patients with IBC and 20 patients with noninflammatory breast cancer. No significant difference in expression level of angiogenic VEGF-A in inflammatory breast cancer was found when compared with noninflammatory breast cancer. However, its receptor (vascular endothelial growth factor receptor 2) was significantly upregulated in IBC versus noninflammatory breast cancer. VEGFR-2 is predominantly expressed in endothelial cells, and its activation results in a mitogenic and migratory response. Most functions of VEGF are mediated through this receptor [46]. Furthermore, it was demonstrated that tumor stromal VEGF-A expression is a valuable

prognostic indicator of breast cancer-specific survival and disease-free survival at diagnosis and can therefore potentially be used to stratify IBC patients into low-risk and high-risk groups for death and relapses [48]. In a retrospective analysis, IBC samples were compared to normal breast tissue from reduction mammoplasty patients. Significantly lower epithelial VEGF-A immunostaining was found in IBC tumor cells than in normal breast tissues, cytoplasmic VEGF-R1 and nuclear VEGF-R2 levels were slightly higher, and cytoplasmic VEGF-R2 levels were significantly higher ($P = 0.04$). Sixty-two percent of IBC tumors had high stromal VEGF-A expression. Stromal VEGF-A levels predicted breast cancer-specific survival (BCSS) and DFS in IBC patients with estrogen receptor positive ($P < 0.01$ for both), progesterone receptor positive ($P = 0.04$ and $P = 0.03$), HER2+ ($P = 0.04$ and $P = 0.03$), and lymph node involvement ($P < 0.01$ for both). Tumor stromal VEGF-A was identified as an independent predictor of poor BCSS (hazard ratio [HR], 5.0; 95% CI, 2.0–12.3; $P < 0.01$) and DFS (HR, 4.2; 95% CI, 1.7–10.3; $P < 0.01$). This might indicate that tumor stromal VEGF-A expression is a valuable prognostic indicator of BCSS and DFS at diagnosis and can therefore be used to stratify IBC patients into low-risk and high-risk groups for death and relapses. High levels of tumor stromal VEGF-A may be useful for identifying IBC patients who will benefit from antiangiogenic treatment. Due to the displayed highly angiogenic features, patients with IBC might benefit from antiangiogenic agents that target VEGF [2]. Bevacizumab is a monoclonal antibody to VEGF and has been shown to inhibit VEGF receptor activation, specifically VEGF-A [2, 42]. However, bevacizumab's indication to treat locally recurrent or metastatic HER2-negative breast cancer has been removed by the Food and Drug Administration (FDA). It stated that no trial in breast cancer using bevacizumab provides evidence of direct clinical benefit and that only modest effects on primarily radiographic outcomes were demonstrated. These modest indirect measures of clinical benefit must be weighed against a marked increase in clinically serious adverse events (gastrointestinal perforations, hemorrhage, surgery, and wound healing complications) and therapy-related deaths. Deaths attributed to bevacizumab ranged between 0.8% and 1.2% as released by the Food and Drug Administration [49]. Despite these concerns involving treatment of breast cancer with bevacizumab, there may still be an indication for a subgroup of patients. For example, since IBC is more angiogenic than noninflammatory breast cancer and has significantly higher levels of VEGF expression, bevacizumab treatment may be useful in IBC patients [43]. Some hints for efficacy of bevacizumab in IBC have been suggested in small clinical studies. The first study demonstrated a significant decrease of 66.7% in phosphorylated VEGFR-2 in 21 patients with inflammatory and locally advanced breast cancer (one patient had NIBC since the study briefly was open to NIBC patients) which were treated with one cycle of bevacizumab, followed by six cycles of bevacizumab with doxorubicin and docetaxel. However, clinical benefit in terms of DFS and OS has not been determined [50]. In another study, 20 patients with IBC and one with locally advanced breast cancer received one cycle of bevacizumab followed by six cycles of bevacizumab with docetaxel-doxorubicin before surgery. Angiogenic markers were measured at baseline before bevacizumab, after bevacizumab, and after bevacizumab plus chemotherapy. VEGF-A was higher at baseline in the responders than nonresponders, demonstrating a trend toward association with response. Moreover, baseline CD31 and platelet-derived growth factor (PDGFR) beta were significantly associated with response to bevacizumab. Patients with IBC with higher tumor gene expression of VEGF-A, CD-31, and PDGFR-beta were more likely to benefit from treatment with bevacizumab with chemotherapy [50]. In a phase II, multicenter, open-label, single-arm, noncomparative trial, patients with histologically confirmed HER2-positive nonmetastatic IBC were enrolled to assess efficacy and safety of neoadjuvant bevacizumab combined with trastuzumab and chemotherapy. Primary end point was pathological complete response. Before surgery, patients were treated with fluorouracil, epirubicin, cyclophosphamide, and bevacizumab (cycles 1–4) and docetaxel, bevacizumab, and trastuzumab (cycles 5–8) in 3-week cycles. After surgery, patients received adjuvant radiotherapy, trastuzumab, and bevacizumab. After neoadjuvant therapy, 33 of 52 patients had a pathological complete response. Furthermore, this treatment regimen seemed to be well tolerated [51]. In another prospective, phase II randomized trial, oral vinorelbine plus capecitabine and bevacizumab (BEVIX) is an active regimen for patients with LBC [52]. Patients with inflammatory or LBC have a poorer prognosis than those with other breast cancers. In the phase II BEVERLY 2 study, women with histologically confirmed HER2-positive nonmetastatic IBC were treated with fluorouracil, epirubicin, cyclophosphamide, and bevacizumab (cycles 1–4) and docetaxel, bevacizumab, and trastuzumab (cycles 5–8) in 3-week cycles [51]. After neoadjuvant therapy, 33 of 52 patients had a pathological complete response [51]. In the phase II PEGASE 02 study, patients with IBC received neoadjuvant chemotherapy with cyclophosphamide, doxorubicin, and fluorouracil [53]. Although the clinical response rate was high (90%), pCR was achieved in only 32% of patients [53]. The AVEREL study evaluated first-line bevacizumab-containing therapy for HER2-positive locally recurrent/metastatic breast cancer [54]. In this study, high baseline plasma VEGF-A concentrations were associated with larger benefit of bevacizumab (not statistically significant) [54]. In another study, patients with stage III locally advanced or inflammatory breast carcinoma received four

3-weekly cycles of FEC (5-fluorouracil, epirubicin, and cyclophosphamide) followed by 12 cycles of weekly paclitaxel in combination with bevacizumab 10 mg/kg every 2 weeks as neoadjuvant therapy [55]. In the intent-to-treat population, the pCR rate was 21%, and the clinical response rate was 59% [55]. A pilot clinical trial evaluated the efficacy of neoadjuvant therapy with bevacizumab, in combination with doxorubicin and docetaxel in 21 previously untreated patients with locally advanced breast cancer, 20 of whom had IBC [11]. Tumor biopsies and dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) were obtained at baseline and after cycles 1, 4, and 7. A median decrease of 66.7% in phosphorylated VEGFR-2 (Y951) in tumor cells ($P = 0.004$) and median increase of 128.9% in tumor apoptosis ($P = 0.0008$) were seen after bevacizumab alone [11]. A phase I trial investigated the efficacy of a small-molecule inhibitor of VEGFR-2, SU5416 (semaxinib), in combination with doxorubicin in 18 patients with IBC [56]. Similar to the outcome with bevacizumab, the authors observed decreased tumor blood flow after treatment, as assessed by DCE-MRI. Lymphangiogenesis is common in LBC [57]. Higher expression of lymphangiogenic factors (VEGF-C, VEGF-D, VEGFR-3, Prox-1, and fibroblast growth factor 2) is detected in LBC than in non-LBC tumor samples [11, 57]. Targeting lymphangiogenesis through the VEGF-C/VEGF-D/VEGFR-3 signaling system would be a reasonable therapeutic approach for LBC, although it will need to be further examined in both preclinical and clinical studies [58]. In the chest wall disease study with capecitabine/vinorelbine and bevacizumab, authors used LBC as a model disease to investigate biological changes associated with an antiangiogenic agent as bevacizumab [52]. The biological study on CEC, CEP, and CPP as surrogate predictive biomarkers showed that at baseline, responders had significantly higher counts of a CEC subpopulation expressing VEGFR-2 and of CPPs (possibly involved in vessel stabilization). Baseline counts of CEPs, of viable CECs, and of the inflammation-related chemokine IL-8 below the median value were associated with a significantly improved overall survival [52]. To date, no molecular feature reliably predicts the response to bevacizumab. Using DNA microarrays, they searched for multigene predictors of response in IBC with lymphangitic spread to the chest wall. They identified 16 genes that clearly separated patients that had achieved PR from those that had no response. A supervised clustering identified 75 genes involved in matrix remodeling (MMP1) and cell cycle regulation (CDKN2A). Our signature was strongly enriched for stroma that clearly highlights the importance of tumor-stroma crosstalk for progression of LBC [52]. A recent study by the World IBC Consortium generated whole-genome expression profiles of 137 IBC and 252 non-IBC (nIBC) samples [59]. They identified a 107-gene signature enriched for immunity-related genes that distinguished between responders and nonresponders in IBC. This signature was strongly enriched for immunity-related genes involved in CD8+ T-cell lymphocyte activation processes (Th1-response), suggesting a prominent role for adaptive immunity in determining response to CT in IBC [59]. The role of bevacizumab in the treatment of metastatic breast cancer is still a matter of debate. The results of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-40 trial [60] and the GeparQuinto (GBG44) trial [61, 62], demonstrating an increase in the rate of pathological complete response in triple negative breast cancer following the addition of bevacizumab to neoadjuvant chemotherapy, are conflicting with the announcement by the Food and Drug Administration (FDA) on November 18, 2011, revoking approval of bevacizumab in combination with paclitaxel for the treatment of metastatic breast cancer. The unresolved issue is whether significant improvements in a surrogate end point like progression-free survival, in the absence of a benefit for overall survival, are potentially predictive of curative benefits in patients with metastatic breast cancer. The ongoing controversy surrounding bevacizumab therapy for breast cancer involves broader questions about the use of surrogate end points in clinical trials, as well as economic issues over the increasing cost of new medicines for cancer treatment. It is through this lens that the NSABP B-40 and GBG44 trials should be viewed, since each of these trials reports a significant improvement with bevacizumab in another putative surrogate clinical end point: pathological complete response. In the context of unsustainable expenditures for cancer care, comparative effectiveness research will drive mechanisms of drug approval in clinical practice, and the absence of any survival benefit of bevacizumab, or other molecularly targeted drugs, will be balanced against the considerable development costs of modern molecularly targeted oncology drugs.

60.9 Chest Wall Disease as a Balance Between Inflammation and Cancer Proliferation

A recent study by the World IBC Consortium generated whole-genome expression profiles of 137 IBC and 252 non-IBC (nIBC) samples. They identified a 107-gene signature enriched for immunity-related genes that distinguished between responders and nonresponders in IBC. This signature was strongly enriched for immunity-related genes involved in CD8+ T-cell lymphocyte activation processes (Th1-response), suggesting a prominent role for adaptive immunity in determining response to chemotherapy in IBC [60]. There is a potential role of immune-checkpoint inhibitors in treating patients with immune-therapeutic approaches. By blocking interactions between PD-L1 or PD-L2 and

PD-1, you may reactivate the immune surveillance, leading to improved antitumor activity. The programmed cell death protein-1 (PD-1) is a critical checkpoint molecule that is expressed by T cells upon activation. The PD-1 checkpoint pathway is thought to act primarily in peripheral tissues to dampen ongoing immune responses and/or to prevent damage to self-tissues. PD-1 is expressed by B cells, natural killer (NK) cells, dendritic cells, and activated monocytes, in addition to T cells. PD-1 ligands—which include PD-L1 and PD-L2, among others—are expressed by macrophages and monocytes, and these can be induced in numerous cell types in an inflammatory environment, like in lymphangitic breast cancer. Some chemotherapies may lead to immunogenic cell death resulting in activation of dendritic cells (DC) and priming of antitumor immune responses [63]. This promotion of DC maturation might also explain the capacity of some chemotherapies to reduce T regulators (Treg). In addition, as a higher frequency of proliferating cells is observed in Treg compared with the non-Treg compartment, chemotherapy, which mostly destroys proliferating cells, may tilt the balance from Treg toward effector T cells [64]. The use of metronomic cyclophosphamide (CTX) is the leading product of this therapeutic class. Reversal of immunological tolerance by CTX via inhibition of suppressor cells has been reported [65]. Selective depletion of Treg induced by CTX or other chemotherapeutic drugs requires the use of these agents at low, so-called metronomic, doses. Some studies in humans have shown improvement of T-cell effector function associated with a reduction in Treg numbers after low-dose CTX administration. We hypothesize that the use of immune-checkpoint inhibitors in combination with metronomic CTX may induce clinical response in chest wall disease.

Conclusions

Chest wall disease represents a presentation of a clinical spectrum ranging from inflammatory to lymphangitic breast cancer. Inflammation and the immune response have long been viewed as a delicate balance that has the ability to promote a durable tumor regression or promote tumor progression. Preclinical models and biomarker studies suggest that inflammatory breast cancer comprises a more important role for the tumor microenvironment, including immune cell infiltration and vasculogenesis, especially lympho-angiogenesis. Across this clinical continuum of the chest wall disease, there is an important role of the inflammation cascade. The activation of mature dendritic cells (DCs) through toll-like receptors (TLRs) or by inflammatory cytokines converts immature DCs into mature DCs that present specific antigen to T cells, thereby activating them. Maturation of DCs is accompanied by co-stimulatory molecules and secretion of inflammatory cytokines polarizing lymphocytic, macrophages, and fibroblast infiltration. It is unknown whether immune cells associated to the IBC microenvironment play a role in this scenario to transiently promote epithelial to mesenchymal transition (EMT) in these cells. Immune and microenvironment factors can induce phenotypic, morphological, and functional changes in breast cancer cells. We can hypothesize that similar inflammatory conditions in vivo may support both the rapid metastasis and tight tumor emboli that are characteristic of chest wall disease and that targeted anti-inflammatory therapy may play a role in this patient population.

Fertility Issues in Patients with Breast Cancer or Survivors

61

Matteo Lambertini, Hatem A. Azim Jr, and Fedro A. Peccatori

61.1 Introduction

Breast cancer is the most common malignancy in women worldwide and the most frequent tumor in female patients during their reproductive age. The incidence appears to be on the rise [1]. Approximately 5% of all breast carcinomas are diagnosed every year in women under the age of 40 [2]. The incidence is even higher in developing countries, reaching up to 20–25% in Africa and the Middle East [3].

Challenges in fertility preservation issues have acquired a growing importance over the past years. Advances in the management of breast cancer have increased survival [2], and thus more attention is being put on quality-of-life issues like chances of subsequent fertility following primary anticancer therapy. On the other hand, it is increasingly recognized that women are delaying childbearing [4], and thus more women are diagnosed with cancer before completing their families.

As recommended by the European Society for Medical Oncology (ESMO), the American Society of Clinical Oncology (ASCO), and the International Consensus Conference for Breast Cancer in Young Women (BCY2), patients should be counseled about the risk of developing treatment-induced premature ovarian failure (POF) and infertility as part of education process before systemic anticancer therapy is initiated [5–7]. All women interested in preserving fertility should be referred to fertility clinic as soon as possible to discuss the available means for fertility preservation [5–7].

61.2 Anticancer Treatments and Gonadal Function

Treatment-induced POF is a possible consequence of anticancer treatments [8]. Acute POF (i.e., occurring during treatment) may be temporary or permanent; however, women who continue to menstruate or resume menstrual function after treatment remain at risk of early menopause and significant reduction of fertility potential [9].

In breast cancer patients, the risk of developing this side effect is mainly influenced by the use of cytotoxic chemotherapy and endocrine therapy. Chemotherapy acts through a direct gonadotoxic effect [10]: cytotoxic agents cause induction of follicle and oocyte apoptosis and vascular damage to the ovaries [11, 12]. Endocrine treatments can affect ovarian reserve both directly (i.e., impairment in ovulatory and endometrial functions) and indirectly (i.e., delay to conception with subsequent ovarian aging) [13].

The key factors for the risk of developing treatment-induced POF are age of the patient at the time of treatment (i.e., older age), type and dose of chemotherapy (i.e., use of alkylating agents such as cyclophosphamide), and need of adjuvant endocrine therapy (i.e., tamoxifen; Table 61.1) [13, 14].

As shown in a large prospective observational study assessing ovarian function after breast cancer treatment, the majority of women older than 40 years had an interruption of their menstrual function after chemotherapy without recovery of bleeding in the follow-up years [15]. On the contrary, a rapid recovery of menstrual cycling was observed in patients under the age of 35 years with approximately 85% reporting normal bleeding at 6 months following the end of chemotherapy; the recovery was less pronounced for women

Table 61.1 The risk of treatment-induced premature ovarian failure in breast cancer patients (modified from the original [14])

Degree of risk	Type of anticancer treatment
High risk (>80% risk of POF)	– CMF, CEF, CAF, TAC × 6 cycles in women aged ≥40 years
Intermediate risk (40–60% risk of POF)	– CMF, CEF, CAF, TAC × 6 cycles in women aged 30–39 years – AC × 4 cycles in women aged ≥40 years – (F)AC or (F)EC × 4 followed by T
Lower risk (<20% risk of POF)	– CMF, CEF, CAF, TAC × 6 cycles in women aged ≤30 years – AC × 4 cycles in women aged ≤40 years
Very low or no risk	– Methotrexate and fluorouracil – Tamoxifen – Trastuzumab (?)

POF premature ovarian failure; *CMF* cyclophosphamide, methotrexate, fluorouracil; *CEF* cyclophosphamide, epirubicin, fluorouracil; *CAF* cyclophosphamide, doxorubicin, fluorouracil; *TAC* docetaxel, doxorubicin, cyclophosphamide; *(F)AC* fluorouracil, doxorubicin, cyclophosphamide; *(F)EC* fluorouracil, epirubicin, cyclophosphamide; *T* taxane

aged between 35 and 40 [15]. Treatment with anthracycline-based chemotherapy (doxorubicin, cyclophosphamide [AC]) resulted in an important decrease in the proportion of patients with regular menstrual function after treatment, with a small further decline in the number of patients with menses with the addition of paclitaxel or docetaxel (T) [15]. On the contrary, cyclophosphamide, methotrexate, fluorouracil (CMF) regimen resulted in a greater proportion of patients with monthly bleeding in the first months after treatment but followed by a steady decrease in the proportion of women with menstrual bleeding in the 3 following years [15]. Finally, the use of tamoxifen resulted in a decreased proportion of women with monthly bleeding 1 year after the end of chemotherapy, although this effect became nonsignificant after 3 years [15].

In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-30 trial, more than 2000 premenopausal patients had information available on menstrual function after treatment [16]. The rate of prolonged amenorrhea at 1 year after the start of therapy was significantly different between the three treatment arms: 69.8% for sequential AC followed by T, 37.9% for AT and 57.7% for TAC [16]. The addition of tamoxifen increased the number of patients who developed amenorrhea. Approximately 61% of women younger than 40 years developed at least 24 months of amenorrhea contrasting with nearly 100% among older patients [16].

International guidelines highlight the importance of discussing with all young patients the risk of treatment-induced POF and infertility due to anticancer treatments [5–7]. Oncofertility counseling should be individualized since the risk of POF and infertility for each woman is variable [13]. Both treatment-related factors (i.e., type and dose of chemotherapy and use of endocrine therapy) and individual characteristics (i.e., age, comorbidities and ovarian reserve at baseline) should be considered in counseling these women [17]. Particularly for young breast cancer patients concerned about the possible development of this side effect, it is crucial for physicians to discuss the expected absolute benefits of the proposed anticancer treatment, such as the need for adjuvant chemotherapy or long duration of endocrine therapy in women at low risk of recurrence [13]. On the other hand, the risk of infertility should not be overestimated, and some women (e.g., very young patients with hormone receptor-negative disease) will not likely require the help of reproductive medicine after treatment [18].

61.3 Pregnancy After Breast Cancer

Approximately 50% of young breast cancer patients desire a future pregnancy at the time of cancer diagnosis [19]. However, less than 8% of these women manage to become subsequently pregnant [20]. As shown in a large population-based matched cohort study, cancer female patients have lower pregnancy rates as compared to the general population (hazard ratio [HR] 0.61; 95% confidence intervals [CI], 0.58–0.64) [21]. Among cancer survivors, women with breast tumors showed the lowest rates for subsequent pregnancies with an overall 67% reduction in the chance of having a pregnancy after cancer treatment as compared to the general population (HR 0.33; 95% CI, 0.27–0.39) [21].

This observation reflects the possible damage to ovarian reserve as a consequence of anticancer treatments but also the concerns of patients and physicians on a possible negative impact of pregnancy on breast cancer prognosis, being a hormonally driven disease. A survey investigating the attitude on fertility among oncologists and breast surgeons dealing with breast cancer showed that only 54% of participants believed that pregnancy does not affect the prognosis of breast cancer survivors and 49% of them thought that an increase in estrogen levels during pregnancy might stimulate the growth of hidden cancer cells [22].

However, the available evidence on this topic suggests that pregnancy after breast cancer does not have any negative impact on patients' prognosis and should not be discouraged, including among patients with endocrine-sensitive disease [13]. We have previously conducted a meta-analysis of 14 retrospective control-matched studies to evaluate the safety of pregnancy in women with prior history of breast cancer [23]. The study showed that women who became subsequently pregnant had a 41% reduced risk of death compared to women who did not get pregnant (pooled relative risk [PRR] 0.59; CI, 0.50–0.70) [23]. No significant differences in survival between groups were also observed

after correcting the data for the so-called "healthy mother effect" (PRR 0.85; 95% CI, 0.53–1.35) [23]. Since no specific data in patients with endocrine-sensitive disease were available, we subsequently performed a multicenter retrospective case-control study to better clarify the prognostic impact of pregnancy in breast cancer survivors according to estrogen receptor status [24]. The study showed no difference in disease-free survival between pregnant and non-pregnant survivors with both estrogen receptor-positive (HR 0.91; 95% CI, 0.67–1.24) and negative (HR 0.75; 95% CI: 0.51–1.08) disease [24]. A better overall survival was observed in the pregnant cohort (HR 0.72; 95% CI, 0.54–0.97) with no interaction according to estrogen receptor status [24]. Importantly, abortion did not show to impact patient outcome in both studies and should not be proposed for therapeutic reasons [23, 24]. Since a higher incidence of birth complications (i.e., preterm birth, caesarean section, babies with low birth weight) has been observed in breast cancer survivors [25], a close monitoring of pregnancy in these women is recommended [26].

Although pregnancy after breast cancer should not be discouraged anymore, it is not clear yet the ideal interval to wait for women to become subsequently pregnant after the end of anticancer treatments. Experts recommend to avoid early pregnancy within 2 years from diagnosis, especially in case of patients at high risk of relapse [27].

In women with hormone receptor-positive breast cancer, the use of adjuvant endocrine therapy for 5 to 10 years is an important issue to be considered [7, 28]. For this reason, it can be challenging for young survivors candidates to adjuvant endocrine therapy to initiate their childbearing plans due to the older age at the time of treatment completion and subsequent natural decline in ovarian reserve [29]. On this issue, the International Breast Cancer Study Groub (IBCSG), Breast International Group (BIG) and North American Breast Cancer Group (NABCG) have recently started a prospective international study directed to young women with endocrine-sensitive early breast cancer who desire to become pregnant and who are disease-free after 18–24 months of adjuvant endocrine therapy [30]. The POSITIVE study investigates the feasibility and safety of a temporary interruption of adjuvant endocrine therapy to allow conception [30].

The reassuring data on the safety of pregnancy after breast cancer highlights the importance of counseling young patients on the possible risk of infertility after anticancer treatments and facilitates the access of women interested in fertility preservation to the centers of reproductive medicine [5–7].

Of note, these data might increase also the number of survivors accessing fertility units after completing their anticancer treatment. To date, there is only one small retrospective study that evaluated the safety of performing assisted reproductive technology (ART) in survivors of breast cancer after the end of treatment [31]. In this study, out of 198 women who became pregnant after breast cancer, 25 patients underwent ART [31]. A total of 36 pregnancies resulted from 37 ART cycles (13 after oocyte donation, 13 ovarian stimulation for in vitro fertilization [IVF], 11 ovulation induction) [31]. Patients who underwent ART tended to have higher percentage of node-negative disease, estrogen receptor-positive and low-grade tumors [31]. With a median follow-up of 50 months, there was no difference in survival outcomes between patients with spontaneous pregnancies (16% developed cancer-related events) and those who underwent ART procedures (8% developed cancer-related events; $p = 0.54$) [31].

61.4 Strategies for Fertility Preservation

For breast cancer patients, different strategies for fertility preservation are available: embryo and oocyte cryopreservation, cryopreservation of ovarian tissue, and temporary ovarian suppression with luteinizing hormone-releasing hormone analogs (LHRHa) during chemotherapy (Table 61.2).

The choice among these options depends on several factors: patient's age and ovarian reserve at diagnosis, type of anticancer treatment planned, time available before starting treatments, and whether the patient has a partner [14].

61.4.1 Embryo and Oocyte Cryopreservation

Embryo and oocyte cryopreservation are standard strategies for fertility preservation [5, 6]. The procedure consists of performing a controlled ovarian stimulation for 10–15 days, followed by egg harvesting; the gold standard time for initiating the controlled ovarian stimulation is the early follicular phase of the menstrual cycle. For oocyte cryopreservation, unfertilized eggs are directly cryopreserved, while for embryo cryopreservation, the oocytes are fertilized using IVF procedures, and the resulting embryos are then cryopreserved. There are two different methods for cryopreservation of embryos or oocytes: slow freezing and vitrification [32]. As shown in a Cochrane meta-analysis, vitrification showed higher pregnancy rate than slow freezing (RR 3.86; 95% CI, 1.63–9.11; $p = 0.002$) [33]. Hence, vitrification has become the most applied technique, although the results are still not as high as with fresh cycles [34].

Main limitations of embryo and oocyte cryopreservation are the possible delay in the initiation of anticancer treatments (due to the need to wait the onset of menses to perform the controlled ovarian stimulation), the need for a minor surgical procedure, and the possibility to preserve fertility but not gonadal function. In some countries, embryo freezing is prohibited by law, and the strategy is not applicable in patients without a partner at the time of cancer diagnosis: in these situations, oocyte cryopreservation is the only possible technique.

Table 61.2 Main characteristics of the available strategies for fertility preservation in women with breast cancer

Type of strategy	Definition	Need for controlled ovarian stimulation	Delay to start anticancer treatment	Surgery required	Preservation of ovarian function	Preservation of fertility
Embryo and oocyte cryopreservation	Harvesting and freezing of unfertilized (oocytes) or in vitro fertilized (embryos) eggs	Yes	Yes	Yes	No	Yes
Cryopreservation of ovarian tissue	Freezing of ovarian tissue and transplantation after treatment	No	Minimal	Yes[a]	Yes	Yes
Temporary ovarian suppression with LHRHa during chemotherapy	Use of hormonal therapies to protect ovaries during chemotherapy	No	No	No	Yes	Yes[b]

LHRHa luteinizing hormone-releasing hormone analogs
[a]Two surgical procedures
[b]Limited data available

In breast cancer patients, due to the need of performing a controlled ovarian stimulation, two main concerns are raised: a possible delay in the initiation of anticancer treatments and short-term exposure to high estradiol level, both could possibly inversely impact patient prognosis.

For patients with early-stage breast cancer, evidence suggests that when the earlier adjuvant chemotherapy is administered, the better patients' outcome can be obtained [35]. Thus, to limit treatment delays for the need to wait the onset of menses, "random-start" protocols have been developed to allow to start controlled ovarian stimulation anytime during the menstrual cycle [36]. Available experience with these protocols showed comparable results in terms of retrieval of oocytes, maturation, and fertilization rates [13].

The increase in estradiol levels is probably the major concern, and thus alternative protocols for controlled ovarian stimulation have been developed for breast cancer patients. In these protocols, tamoxifen [37] or letrozole [38] is added during the stimulation phase: several studies suggested that this approach does not significantly affect the quality of the oocytes collected [37, 39], and similar pregnancy rates as those observed in infertile non-oncologic population can be obtained [40].

To date, only one prospective study evaluated the safety of performing a controlled ovarian stimulation with letrozole supplementation (COSTLES) in breast cancer patients [41, 42]. In this study, out of 337 breast cancer patients who underwent fertility counseling before chemotherapy, 120 patients elected to undergo embryo cryopreservation, while 217 did not undergo any fertility-preserving procedure and served as controls [42]. With a median follow-up of 4.9 years, there were six (5.0%) patients who developed disease recurrence in the fertility preservation cohort and 12 (5.5%) in the control group ($p = 0.86$) [42]. There was no significant difference in relapse-free survival between the two groups (HR 0.77; 95% CI, 0.28–2.13) [42]. Although with very limited numbers, the subgroup analyses according to BRCA gene mutation status ($p = 0.57$), hormone receptor status ($p = 0.75$), and timing of stimulation (before or after breast surgery: $p = 0.44$) confirmed the lack of negative impact of controlled ovarian stimulation on patients' survival outcomes [42].

The same group has recently reported also the feasibility and safety of performing two consecutive cycles of controlled ovarian stimulation with the use of letrozole before the initiation of anticancer treatments [43]. However, further research in this filed (i.e., larger number of patients and longer follow-up) is needed to confirm these findings.

Most of the available data on the success of embryo and oocyte cryopreservation derive from the infertile non-oncologic population. The age of the patient and the number of stored oocytes or embryos are crucial factors for the success of the procedures [13]. Pregnancy rate after embryo thawing ranges from more than 40% in women under the age of 35 years to less than 20% in women older than 40 years [44]. In experienced centers, similar results are observed with the use of cryopreserved oocytes [45, 46].

In cancer patients, a possible weaker response to controlled ovarian stimulation might be expected [47]. Several issues might negatively impact on the success of this procedure in the oncologic population as compared to infertile patients, mainly related to the particular protocols used (i.e., "random-start protocols" or the use of tamoxifen or letrozole) and/or the presence of a possible underlying reduced ovarian reserve at baseline (e.g., in patients with BRCA mutations) [48]. Very limited data exist on pregnancies following embryo and oocyte cryopreservation in cancer patients. A study reported fertility outcomes in 357 women who underwent oocyte cryopreservation after cancer diagnosis [49]. A total of 11 (3.1%) cancer survivors (8 with breast cancer, 1 with

endometrial adenocarcinoma, 1 with thyroid cancer, and 1 with Hodgkin lymphoma) returned for ART after the end of treatments [49]. A total of 4 pregnancies were obtained and delivered at term with no malformations in the newborns; the delivery rate per cycle was 36.6% [49]. Even more recently, Oktay and colleagues reported the fertility preservation outcomes of breast cancer patients who underwent controlled ovarian stimulation with letrozole supplementation for embryo cryopreservation within their prospective study [40]. A total of 33 women underwent 40 attempts to transfer embryos after more than 5 years from the time they underwent embryo cryopreservation: 17 women had at least one child resulting in a fertility preservation rate of 51.5% [40]. A total of 18 pregnancies were obtained resulting in 25 live births with no malformations (seven pregnancies were twins) [40]. The overall live birth rate per embryo transfer showed to be similar to that of the infertile non-oncologic population of a similar age (45.0 vs 38.2; $p = 0.2$) [40].

Despite these encouraging results, during oncofertility counseling, breast cancer patients should be aware that available data on the success of embryo and oocyte cryopreservation derive mainly from infertile non-oncologic women and that a different response to controlled ovarian stimulation cannot be ruled out [13].

61.4.2 Cryopreservation of Ovarian Tissue

Cryopreservation of ovarian tissue is an effective, yet still experimental, surgical strategy for fertility preservation. Major advantages compared to embryo and oocyte cryopreservation are the possibility to preserve both fertility and ovarian function, ovarian tissue cryopreservation causes a minimal delay in the initiation of anticancer treatment, and sexual maturity is not required. Moreover, this strategy can be performed at any time of the menstrual cycle, and no hormonal stimulation is required. However, it is an expensive technique that should be performed only in centers with the adequate expertise. Moreover, two surgical procedures are required: before the initiation of anticancer therapies, the cortical ovarian tissue is removed and then cryopreserved; after the end of treatment, the tissue is transplanted, preferably into the pelvic cavity (orthotopic site) [50].

Following successful transplantation of ovarian tissue, a rapid recovery of ovarian function (within 3–6 months) is expected in almost all cases, with possible sustained longevity of gonadal function [51, 52]. A total of 37 live births have been reported in cancer patients after transplantation of cryopreserved ovarian tissue [53]. It is hard to accurately estimate the actual pregnancy rate based on available data [54]. Recently, Donnez and colleagues combined results from four fertility centers: out of 80 women transplanted, 20 conceived resulting in a pregnancy rate of 25% [53].

It is important to note that the patient's ovarian reserve is a key factor for the success of the procedure; hence, patients older than 40 years or with reduced ovarian reserve at baseline should not be considered for cryopreservation of ovarian tissue [55].

Although this technique is still considered an experimental strategy according to major international guidelines [5, 6], it remains an option for selected patients who cannot delay the initiation of anticancer treatments [56] and in women who have already received chemotherapy [57].

Of note, it should be considered a potential risk of reintroducing malignant cells when the cryopreserved tissue is transplanted especially in patients with aggressive hematologic malignancies; however, to date, no malignant cells have been found in ovarian tissue from breast cancer patients [58].

Moreover, specific issues should be also considered in breast cancer patients carrying BRCA mutations: due to the high lifetime risk of developing ovarian cancer, bilateral salpingo-oophorectomy is generally recommended before the age of 40 years and upon completion of childbearing [59]. Due to the lack of data on the safety of this procedure in patients with BRCA mutations, cryopreservation of ovarian tissue should not be proposed to these patients [29].

Due to the relatively low number of procedures performed to date and the technical difficulties in cryopreserving ovarian tissue, referral to centers with the known expertise would be advisable [5, 6]. While the harvesting of the tissue can be performed locally, its subsequent freezing and storage should be centralized; for this reason, a well-organized network between fertility units is required [13].

61.4.3 Temporary Ovarian Suppression with LHRHa During Chemotherapy

Pharmacological protection of the ovaries during chemotherapy is an attractive option to preserve ovarian function and fertility of women candidates to cytotoxic therapy. It is easy to administer, is relatively cheap, and does not require surgery without delaying treatment initiation [29]. In addition, it can potentially protect both ovarian function and fertility [29].

The hypothesis behind the development of this technique is that the inhibitory effect of LHRHa on gonadal function may reduce the toxicity of chemotherapy on the ovaries [60]. Animal experiments in rats and monkeys supported this hypothesis showing a reduced loss of follicles during cytotoxic therapy with concurrent administration of LHRHa [61]. Several observational and phase II studies showed that this strategy was associated with resumed ovarian function in the large majority (from 70% to 100%) of treated breast cancer patients [62].

Following these promising results, several phase III studies evaluated the efficacy of this procedure. In these trials, patients with breast cancer were randomly allocated to receive (neo)

adjuvant chemotherapy with or without concurrent LHRHa [13]. These studies produced relatively conflicting results with some suggesting a protective effect while others showing no relevant impact of concurrent administration of LHRHa on reducing the incidence of chemotherapy-induced POF [13]. Of note, these studies were not identical in terms of patient population, treatment given, and definition of endpoints, which possibly contributed to the observed conflicting results.

However, despite the extensive debate on the efficacy of the procedure over the last years [63–66], in 2015, some important news on this topic have become available [67], suggesting the efficacy of temporary ovarian suppression with LHRHa for preserving ovarian function and fertility particularly in breast cancer patients [68].

Two large phase III studies reported favorable results on the efficacy and safety of the procedure [69, 70]. The POEMS-SWOG S0230 study enrolled 257 premenopausal breast cancer patients with hormone receptor-negative breast cancer, while in the PROMISE-GIM6 study, approximately 80% of the 281 included patients had hormone receptor-positive disease [69, 71]. Both studies showed that temporary ovarian suppression with LHRHa was associated with a significant reduction in the incidence of POF, 2 years after the end of chemotherapy in the POEMS-SWOG S0230 study (from 22% to 8%; odds ratio [OR] 0.30; $p = 0.04$) [69], and 1 year after the end of cytotoxic therapy in the PROMISE-GIM6 study (from 25.9% to 8.9%; OR 0.28; $p < 0.001$) [71]. In the PROMISE-GIM6 study, the protective effect on ovarian function recovery was confirmed also at a longer follow-up with a 5-year cumulative incidence estimate of menstrual resumption of 72.6% in the LHRHa arm and 64.0% in the control arm (age-adjusted HR 1.48; $p = 0.006$) [70].

Moreover, more patients treated with LHRHa during chemotherapy had a subsequent pregnancy as compared to those undergoing chemotherapy alone: 22 vs. 12 (OR 2.45; $p = 0.03$) in the POEMS-SWOG S0230 study [69] and 8 vs. 3 in the control arm (age-adjusted HR 2.40; $p = 0.20$) [70]. Finally, both studies showed no negative impact of concurrent administration of LHRHa and chemotherapy on patients' prognosis [69, 70].

A large and updated meta-analysis evaluating the role of temporary ovarian suppression with LHRHa during chemotherapy in young women with breast cancer confirmed the potential efficacy of the procedure in preserving both ovarian function and fertility [72]. In the 12 randomized studies included in the analysis, for a total of 1231 patients, the use of LHRHa was associated with a significant reduced risk of developing chemotherapy-induced POF (OR 0.36; $p < 0.001$) [72]. In the five studies reporting number of patients achieving pregnancy, more women treated with LHRHa become pregnant after treatment (33 vs. 19; OR 1.83; $p = 0.041$) [72].

An individual patient data meta-analysis of randomized studies in breast cancer patients (the MOMMY study; PROSPERO registration number: CRD42014015638) is currently ongoing and is awaited to corroborate these findings [13].

According to the recently released BCY2 recommendations taking into account all the recent data on the topic, the expert Panel agreed that this strategy can be discussed with women interested in potentially preserving ovarian function and/or fertility [7]. Updated recommendations from ESMO and ASCO on this topic are warranted.

Conclusions

Fertility preservation and the possibility to have a family after cancer diagnosis and treatment have an important impact on quality of life of breast cancer survivors. The importance of preserving fertility at the time of diagnosis is also confirmed by the fact that pregnancy after breast cancer showed to be safe also in patients with hormone receptor-positive disease [24].

Fertility preservation strategies should be discussed with patients as soon as possible after breast cancer diagnosis [5–7] (Fig. 61.1).

For patients interested in fertility preservation (i.e., to become pregnant after treatment), embryo and oocyte cryopreservation are standard strategies and should be offered as first choice. The best candidates for these strategies are patients under the age of 38, with normal ovarian reserve at baseline and the possibility to delay the initiation of anticancer treatments for 2 weeks (Fig. 61.1). The use of "random-start" protocols and letrozole or tamoxifen for controlled ovarian stimulation should be considered in breast cancer patients [13]. In those patients who cannot delay anticancer treatment, cryopreservation of ovarian tissue can be offered (Fig. 61.1). In both scenarios, as well as for patients with no access to cryopreservation strategies, temporary ovarian suppression with LHRHa can be offered during chemotherapy to increase the chances of post-treatment recovery of ovarian function and fertility (Fig. 61.1).

For patients interested in ovarian function preservation (i.e., to avoid the negative consequences of treatment-induced POF) more than fertility preservation, temporary ovarian suppression with LHRHa during chemotherapy can be offered (Fig. 61.1).

Although several efforts in the field have been done in the last years, the lack of large prospective studies and randomized trials highlights the importance of further research. Registries and prospective studies are currently ongoing with the aim to better evaluate the efficacy and safety of the available strategies for fertility preservation. The participation to these studies should be encouraged to acquire more robust conclusions on these crucial issues.

Breast Cancer and Sexuality with Focus in Young Women: From Evidence-Based Data to Women's Wording to Treatment Perspectives

62

Alessandra Graziottin

62.1 Introduction

Sexuality is an integral part of quality of life. Young women affected by breast cancer (BC) face a very demanding disease, both physically and emotionally devastating [1–3]. They constitute a minority of BC patients (www.cancer.org): approximately 2% of breast cancers occur in young women between 20 and 34 years of age and 11% between 35 and 44 years of age [4], or 7% before the age of 40, but commonly have distinct concerns and issues compared with older women, including queries regarding sexual dysfunctions, fertility, contraception, pregnancy, premature menopause and couple intimacy. Young women' sexuality is threatened by BC in all its dimensions: sexual identity, sexual function and sexual relationship [2, 3].

The younger the woman, the less realized the different key goals of her life cycle (falling in love, having a satisfying sexual life, forming a stable couple, getting married, having a family), the more pervasive the consequences on her sexual identity, sexual function and sexual relationship can be [5, 6].

In 1–2 years after the diagnosis, a young woman may have to face three important losses: loss of physical integrity, as BC diagnosis and treatment may deeply affect her body image [3], her sense of health, physical energy, wellbeing, femininity and sexuality; loss of her possibility to become a mother and have her own children when iatrogenic menopause destroys the ovarian reserve [5, 6]; and loss of the couple relationship when progressive sexual dysfunctions disrupt the couple intimacy [2, 3, 5, 6] and/or when he abandons her as he cannot accept to remain childless because of her iatrogenic infertility.

A. Graziottin, M.D.

Psychological and psychosexual factors in young cancer survivors have been well studied [7–25], while biological factors contributing to sexual impairment are underestimated, underinvestigated and undertreated, with far less data [26–31], fortunately recently increasing [32–38]. Key issues of BC in young women are distilled in Table 62.1.

This paper will focus more on the biological side of the sexual concerns. As data specifically focused on younger women' sexuality are limited, the impact of BC on sexuality is (also) based on the evidence gathered from women of all ages, with notes on data gathered in the young. The impact of early iatrogenic menopause on sexuality will be carefully considered, analysed through the extensive clinical experience with young cancer survivors of the presenting author (AG). Attention to women's wording will be privileged, as individual experiences cannot be conveyed in controlled studies, and so many intimate issues can be transmitted by a single sentence. *Wording's reporting is focused on the experience of women who have more difficulties to cope with* the many challenges breast cancer carries with it, with the specific goal of increasing healthcare providers' awareness on issues usually marginalized in the oncological conversation with the patient. Moreover, this paper will focus on sexual concerns and touch fertility and pregnancy-related problems only in their specific impact on young women's sexuality. A concise paragraph on multimodal approach to sexual concerns and problems in young breast cancer survivors will conclude it.

Table 62.1 Key issues in young BC women, in comparison to older

BC is uncommon in young women, less than 2% under the age of 34 and 11% between 35 and 44
It is more aggressive, with later diagnoses and poorer outcomes
When breast-conserving therapy is performed, the rate of local recurrences is higher
Different key goals of a woman's life cycle may not yet be realized in younger women. Therefore issues on fertility preservation, pregnancy, sexuality, couple's erotic intimacy and premature menopause must be taken into the highest consideration and openly discussed with patients and, when appropriate, with couples

62.2 Young Women's Wording on their Sexuality After Breast Cancer

To set the scenario, listening to women's words is essential. They well describe the overall sense of health and sexual loss they feel when early breast cancer diagnosis disrupts their lives. "Without my breast I do not feel a woman any more", "My breast is cold now, it does not belong to me anymore. It is like having a stone there". "I can't look at it myself, how can I show it to my partner?"; "I had breast cancer at 34 and underwent contralateral mastectomy at 37. None told me that I would have had chronic breast pain, besides losing all my sexual pleasure"; "I used to be a fighter. I went through surgery, radio and chemotherapy with lots of courage. My oncologist congratulated me at every visit. Since I started aromatase inhibitors, my insomnia went worst, I have night tachycardia, in the morning I get up exhausted, I have no more energy and no sex drive; but the worse of all is my joint pain. I feel trapped in an armour of sadness and rust. I do not recognize myself anymore"; and/or "Why should I make love, If I cannot have children anymore?": all these sentences concisely explain why sexual identity, the sense of femininity and sexual attractiveness and the potential for pregnancy are perceived as definitely wounded or lost.

"It's a disaster, doctor, my breast is frigid. And I'm becoming all frigid as well. I can't help"; "Since I lost my periods, after the chemotherapy, my sexual desire faded away. I do not have any sexual interest, for anybody. I feel sexually invisible"; "Since I became menopausal I have a worsening vaginal dryness; sex is no more fun. Now it hurts! And I have cystitis two-three days after the intercourse. But nobody cares. My oncologist keeps on saying: your life is more important. But which life is this, if I cannot make love anymore, at 32?!"; "I find any excuse to avoid sex with my partner: it only means pain": these sentences focus more on sexual function.

"We were looking for our first child. The breast cancer diagnosis shocked us deeply. At the beginning, my husband was very supportive. But when he realized I was getting menopausal because of chemo, he became more and more depressed. He was so longing for a child, and he said he cannot accept to remain childless. Please give me all the info on how I can get pregnant. Do I have a last chance with my ovary? Is ovodonation safe, after breast cancer? I do not want to lose him. We feel so lone and yet we cannot make love anymore...": this story focuses on sexual relationship.

These requests for a complex sexual help indicate how pervasive the discovery of a breast cancer and associated premature menopause can be for the three dimensions of young women's sexuality [2, 3, 5–33] and how we must keep in mind the complexity, to offer a well-tailored, individualized sexual help. A multidisciplinary approach, medical and psychosexual, may offer the most comprehensive and satisfying outcomes [2, 34, 37, 38].

62.3 Female Sexual Identity Issues in Young BC Women

Female sexual identity defines the satisfied sense of belonging to the female gender [2]. Such a comprehensive concept stems from basic dimensions such as femininity, maternity and eroticism, while social role can be considered a more recent contributor [2]. The perception of female sexual identity may be variably affected by BC diagnosis and treatment; the younger the woman, the more pervading the negative effect.

1. Femininity may suffer a major insult, for a number of biological reasons:
   (a) *Changes in appearance, dimensions, skin temperature and erotic feelings of the breast,* which is a prominent personal and social sign of femininity. *Body image* is one of the parameters considered to be more affected by the type of surgery performed. However, if women's wording is carefully listened to, the more recurrent word is "body feelings": "I cannot accept any caress or kiss on my breast: I feel nothing!". Short-term impact depends on the type of surgery performed: lumpectomy versus mastectomy, with immediate or delayed reconstruction, and their cosmetic result and the need or not of adjuvant radio- or chemotherapy and hormonotherapy [2, 3, 10–12, 15, 20, 25, 36]. Body image is not only visual, but is biologically based as well on proprioceptive, tactile and pleasure-related sensations [3]: "I underwent mastectomy and reconstruction. I was very proud with the cosmetic result. Then I realized that caresses, kisses, all was *fiction of sex without feelings*. I felt my breast has been killed twice. *It's a show without music*". Nipple sparing techniques may contribute to maintain a better body image, better feelings in the nipple, areola and breast and better sexual function. However specific studies focused on this aspect have not yet been carried out in the author's knowledge. Contralateral (CPM) and bilateral prophylactic mastectomy (BPM) adds further concerns to women' sense of femininity [3, 39, 40].
   (b) *Arm lymphedema* that causes a disfigured body image and impaired self-perception: "You can mask your breast surgery, but lymphedema reminds you and everybody around you that you had a breast cancer. I always have to wear long sleeves, like a

"chador". I can't even undress in front of my partner". Lymphedema wounds the inner sense of femininity, leading to depression and avoidant coping strategies [2, 3, 10, 11]. It has an average reported incidence of 15–30% [16, 29, 30], up to 42% in the more recent prospective research of Norman et al. [32]. It is the more serious side effects of axillary lymphadenectomy; however, it is reported in 1,8% of women who underwent the lymph node' sentinel biopsy. It may develop up to 20 years after breast and axillary surgery [30]. "Arm problems" are quoted by 43 to 72% of patients, according to the different arm symptoms (pain, pins and needles, numbness, skin sensitivity, swelling) that were mentioned in Ganz et al. [13], by 26 to 36% in Dorval et al. [10]. Unpleasant feelings ("paraesthesias") up to frank pain are frequently reported. Breast cancer is more advanced in younger women and requires more frequently mastectomy and lymphadenectomy [1, 33]: lymphedema and associated signs and symptoms can be significant (and underappreciated) contributors of the femininity crisis in the youngest BC cohort.

(c) *Iatrogenic menopause* is the third biological factor that may wound the sense of femininity of *younger patients* (25% of breast cancer patients are premenopausal, and 13% are diagnosed before the age 45) [1, 4]. Polyagent adjuvant chemotherapy may cause early menopause in 56 to 89% of BC women [41]: "It kills your femininity because getting menopause so young makes you feel suddenly old and lost for the love play". Things can be worse for the sense of femininity when chemotherapy causes both hair loss and premature ovarian failure (POF) or insufficiency (POI) [5, 6]. "I had beautiful, long black hair with blue nuances. It was my pride. During chemotherapy, I had a massive loss. My hairdresser was moved to tears when he had to cut them short. My whole femininity has gone with my hair". Loss of oestrogens triggers neurovegetative, affective and cognitive symptoms, increases vulnerability to depression, low sexual desire, vaginal dryness and dyspareunia and determines an accelerated ageing of sexual organs [2–6]. The disrupting role of premature iatrogenic menopause on sexuality has been extensively reviewed in previous papers [2, 3, 5, 6], with new contributions on young BC women [34–37]. Tamoxifen and aromatase inhibitors may further worsen the impact of iatrogenic menopause on the wellbeing and femininity [2, 3].

(d) *Age* is the fourth biological factor that may worsen the impact of BC on female sexual identity. Its specific weight is related to:

- Biological factors: BC in younger women has a more aggressive course and poor prognosis and requires more aggressive treatments (local recurrences are higher in younger patients) [1, 32], with a higher biological price in terms of short- and long-term side effects of treatments and comorbidities [41] and higher risk of a systemic disease at diagnosis [1, 32].
- Psychosocial factors: key social tasks and goals of women's reproductive years have different priority in different decades: the younger the woman, the higher the probability that key goals will not be achieved: "At 30, I'm alone. I lost my periods and my desire. I do not have a boy-friend, I feel I'm invisible. Sexually, I mean. I do not have children. The only thing I do have is a cancer that destroyed all my hopes of a worthy life". Problems associated with breast cancer continue to persist several years after diagnosis, and even worsen, at least for a consistent percentage of young women [24, 25], who should therefore be considered at higher risk of negative QOL outcomes after breast cancer and be offered a specific help [2, 3, 5–8, 14, 16–18, 25, 36].

2. Maternity: in young breast cancer patients who were childless at the moment of the diagnosis, it may become the core of a major sexual identity crisis [2] and trigger a critical fracture in the relationship. As the mean age at first pregnancy has rapidly increased in recent decades in high-income countries, the possibility that a woman has a cancer still being childless is growing: "The oncologist started the chemotherapy without mentioning that it would destroy my ovaries. Had I been informed, I could at least have saved my oocytes. Cancer is serious, but destroying my fertility is much more unbearable for me". Appropriate counselling on the POF risk and possibility of cryoconservation of oocytes before chemotherapy should be mandatory.
3. *Eroticism*: BC may affect sensuality, sexiness and receptiveness through:
   (a) The major insult of breast surgery on breast eroticism: 44% of women with partial mastectomy and 83% of those with breast reconstruction ($p < 0.001$) report that pleasure with breast caresses and sexual feelings have decreased [20], because of the local nervous damage. Surgery for breast cancer leaves women sore and tender in the breast and chest area on an immediate basis. Likewise, radiation therapy can cause skin to become red, tender and irritated. While pain and irritation might subside as the wound heals, either the woman or partner may avoid sexual interaction during this time period. This "collusion of avoidance" may dramatically impair the sexual importance of the breast [2, 3]. The dramatic loss of

Table 62.2 Negative changes in sexual enjoyment after BPM

Effect	Odds ratio
Lost/very impaired sexual sensitivity in the breast after BPM	8.631
Pain experiences in the breast after BPM	2.604
Discomfort feelings in the breast after BPM	3.887
The breast had great sexual importance before BPM	25.704

Adapted from Gahm et al. [40]

the "sexual meaning" of the breast has been demonstrated by the work of Gahm et al. [40] to be very significant also in women undergoing BPM, with an OR = 25.70 (Table 62.2);

(b) The menopause. Symptoms (hot flushes, sweating, night tachycardia, mood swings, insomnia, depression, joint pain, loss of desire, arousal difficulties, orgasmic difficulties, dyspareunia) [2, 3, 5, 6, 36], signs: wrinkles, weight gain [36], modified body shape ("the menopausal look"), swollen and painful joints, reduced muscle mass and strength ("sarcopenia"), mouth dryness, vaginal dryness [2, 3], vulvar dystrophy and quality of life impairment secondary to iatrogenic (chemotherapeutic) and/or nonhormonally treatable natural menopause may dramatically devastate the woman's sense of eroticism [2, 3, 20], besides the impact on her femininity. Moreover, these symptoms threat the core of the erotic perception a woman may have: "I loved to have sex, I used to be considered very sexy. Breast cancer shocked me, but the worse was the unexpected menopause that killed my sense of being a sexy woman. And the hormonal treatment I have to do makes me feel even worse. At 36, I cannot accept a life without sex, I'd rather die";

(c) The worsening impact of depression and anxiety, reactive to BC, that may affect self-perception, sense of sexiness and eroticism via nonhormonal pathways. It is reported in average 17 to 25% of breast cancer patients [37]. "When the immune system subjugates the brain" [42]: the inflammatory nature of the biological component of depression [43, 44] may explain why cancer patients are significantly more depressed than non-oncologic patients and why depressed cancer patients die more than nondepressed cancer controls.

4. Social role may represent an area relatively safe from BC, particularly in well-educated women [2, 45], except in the acute phase or in the more severe and aggressive cases. A strong and positive social role and a gratifying professional career may reduce the impact of BC on other dimensions of femininity [2, 13]. However, 20% of BC survivors report a reduction of energy, psychological distress, cognitive problems and difficulties in concentrating, in remembering and in thinking clearly that may affect their professional competence and role [13]. Cognitive deficits after post-operative adjuvant chemotherapy for BC have been described in a broad domain of functioning, including attention, mental flexibility, speed of information processing, visual memory and motor function [46]. This cognitive impairment is unaffected by anxiety, depression, fatigue, and time since treatment [46]. It may be more disturbing in women who rely on their professional and social role for their sense of identity and self-esteem.

62.4 Female Sexual Identity Issues After Bilateral or Contralateral Prophylactic Mastectomy

9 to 10% of women with breast cancer may have a genetic predisposition [1, 40]. The majority of these (55–70%) are caused by mutations of either *BRCA1* or *BRCA2* tumour suppressor genes and are associated with an increased risk of ovarian cancer. Bilateral prophylactic mastectomy (BPM), a preventive option in women carriers of these mutations, may specifically affect women's sexual identity and body image.

A Cochrane review focused specifically on outcomes of women undergoing BPM or contralateral prophylactic mastectomy (CPM) after breast cancer diagnosis [39]. Twenty-three studies, including more than 4000 patients, met inclusion criteria. All studies had methodological limitations. Most reported *high levels of satisfaction with the decision to have BPM* but more variable satisfaction with cosmetic results. *More women were dissatisfied* than satisfied *with the support they received in the healthcare setting*, which parallels the dissatisfaction on this domain after breast cancer diagnosis. Worry over breast cancer was significantly reduced after BPM when compared both to baseline worry levels and to the groups who opted for surveillance rather than BPM. Three studies reported *body image/feelings of femininity outcomes*, and all reported that a *substantial minority (about 20%) reported BPM had adverse effects* on those domains. Two case series were exclusively focused on adverse events from prophylactic mastectomy with reconstruction, and both reported rates of *unanticipated reoperations from 30% to 49%*. Of the psychosocial outcomes measured, *body image and feelings of femininity* were the most adversely affected [39]. Cochrane reviewers conclude that while published observational studies demonstrated that BPM was effective in reducing both the incidence of, and death from, breast cancer, more rigorous prospective studies (ideally randomized trials) are needed.

Gahm et al. [40] quoted that 85% of women reported reduced sexual sensations after BPM. Loss of breast's sexual meaning and even pain after BPM should be discussed

before surgery as they are even more relevant in the decision-making process when a preventive intervention is considered. On the surgeons' side, attention to the most skilled nerve preserving BPM, to maintain erotic sensitivity, with special attention to intercostobrachial nerve to prevent pain, is of the highest importance to minimize long-term negative sexual outcomes [47].

Recent studies on psychosocial effects of CPM confirmed the same data, even when a long follow-up period is considered (mean 10.3 years) [15, 48]. Decreased satisfaction with CPM was associated with decreased satisfaction with appearance, complications with reconstruction, reconstruction after CPM and increased level of stress in life [48]. Counselling on BPM and CPM should (also) discuss psychosexual and body image-related issues [40].

In summary Women's sexual identity in young women with breast cancer may be variably affected according to a number of biological factors: age at diagnosis; stage and type of treatment; type and cosmetic outcome of surgery, including the nipple sparing or not; presence and severity of lymphedema; accomplishment or not of childbearing before diagnosis; infertility; induction of POF leading to menopause with its cohort of symptoms and signs; severity of depression; and biological mental damage from chemotherapy and inflammation, further triggered by BC treatment and chronic loss of oestrogens and testosterone. The preventive meaning of BPM and CPM conveys specific issues for female sexual identity. The differentiation of the relative weight of these factors with respect to psychosocial variables deserves further prospective studies.

62.5 Female Sexual Function and Dysfunction in Young BC Women

Human sexual function can be simplified as a circuit, with four main stations: sexual desire and central/mental arousal, peripheral arousal with genital congestion and lubrication, orgasm and satisfaction that includes both the physical phase of resolution, with its homeostatic function of returning to baseline, and the emotional/affective evaluation of the experience [2] (Fig. 62.1). Sexual dysfunctions may anticipate breast cancer, be concomitant to it or consequent to treatment [2, 3]. They can as well be worsened by partner's attitudes [49]. Young BC survivors had significant poorer sexual functioning in every area of sexual functioning than normal control groups [26, 31, 33–36, 47, 48]. Interdependence of different aspects of sexual functions [50] translates in a complex vulnerability in all sexual function domains, more so in young women challenged on so many fronts of their life [51–53].

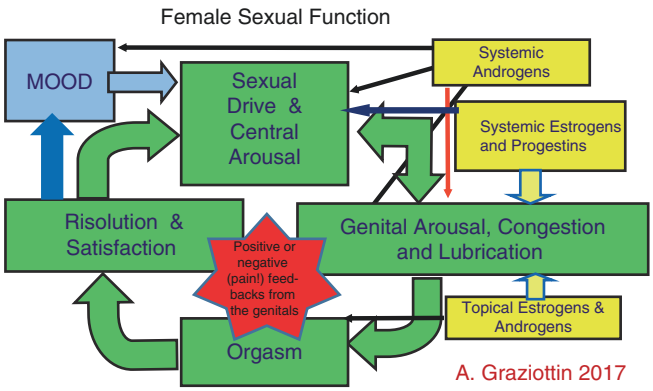

Fig. 62.1 This model, formulated by the author, indicates: (a) the interdependence of different biological dimensions of women's sexual function, desire and central arousal, genital arousal and lubrication, orgasm, resolution and satisfaction; (b) the possibility of positive or negative feedbacks, starting from any of the sexual dimensions; (c) the role of systemic sexual hormones in modulating the biological basis of sexual response in the brain, in the body and in the genitals and their key role in mood modulation; and (d) the role of topical/genital hormones in potentially improving the biological basis of vaginal lubrication, genital congestion and orgasm

Young women who received *chemotherapy*, and underwent POF, tended to desire less frequently ($p < 0.032$), had more vaginal dryness ($p < 0.001$) and dyspareunia ($p < 0.001$) and had sex less frequently ($p < 0.013$); the ability to reach orgasm through intercourse tended to be reduced ($p < 0.043$), although their ability to reach orgasm through noncoital caressing did not differ from that of other women [20]. Coital receptiveness is therefore selectively damaged [20]. This vulnerability depends on the effect of loss on oestrogens on vaginal lubrication and trophism [54]. The progressive thinning of the vaginal mucosa, vaginal dryness and dyspareunia, vulnerability to coital microabrasion, increase of the vaginal pH and altered vaginal ecosystem with increased vulnerability to infection and vaginitis from colonic germs, consequent to the early menopause, all reduce the possibility of enjoying intercourse [54]. Overall sexual satisfaction was significantly poorer ($p < 0.001$) [20]. In particular, Speer comparing BC survivors (age range 41–69 years, average time since diagnosis 4,4 years) vs. women affected by FSD and normal women obtained similar FSFI score (female sexual functioning index) between the first two subgroups vs. normal control group (<.001) [26]. Biglia et al. [36] confirm that young BC patients report significant reduction in frequency of intercourse and reduction in the mean score related to sexuality domain that worsens after 1 year of follow-up. Interestingly, only romantic/implicit stimuli significantly increased in power of evoking sexual interest after 6 months from surgery.

Young women who receive *hormonotherapy* may have a further sexual burden [31, 55–57]. Oestrogen receptor-positive BC women have been treated with *tamoxifen* (TAM)

for almost four decades. Although reasonably well tolerated, this worldwide used drug may specifically affect sexual function [31, 55–57]. The research of Merits et al. indicates that during tamoxifen therapy the most frequent complaints were hot flushes (85%), disturbed sleep (55%), vaginal dryness and/or dyspareunia (47%), decreased sexual desire (44%) and muscular-skeletal symptoms (43%) [55]. Disturbed sleep correlated with hot flushes ($p < 0.0005$) and concentration problems ($p < 0.05$). Decreased sexual interest correlated with vaginal dryness ($p < 0.0005$) and/or dyspareunia ($p < 0.0005$). After discontinuation of tamoxifen, symptoms decreased significantly [55]. Moreover it has been demonstrated that women taking TAM have more difficulties achieving orgasm than women who are not taking this drug [57].

Treatments with *aromatase inhibitors* (AI), such as anastrozole, letrozole or exemestane which inhibit the conversion of androgens to oestrogens, have a negative impact on sexual response in oestrogen-depleted women, as they may exacerbate menopausal symptoms and sexual sequelae [55–57]. Morales et al. [56] published the results of a prospective study including 181 postmenopausal BC survivors scheduled to start endocrine treatment. A menopause questionnaire had been fulfilled at the baseline, after 3 and 6 months of therapy. Both first-line TAM and AI induced an increase in the occurrence and severity of hot flushes ($p < .0001$ and $p = .014$, respectively). Musculoskeletal pain and dyspareunia significantly increased under AI ($p = .0039$ and $p = .001$, respectively). Sexual desire was reduced only under TAM treatment ($p < .0001$). Younger patients suffered more of hot flushes and/or vaginal dryness ($p = .02$) [56].

Different dimensions of sexual function are interconnected. In parallel, interdependence exists among sexual dysfunctions. Research data indicate that comorbidity among sexual dysfunctions is prominent also among young BC patients [2, 3, 14–16, 19, 20, 22, 26, 31, 35, 36, 39, 40, 51–53, 55–57]. However, as specific pathophysiologic vulnerabilities exist in each sexual domain, a concise analysis of each sexual dysfunction in young BC women will be reported.

62.6 Sexual Desire Disorders in Young BC Patients

Sexual desire encompasses **biological**, **motivational-affective** and **cognitive** contributors [50].

1. *Biological roots* of sexual desire depend first on sexual hormones, which are necessary but not sufficient factors to maintain a satisfying human sexual desire [2, 5, 6]. *Hormones* seem to control the *intensity* of libido and sexual behaviour, rather than its direction [5]. Loss of desire up to a frank hypoactive sexual desire disorder (HSDD) is the most frequent sexual complaint in young BC patients, reaching 64% of BC survivors [51]: vulnerability increases after iatrogenic premature menopause [28, 35, 36, 51–53] and if hormonal treatment are used [31, 32, 36]. After BC treatment, loss of oestrogens, secondary to iatrogenic or naturally occurring menopause, may contribute to inhibit the sexual drive and the physical receptiveness; loss of androgens [35], secondary to chemotherapy or ovariectomy, may further worsen the picture. *Depression* is currently understood as a systemic disease with a major inflammatory basis [42–44]. It is the psychiatric disorder more frequently associated with loss of desire in women and in men and is significantly increased in young BC patients. A lower mood level in young BC patients was detected in 63.6% of the study population, reporting irritability, retardation in daily activities and episodes of crying [36]. A reduced desire score, evaluated by FSFI scale, among BC vs. normal women ($p < .001$) has been reported [26]. Loss of sexual desire is a multifactorial problem that may be as well *secondary to* arousal disorders, with vaginal dryness and dyspareunia, orgasmic disorders, sexual dissatisfaction and relationship issues [2–6, 31].
2. *Motivational-affective and cognitive aspects* of sexual desire may be impaired by the negative impact breast surgery has on body image, femininity, eroticism, seductive confidence a woman feels and overall quality of life [2, 3, 51–56]. The shift of couple relationship towards more affective dynamics may increase emotional intimacy but reduce the physical component of sexual drive in both partners [2, 3, 45, 49].

62.7 Sexual Arousal Disorders, Vaginal Dryness and Dyspareunia in Young BC Women

Sexual arousal indicates a mental and physical state with specific feelings, usually attached to the genitals [54]. Breast cancer survivors may suffer from complex arousal disorders, secondary to:

1. *Biological central/mental difficulties* caused by the loss of sexual hormones, secondary to iatrogenic or spontaneous menopause, which may be made worse by depression, anxiety, chronic stress and insomnia [54], triggered by the cancer diagnosis and worsened by oestrogen loss and/or hormonal treatments [2, 51–53, 55–57]. Reduced frequency of erotic dreams, of fantasies, of sexual day dreams and of spontaneous mental arousal are the clinical

consequences of central arousal difficulties that can be reported to the listening physician in young BC patients: "The first thing that made me feel in love were erotic dreams; now nothing thrills my fantasies again" or "I'm so sexually indifferent now that it takes ages of foreplay to be turned on".

2. *Problems in non-genital peripheral arousal* may be better exemplified by "touch-impaired" disorders: nipple erection and feelings may be reduced by decreased breast sensitivity, secondary to surgery: this is a most frequent (and neglected) complaint after BC surgery [3, 40]. Nipple and breast loss of arousability can be worsened by the shame some women feel in exposing the operated breast and having it touched or caressed by the partner [3].
3. *Inadequate genital arousal, reducing: a) vaginal lubrication, causing vaginal dryness, and b) cavernosal bodies congestion, leading to reduced/absent clitoral and cavernosal bodies arousal.* Oestrogens have a prominent "permitting" role on the action of vasoactive intestinal peptide (VIP), the most important neurotransmitter that "translates" sexual drive into vaginal lubrication, while testosterone is the permitting factor for nitric oxide (NO) that mediates most of the cavernosal body congestion [54]. Without oestrogens, *vaginal dryness* and *dyspareunia* are complained of by 47 [55] to 61% [13] of young breast cancer survivors: "I feel dry in spite of a very loving and careful partner. My vagina has forgotten what being wet was. And it hurts most of the time". Pre-existing arousal disorders may be further worsened by the menopausal loss of oestrogens and loss of libido many women complain of after breast cancer [2, 3]. Loss of testosterone, caused by the iatrogenic menopause [35] that significantly reduces the ovarian production by the Leydig cells, explains the increase in the time needed to get a pre-orgasmic clitoral congestion—"It takes ages to get aroused"—and consequent orgasmic difficulties. Another biologic cause of arousal difficulties is the *defensive spasm of pubococcygeus muscle*, either primary, in patients who were suffering from vaginismus and lifelong dyspareunia, or secondary to vaginal dryness and coital pain [2, 3, 58] that further narrows the entrance of the vagina, worsening the vestibular pain until it may contribute to vulvar vestibulitis/vulvodynia: "After the chemotherapy was completed, I started having pain at the entrance of the vagina because I'm dry and tight. And after the intercourse, I have the feeling of many little cuttings in the vagina that burns for two-three days. It's becoming a nightmare. The worst is that I consulted three gynaecologists and they say I have nothing and it must be a psychological problem. But I'm inventing nothing! It really hurts!" [58].

Overall, in the prospective longitudinal study of Ganz and co-workers [13], difficulty in becoming sexually aroused was reported by 61% of BC patients, while difficulty in getting lubricated was found in 57% of the patients. Interestingly, Ganz et al. [13] found that BC survivors attain maximum recovery from the physical and psychological trauma of cancer treatment by *1 year* after surgery. A number of aspects of QOL, rehabilitation problems (mostly *arm problems*) and *sexuality* significantly *worsen* after that time, suggesting that some biological factors might be responsible for this unfavourable trend. According to the retrospective study of Schover et al. [19], BC women who received chemotherapy reported more vaginal dryness ($P < 0.001$) and dyspareunia ($P < 0.001$). Overall, postmenopausal BC women (both for natural or iatrogenic early menopause) were more likely to report vaginal dryness and tightness with sexual activity ($P < 0.001$) and genital pain with sexual activity ($P = 0.004$). The role of the possible *worsening over time* of the biological basis of the sexual response deserves to be tested in new prospective studies, analyzing biological factors from a stringent pathophysiologic point of view.

62.8 Orgasmic Disorders in Young BC Patients

Orgasmic difficulties may be the end point of a number of biological, as well as motivational-affective, cognitive and behavioural factors, such as the quality of the foreplay, affecting desire, central and peripheral arousal, with reduced genital vascular, nervous and muscular response. In BC patients difficulty in reaching orgasm is reported in 55% of patients in the prospective longitudinal study of Ganz et al. [13], with a significant worsening in sexual functioning over the 3 years of follow-up. A very frequent finding in young BC patients after an iatrogenic menopause is the following: "I had an early menopause at 35, after chemo. Now, at 39, it takes ages to get aroused, my orgasm is difficult to reach and very weak. I'm more and more frustrated".

In the Schover et al. retrospective study [20], the ability to reach orgasm through intercourse tended to be significantly reduced in women who received chemotherapy ($P = 0.043$) although their ability to reach orgasm through noncoital caressing did not differ from control women. Inhibitory effect of dyspareunia on vaginal orgasm might explain this difference. FSFI score about orgasm was higher in BC survivor patients vs. FSD women, but lower vs. controls ($p < .001$) [26]. Orgasmic dysfunction ranges from 16–36% of young BC women in more recent studies [51–53]. 41% of women on tamoxifen treatment report orgasmic difficulties in Merits' et al. study [55].

62.9 Sexual Dissatisfaction in Young BC Patients

Sexual satisfaction is a comprehensive and yet elusive word [2]. It includes both physical and emotional satisfaction that should probably be investigated as separate parameters. Pain and an overall disappointing sexual experience might also be responsible for the significantly reduced satisfaction ($P < 0.001$) reported by BC survivors in the retrospective study of Schover et al. [20] and in the prospective study of Dorval et al. [11] who as well report a significantly reduced satisfaction ($P < 0.003$) in BC survivors, 8 years after primary treatment, in comparison to age-matched controls. "I force myself to have sex with my husband not to lose him, but I have no satisfaction at all. It's the last homework before sleeping. I'm so frustrated…". Recently, scoring satisfaction with FSFI, Speer showed a reduced average satisfaction among BC satisfaction vs. controls and vs. non-cancer FSD women ($p < .001$ and $p < .05$, respectively) [26].

In Summary Breast cancer in young women affects almost every domain of **sexual function**, causing loss of sexual desire, arousal difficulties with vaginal dryness and dyspareunia, orgasmic difficulties and dissatisfaction in a significant proportion of patients; the younger the woman, the higher the vulnerability. Biological factors dramatically impair the pathophysiology of sexual response, while psychosocial issues may further contribute.

62.10 Sexual Relationship in Young BC Women

Quality of affective bonds, and specifically of sexual relationships, both homo- and heterosexual, is a critical part of human wellbeing and adult satisfaction. A good quality of emotional intimacy may explain why 62% of BC patients found it easier to discuss their sexual problems with their partner during their illness than with doctors and psychologists, to whom only 15% of BC patients dared to openly express their concerns [14].

Cancer diagnosis is a tremendous strain factor on the couple relationship and on the family [3, 18, 49, 59]. Young women and couples are particularly vulnerable as sexuality is a prominent need in young human beings, deeply motivated by the pursuit of physical pleasure and passion. "Sex was the best part of our marriage. After my breast cancer, I could not have sex anymore because of pain at intercourse, and my dry vagina. I'm so worried that my husband will leave me because of that…". Frustration of sexual needs is therefore more difficult to cope with and to be accepted in young subjects and couples in comparison to older ones.

Studies indicate that younger women experience more emotional distress than older women [18, 59]: "Since I started the aromatase inhibitors, the vagina became more and more dry. I want to have sex in the dark, so that my husband will not see tears pain at intercourse causes me... Why do I want to have sex if it hurts so much? You know, I have a metastatic disease. Making love together makes me feel so deeply connected. I need it now more than ever". Younger husbands reported more problems carrying out domestic roles ($P < 0.001$) and more vulnerability to the number of life stressors they were experiencing ($p < 0.01$) in comparison to older husbands. "At the beginning my husband was very supportive with me and the children and seems to cope well with the nightmare my cancer caused to all of us. But I was devastated when I discovered he had an affair with a beautiful and healthy woman…". When BC is diagnosed the demands of illness are superimposed on the normal routine of family life, and this may have a different impact on the family relationships depending on the phase of the family life cycle when the cancer is diagnosed [18].

Focusing on the physical aspect of the problem, breast surgery may affect physical attractiveness and reduce easiness with breast foreplay in the partner, although this is difficult to be openly admitted as it seems rough, insensitive and/or unfeeling [3]: "Since I got breast surgery, my husband didn't want me anymore", she says, while he says: "I did not dare to make any sexual advance to my wife, as I felt she was so shocked by the cancer diagnosis, and treatment was so hard on her…". Lack of communication may create a kind of "glass wall" between the partners that hurts both of them.

Loss of oestrogen may also make penetration more difficult because of vaginal dryness [2, 5, 6]. It may precipitate an erectile deficit, when dryness itself challenges the quality of the erection or when the partner perceives vaginal dryness as a sign of refusal or somehow an indication of the "insensitivity" of his sexual request and approach [2, 5, 6]. It may impair male physical and emotional satisfaction, when the instinctual drive is braked by physical difficulties and emotional concerns. The concept of "symptom inducer" and "symptom carrier", experienced in many sexually dysfunctional couples, may explain why addressing sexual issues with couples may be more effective than working with the individual BC woman [2, 34, 60].

In Summary Sexual relationships in young BC women can be more affected than in the older group because of the severity of the biological impairment of the sexual response, due to the sudden negative consequences of iatrogenic menopause and hormonal treatment; the stronger meaning sexual pleasure has in young people; the heavier burden of routine tasks in young families; and lack of communication between partners.

62.11 Treatment Options in Young BC Women with Sexual Concerns

The majority of young BC women complain that their sexual problems remain unaddressed, more so from the physical point of view: "I'm fed up of talking about feelings and mourning my losses with my psychologist. I need someone very practical that helps me to get rid of all my vagina pain and have a decent sex back!".

Recommendations to ease the difficult sexual life of young BC patients are based most on clinical experience of the author; evidence-based data will be quoted when available.

1. Lifestyle intervention:
   (a) *Daily exercise*—1 h crispy walking, gym, swimming, jogging, yoga, etc. may improve:
   (a) body shape and body weight, general mental tonus, assertiveness and self-confidence, contributing to a better body image and better sexuality [61]; (b) mood, sleep, appetitive-seeking-lust system and endorphins, reducing irritability, tension and aggressiveness [62]; (c) It reduces the burden of negative emotions associated with BC diagnosis and treatment; (d) Experimental data show that 20 min of jogging before sexual stimulation significantly improves genital arousal in normal women and women taking antidepressants [63]; (e) Breast cancer risk of recurrence is significantly reduced by regular exercise, possibly (also) through a reduction of systemic inflammation; (f) Lymphedema risk is reduced, while body image, body feelings and sexuality are improved by reducing body weight and by daily exercise [64];
   (b) *Appropriate diet*, with preference for legumes, cereals, fruits and vegetables, and no alcohol, to contrast the tendency to increase body weight after the earlier menopause [36], synergize with physical exercise in maintaining a younger, more gratifying body shape and body image [61], reducing neuroinflammation and systemic inflammation and reducing the risk of recurrences.
   (c) *No smoking* should be recommended, as it has specific negative effects on genital arousal (besides its oncogenic potential) in women, as it is well known in men, and specifically reduces genital congestion and vaginal lubrication [65], contributing to vaginal dryness and dyspareunia.
   (d) *Breast self-massage*: (a) to improve the quality of scarring, when appropriate, with medicated cream/oil, and reduce negative breast/arm sensations/feelings through the nervous "gate control" system; (b) to promote at least a partial "neuro-rehabilitation" of nipple and breast sexual feelings through the recall of former pleasurable sensations during the massage itself; and (c) to (re)integrate the breast in the body image, body feeling and body love map.
   (e) *Vaginal self-stretching and self-massage*, to relax the hyperactive pelvic floor, reduce pain associated with levator ani myalgia (underdiagnosed and undertreated in BC women) [58] and ease penetration. Gentle stretching and massage can be taught to a caring partner and included in the foreplay [58].
   (f) *Resume sexual intercourse soon after BC surgery*, if desired, with appropriate suggestions to ease it. There is no medical contraindication to sexual activity in BC patients, but it should be clearly mentioned to the couple by the consulting physician. Moreover, it has been found that regular sexual activity decreases symptoms of atrophy, both in medical examination and patients reporting, increases sensation and improves sexual satisfaction in normal women [66]. Research is needed in BC patients.
2. Physiotherapy:
   (a) To prevent and reduce *lymphedema* [64], when indicated
   (b) To relax the *pelvic floor* and reduce the hyperactivity associated with coital pain at the entrance of the vagina ("introital dyspareunia"), contributing to vestibular pain/vulvodynia and/or post-coital cystitis [58, 67]
3. Pharmacological interventions:
   a. NON hormonal drugs:
      - *Systemic*
        – *To reduce:*
        Hot flushes: gabapentin, low-dose SSRI, with attention to possible interactions with cytochrome P450 [34]
        Insomnia: melatonin
        Depression: SSRI at low effective doses, to minimize the potential negative effect on sexual function
        – *To improve sexual function:*
        Bupropion has been shown to increase sexual desire, arousal, orgasm intensity and overall sexual satisfaction in healthy women, and it may be considered for BC women; studies are needed [68]
        Phosphodiesterase type 5 (PDE 5) inhibitors (tadalafil, sildenafil, vardenafil) to improve genital arousal and lubrication, used despite the lack of FDA approval [34]
        Ospemiphene, a selective oestrogen receptor modulator (SERM) to be used after completion of adjuvant therapies
      - Topical (vaginal) nonhormonal:
        hyaluronic acid
        colostrum gel

Evidence support their efficacy in non-BC women complaining of vaginal dryness. They are intrinsically safe for

BC patients, as they do not contain oestrogens nor other sexual hormones, although specific studies on the effectiveness in BC patients deserve prospective studies.

- Topical (genital) hormonal drugs to improve:
  - Vaginal/bladder symptoms:
    Vaginal promestriene (the weakest synthetic oestrogen with less than 1% absorption), where available.
    Vaginal estriol and estradiol to relieve vaginal atrophy/dryness, post-coital cystitis and dyspareunia [58, 69, 70] to be decided in individual cases when they remain unaddressed with conventional non-pharmacologic treatments such as lubricants. Ospemiphene might offer a new treatment opportunity, oncologically impeccable at the end of the adjuvant treatment.

Oestrogens remain controversial and contraindicated in BC patients. However many physicians advocate a tempered approach aiming at tailoring the use of minimally absorbed local vaginal oestrogens, at least in those women complaining of a critical and unacceptable worsening of their intimate life. Patients should be appropriately counselled and consented and the conversation carefully documented in the medical record [34].

  - Vulvar symptoms of dryness and low arousability:
    Topical testosterone, propionate 1 or 2% cream in Vaseline or vitamin E gel, or testosterone of vegetal derivative in Pentravan (galenic preparation) is used off-label: same concerns and cautions as for vaginal oestrogens must be considered; preliminary studies on topical testosterone gel are ongoing [71], and new data suggesting the antiproliferative role of testosterone are raising new hopes on the possibility of safely using it to improve genital and sexual symptoms.
    Topical dehydroepiandrosterone (DHEA) cream (Labrie data) is the precursor of oestrogens, testosterone and progesterone. It interacts with oestrogen receptor beta, with antiproliferative and reparative actions. At the doses studied by Labrie and co-workers, it has only vaginal activity with no systemic absorption. Data in normal women treated with DHEA, in vaginal ovules, suggest efficacy with vaginal atrophy and no statistically significant changes in hormonal level [72]; it could therefore be considered in BC patients to improve vaginal lubrication and genital arousal. However, prospective data are needed in BC patients to confirm efficacy and safety.

4. Non-pharmacological methods:
   (a) The *Eros clitoral therapy device*, a clitoral vacuum pump approved by the FDA, can improve clitoral congestion [34].
   (b) *Vibrators* can be helpful for extra stimulation of vagina and clitoris in BC women. However both methods may be difficult to be accepted by many patients. Besides, loss of oestrogens and testosterone, and the parallel involution of the cavernosal bodies, reduces progressively the anatomic basis (and potential) of an appropriate genital congestion, even with stronger mechanical stimulation.
   (c) *Lubricants*: water-based and silicone lubricants can be used, as they do not reduce condom efficacy; over-the-counter products such as warming agents, bactericides, spermicides, perfumes and artificial flavours should be avoided as they may irritate the vaginal mucosa and worsen local symptoms and pain [34]. However, some younger patients and partner object that lubricants are "a humiliating fiction of arousal". That's why treatments that enhance the physiologic genital arousal response would be very welcomed, particularly in the younger BC cohort.
5. Individual intervention:
   (a) *Mindfulness-based interventions*: this kind of meditation reduces fear of recurrence, decreases stress, anxiety and depression and has been proven useful in BC patients [73]. It also improves disturbed sleep, promotes higher energy, combats fatigue and increases calm and wellbeing in a non-cancer population, potentially improving sexual function as well. Research is needed in young BC patient;
   (b) *Psychoeducational intervention*: this 6 weeks trial improved relationship adjustment and communication and increased sexual satisfaction [60].
6. Couple intervention:

Relationship enhancement intervention: a six-session biweekly trial, aimed at improving emotional expressiveness, problem-solving skills and self-growth, was performed in BC patients. It improved sexual functioning [74]. The background of this approach is that the women's view of her body is heavily influenced by her partner's response to her body. Its efficacy stresses the importance of couple-based approaches [74]. Controlled studies suggest that interventions focused on the couples rather than on the individual woman have the most likelihood of producing statistical and clinical improvement. The clinical experience supports this finding: it's crucial to give more balanced help also to partners of BC survivors [2]. All the more as husbands and couples express their relief and gratefulness when these issues, potential difficulties and/or misunderstandings are openly and spontaneously raised by the physician during the consultation and when practical suggestions are given to overcome physical and emotional sexual problems.

7. Partner support:

Medical and/or psychosexual support may be indicated for his or her partner, when needed.

62.12 Future Treatment Options for Young BC Women

1. Hormonal:
   (a) *Estetrol (E4)* systemic or vaginal: this weak foetal oestrogen has antioestrogenic effect on the breast and very promising oestrogenic effects on the brain, bone, joints and vagina. If safety and efficacy data will be confirmed, E4 could be the drug of the future to help BC patients of all ages, as it may reduce/eliminate all the menopausal symptoms while maintaining the antioestrogenic protective effect on the breast [75]. Studies are ongoing.
   (b) *Testosterone, systemic*: it still evokes discussion in BC patients because of the possible aromatization of testosterone to oestrogens. More research is needed in terms of systemic testosterone and its safety in BC patients [76].

62.13 Conclusions

Breast cancer may affect young women's sexual identity, sexual function and sexual relationship in a complex way, involving both psychosocial and biological factors, so closely interacting that it is difficult to assert the relative weight of hormonal and overall physical changes on psychosexual variations in BC survivors.

A multidisciplinary approach is needed, to offer the best consultation(s) for the individual case. Attention to the anatomy and function of the pelvic floor and pathophysiology of sexual response should become a mandatory part of a thorough clinical gynaecological and sexological examination, to give BC survivors the right to a full diagnosis and competent help.

New promising drugs and psychosexual interventions to improve women's and couple's sexuality after BC are under investigation. Meanwhile many practical suggestions can be offered from the lifestyle, pharmacologic, physiotherapic/rehabilitative and psychosexual point of view. Avoidance of the minimalistic and depressing wording "Be happy that you are alive" should be mandatory.

Finally, the fact that overall adjustment and QOL of BC survivors are positive in average 70–80% of cases should not mask a more painful truth: that this is true for many areas of QOL, *except* for all the dimensions of women's sexuality particularly in young BC women. An understanding and competent physician could help the woman and the couple to cope better with the tremendous strain of breast cancer, also from the sexual point of view: without giving up the sexual intimacy, that is such a critical part of QOL, particularly in younger women and couples. But it is difficult to provide an effective intervention, if there is no mention of a problem. That is why asking "How is your sexual life, now?" should become routine part of the oncological consultation in BC women, at least to make an appropriate referral, while promoting a better quality of life.

Appendix 1

Breast Cancer In Young Women: The Sexual Price

Executive Summary

Breast cancer may affect female sexual identity, sexual function and couple relationship in a complex way, involving both psychosocial and biological factors, by the many changes and challenges the woman has to face when breast cancer diagnosis and treatment disrupt her life and that of her relatives.

Psychosocial and biological factors are so closely interacting that it is difficult to assert the relative weight of hormonal and overall physical changes on psychosexual variations in breast cancer survivors. Physicians should improve their skill in understanding and listening to sexual concerns and in addressing the basic biological issues that breast cancer raises for female sexual identity, sexual function and sexual relationship.

Sexual Identity

Femininity, maternity, eroticism and social role all contribute to the perception of female sexual identity and may be variably affected by breast cancer diagnosis and treatment.

Femininity may suffer a major insult, for a number of biological reasons:

(1) *Body image*. Short-term impact depends on the type of surgery performed and the need or not of adjuvant radio- or chemotherapy and hormonotherapy. However, more conservative treatments do not appear to significantly modify quality of life nor women's sexuality in the long term.
(2) *Arm lymphedema*. "Arm problems" are quoted by 26 to 72% of the patients, according to the different arm symptoms (pain, pins and needles, numbness, skin sensitivity, swelling).
(3) *Iatrogenic menopause*. Younger patient are more vulnerable because a longer lacking period of adequate oestrogen and testosterone levels may affect the quality of ageing of

the brain and of sensory organs that are sexual targets and sexual modulators of sexual desire and central arousal.

(4) *Age*. Its weight is not limited to the potential impact of the menopause, but to the different individual and social tasks and goals of women's reproductive years, tasks that have different priority in different decades: young women should therefore be considered at higher risk of negative quality of life (QOL) outcomes after breast cancer and be offered a specific help.

Maternity: it may become the core of a major identity crisis for the 25% who is diagnosed during the fertile age. Since most breast cancer recurrences appear within 2 to 3 years after initial diagnosis, patients should be advised to postpone pregnancy for at least 2 years. If a patient has axillary node involvement, the recommendation to defer pregnancy should be extended to 5 years, but this recommendation is based on opinion only. Women treated for breast cancer who wish to become pregnant should be counselled that pregnancy is possible and does not seem to be associated with a worse prognosis for their breast cancer. Anyway, prior to attempting pregnancy, a breast cancer survivor should be referred for a full oncologic evaluation.

Eroticism: breast cancer may affect sensuality, sexiness and receptiveness through:

(1) *The loss of pleasurable sensations in the breast*, after surgery (partial mastectomy, in particular in case of breast reconstruction), which may reduce sexual arousal.
(2) *Menopause*: iatrogenic (chemotherapeutic) and/or nonhormonally treatable natural menopause may dramatically devastate the woman's sense of eroticism.
(3) *Depression and anxiety*, reactive to breast cancer, that may affect self-perception and sexual function (in particular sexual desire) via nonhormonal pathways, are reported in average 17 to 25% of breast cancer patients.
(4) *Social role* may represent an area relatively safe from breast cancer, particularly in well-educated women and ones with a strong and positive social role, except in the acute phase or in the more severe and aggressive cases.

Women carriers of BCRA mutations, who might consider bilateral prophylactic mastectomy, may have a specific iatrogenic impact of surgery on their self-image and femininity.

Sexual Function

The most common sexual symptoms in BC survivors, which can be referred to the loss of sexual hormones, altered body image and secondary to surgery or to other sexual disorders, are *loss of libido*, *arousal disorders* (arousal difficulties may be central, non-genital peripheral and genital), *dyspareunia* (lifelong or acquired, secondary to arousal disorder, it can be worsened by the defensive spasm of pubococcygeus muscle), *anorgasmia* (common after chemotherapy, worsening with time) and *loss of satisfaction* (pain and an overall disappointing sexual experience might also be responsible for the significantly reduced satisfaction reported by breast cancer survivors).

Attention to the anatomy and function of the pelvic floor should become a mandatory part of a thorough clinical gynaecological and sexological examination, to give BC survivors the right to a full diagnosis and competent help.

Couple Relationship

The fact that overall adjustment and QOL of breast cancer survivors are positive in average 70–80% should not mask a more painful truth: that this is true for many areas of QOL, *except* for sexual function and satisfaction. An understanding and competent physician could help the woman and the couple to cope better with the tremendous strain of breast cancer, also from the sexual point of view: without giving up the sexual intimacy, that is such a critical part of QOL, particularly in younger women and couples.

Treatment

Recommendations to ease the difficult sexual life of young BC patients are based most on clinical experience of the author and include: lifestyle intervention (daily exercise, appropriate diet, no smoking, breast self-massage, vaginal self-stretching and self-massage, resume sexual intercourse soon after BC surgery, if desired), physiotherapy, pharmacological interventions (nonhormonal and hormonal drugs, when appropriate and oncologically feasible), nonpharmacological methods (Eros clitoral therapy device, vibrators, lubricants), individual intervention (mindfulness-based interventions, psychoeducational intervention) and partner medical and/or psychosexual support.

Future hormonal treatment options may include estetrol (E4), ospemiphene [77], DHEA and testosterone (intravaginal gel or systemic): controlled studies are ongoing.

Male Breast Cancer

63

Laura Ottini and Carlo Capalbo

63.1 Introduction

Breast cancer (BC) is often mistakenly thought of as a female-only disease. Aside from the expected cultural explanations, the simple fact is that male BC (MBC) is rare. To date, in Western countries, MBC accounts for less than 1% of all cancers in men and less than 1% of all BCs, but its incidence is increasing [1, 2].

The earliest reference to BC in the Edwin Smith Surgical Papyrus from Egypt (3000–2500 BC) appears to have referred to a man [3, 4]. The first clinical description of an MBC case is in the early fourteenth century and is attributed to John of Arderne (1307–1390) who recorded the several-year evolution of nipple ulceration in a priest, with the subsequent development of BC [5]. Many years later, in 1842, Domenico Antonio Rigoni-Stern showed to the Congress of the Italian Scientist that the risk of BC was greatly increased in nuns compared to other women, and, intriguingly, he concluded his presentation saying that "the four men found to have died of BC were all priests" [6].

Because of its rarity, MBC is often compared with FBC, and our current understanding regarding MBC biology, pathology, and treatment strategies has been largely extrapolated from the more common female counterpart. Current epidemiologic and pathologic data, such as age-frequency distribution, age-specific incidence rate patterns, and prognostic factor profiles, suggest that MBC is like postmenopausal FBC [7]. Although MBC resembles postmenopausal FBC, clinical and pathologic characteristics of MBC do not exactly overlap FBC. Compared with FBC, MBC occurs later in life with more advanced stage, lower histologic grade, and more frequent estrogen receptor (ER)- and progesterone receptor (PR)-positive (ER/PR+) status [8, 9]. Higher stage and advanced age at diagnosis are negative prognostic factors, and, although rare, MBC remains a substantial cause for morbidity and mortality in men.

There is very little research on the management and care of MBC, and, due to the low incidence of MBC, studies are often small and underpowered. Thus, to date, therapy has been based largely on biomarkers developed for FBC, and MBC treatment generally follows the same indications as postmenopausal FBC. The outcome for men is the same as women stage for stage, but overall the prognosis tends to be worse in MBC [7]. This is usually due to a delay in presentation, leading to a large proportion of patients presenting with advanced-stage disease, and older age at diagnosis, leading to the coexistence of possible comorbidities. Overall, BC mortality and survival rates have improved significantly over time for both male and female BC, but the improvement for male is smaller if compared to female patients [9]. The different treatment outcomes may suggest a non-appropriate utilization of treatment options and a possible existence of different underlying pathogenetic mechanisms between male and female BC.

Today, thanks to the increasing number of collaborative studies and to the combination of data derived from new high-throughput technologies, we are now able to hypothesize that despite the similarities between female and male BC, MBC could be rather considered a distinct pathology.

63.2 Epidemiology

MBC incidence varies greatly in different geographical areas and ethnic groups and is correlated with FBC incidence worldwide [10]. Indeed, the worldwide variation of MBC resembles that of FBC, with higher rates in North America and Europe and lower rates in Asia [11]. A substantial high proportion of MBC cases have been reported in Africa, particularly in Uganda and Zambia [12]. These relatively high rates have been attributed to endemic infectious diseases causing liver damage leading to hyperestrogenisms. Overall, black men have a higher incidence of MBC (1.8 per 100,000)

L. Ottini (✉) • C. Capalbo

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_63

compared to the average incidence. By contrast, the annual incidence of MBC in Japan is significantly lower (5 per 1000,000) than the average incidence (1 per 100,000), comparable to the lower than the average incidence of FBC in this country [8, 13].

MBC incidence is increasing [2]. Data from the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database indicates that in the USA the incidence of MBC has been increasing during the last 20 years, from about 1 per 100,000 to around 1.2 per 100,000 (SEER 13 Registries Database). Data from the United Kingdom Association of Cancer Registries (UKACR) have reported that in the UK, MBC incidence is on the increase and parallels US data over a similar period of time [14].

Age-specific incidence rates for MBC increase linearly and steadily with age with a peak incidence in the late 60s. In contrast, FBC increases rapidly until around age 50 and then increases at a slower rate for older women (Fig. 63.1). MBC cases are diagnosed at a more advanced age than FBC. Age of BC presentation in males is mostly in the late 60s, which is about 10 years greater than in female. In the SEER database, the median ages at diagnosis of BC were 68 and 61 years in males and females, respectively. The differences in incidence rates and time trends between males and females may reflect gender-related differences in risk factors and/or different underlying pathogenetic mechanisms. On the other hand, the correlation between male and female BC incidences indicates the existence of common risk factors for BC in both genders.

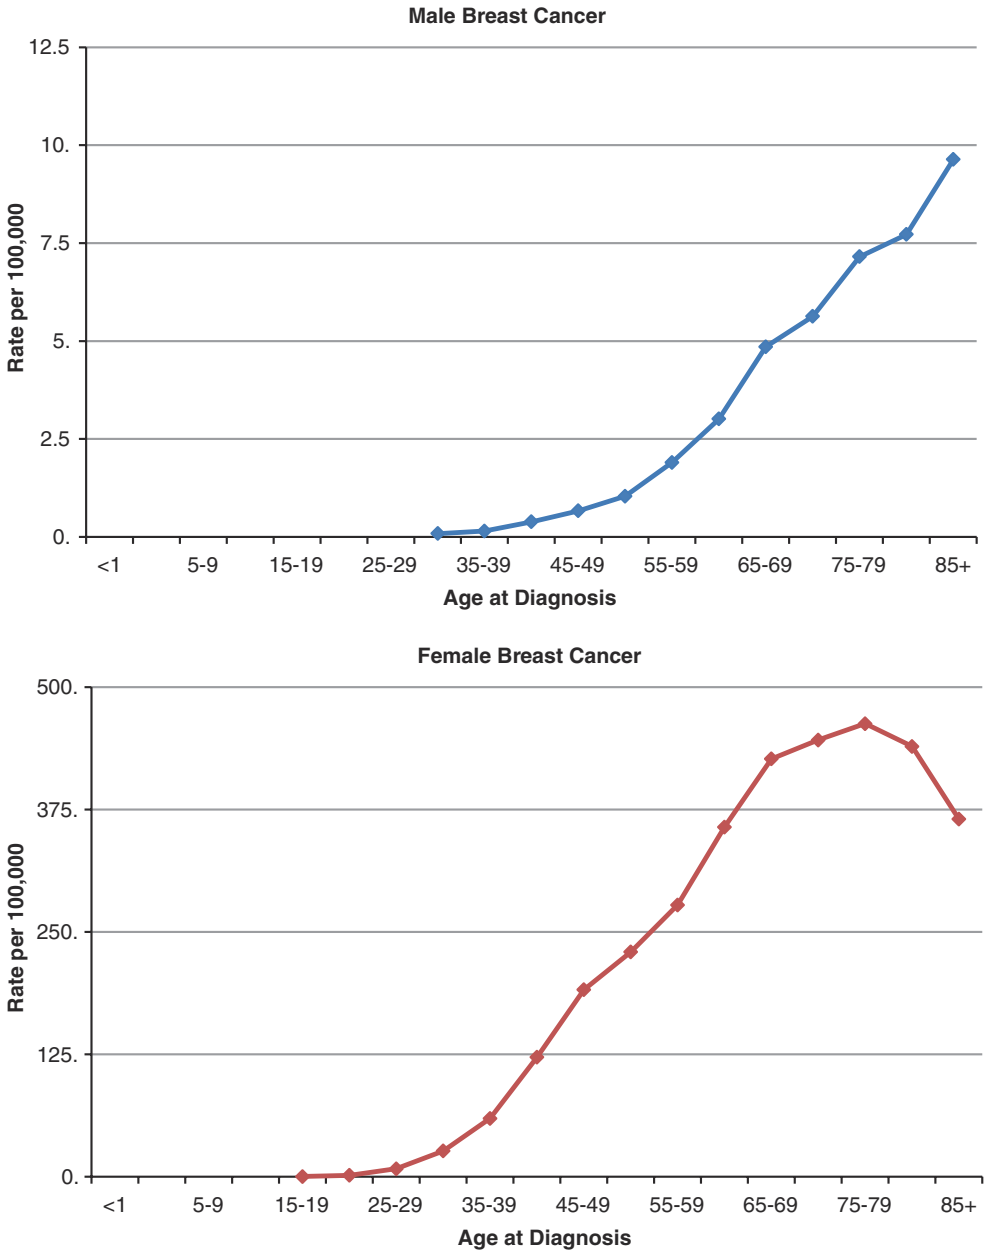

Fig. 63.1 Age-specific incidence rates (per 100,000) for male and female invasive breast cancer in white US population. Data source: SEER 18, years 2003–2012

Table 63.1 Risk factors for male breast cancer

Risk Factors	Genetic	Hormonal	Environmental
Well established	Breast cancer family history	Increased estrogen exposure	Radiation
	BRCA1/BRCA2	Deficiency of testosterone	
	Klinefelter's syndrome	Testicular disease	
Possible	*CHEK2*	Obesity	Heat
	PALB2	Diabetes	Electromagnetic fields
	SNPs	Liver damage	Polycyclic aromatic hydrocarbons
Suspected	Cowden syndrome	Gynecomastia	Alcohol
	Lynch syndrome		Tobacco

63.3 Risk Factors

Risk factors for MBC include genetic, hormonal, and environmental factors (Table 63.1).

63.3.1 Genetics

About 20% of male patients with BC have positive family history for BC. Men with a positive first-degree family history have a twofold increased risk of BC. The risk increases with increasing numbers of first-degree relatives affected, and a particularly enhanced risk (more than ninefold) is reported for cases with both an affected mother and an affected sister [15]. About 2% of male patients with BC develop a second primary BC, and more than 20% develop a second non-breast tumor, more frequently prostate, colon, and genitourinary cancer. Men who have family members with Cowden syndrome and Lynch syndrome are also at increased risk for BC [16, 17]. As both these syndromes and MBC are rare, it is difficult to determine as to whether germline mutations in these genes increase the risk of MBC.

Mutations in the two major high-penetrance BC genes, *BRCA1* and, predominantly, *BRCA2*, account for approximately 10% of MBCs, outside populations with *BRCA* founder mutations [18]. In Icelandic population, for example, the *BRCA*2 999del5 founder mutation is implicated in about 40% of MBC cases [19]. Mutations in *BRCA1* and *BRCA2* genes are often found in MBC patients who have multiple cases of breast and/or ovarian cancer in their family, but have also been found in MBC patients with no breast and/or ovarian cancer family history. This evidence and the rarity of the disease indicate that every man who has BC should be routinely screened for *BRCA1* and *BRCA2* mutations, regardless of family history, which could prove to contribute invaluable genetic information to family members. Men with *BRCA1/2* mutations have an increased risk of BC compared with general population and develop BC at younger age compared with non-mutation carriers. The lifetime risk of developing MBC has been estimated to be in the range of 1–5% for *BRCA1* and 5–10% for *BRCA2* mutation carriers, compared with a risk of 0.1% in the general population [20, 21]. The median age at BC diagnosis in male *BRCA1* and *BRCA2* mutation carriers is earlier (62 years) than that of the general population (68 years) (SEER 13 Registries Database).

Two genes, *CHEK2* and *Partner/Localizer of BRCA2* (*PALB2*), both functionally related to *BRCA1* and *BRCA2* in DNA repair pathways, also play a role in MBC susceptibility as moderate-penetrance genes. In certain populations, the *CHEK2* 1100delC mutation confers an increased risk of MBC, particularly in *BRCA1* and *BRCA2* mutation-negative BC families. However, this association is not so evident in MBC cases unselected for family history, and the contribution of the *CHEK2* 1100delC variant to MBC predisposition varies from one ethnic group and from one country to another [22–24]. Mutations in *PALB2* have been reported in families with female and male BC cases [25–27]. A fourfold higher frequency of MBC among relatives of *PALB2* mutation carriers has been shown. BC risk estimates for male *PALB2* mutation carriers still remain to be precisely assessed; however, *PALB2* may have an important role in MBC predisposition, at a comparable extent as for FBC [28].

A number of single nucleotide polymorphisms (SNPs) are implicated as low-penetrance alleles in MBC genetic predisposition [29]. The majority of SNPs that are associated with MBC risk are the same as those associated with FBC risk, but it appears that the magnitude of risk conferred by them differs between the two diseases. In particular, two SNPs (rs3803662 and rs1314913) have been identified significantly associated with MBC risk [30]. The rs3803662 localizes to the TOX High Mobility Group Box Family Member 3 (*TOX3*) gene (mapping to 16q12.1) and is a known modifier of FBC risk [31]. As shown for rare variants in *BRCA2* and *CHEK2* genes, the association with risk for this SNP is greater in males compared with females [30]. The rs1314913 SNP, located in intron 7 of the *RAD51B* gene (mapping to 14q23-24.2) belonging to RAD51 DNA repair family, is specifically associated with increased MBC but not FBC risk, supporting defined difference between male and female disease [32]. While the risk associated with these SNPs is low, they are likely to be

responsible for a substantial percentage of hereditary and sporadic MBCs because of their high frequency in the population.

63.3.2 Endocrine

MBC is recognized as being a hormone-dependent malignancy, and it is widely accepted as an estrogen-driven disease, specifically related to hyperestrogenism [33]. Clinical disorders associated with imbalanced estrogen/androgen ratio that result in abnormal estrogen exposure represent a major risk. Men affected with Klinefelter's syndrome, a rare congenital condition characterized by a 47 XXY karyotype and high levels of estrogens and low levels of testosterone, have been shown to have 20- to 50-fold increased MBC risk [34].

Other medical conditions linked to altered endogenous hormones including diabetes, orchitis, cryptorchidism, and gynecomastia have possible influences on MBC risk [35]. In addition, liver disease, leading to hyperestrogenism, emerged as a significant risk predictor of MBC, particularly among black men [36]. Conditions increasing exposure to estrogen or decreasing exposure to androgen, such as the long-term use of antiandrogens and estrogens in the treatment of prostate cancer, the exogenous administration of estrogen to transsexuals, or abuse of steroids for physical performances, have also been implicated as causative factors for MBC [37–39]. Elevated risks of MBC have also been related to a variety of other conditions associated with altered endogenous hormones, with the most consistent association being observed with obesity [40, 41]. Obesity is associated with an increased risk of postmenopausal FBC, presumably through peripheral conversion of androgens to estrogens. In men, obesity is associated with decreased testosterone and sex hormone-binding globulin levels but increased estrogen levels [42, 43], thus leading to greater estrogen bioavailability.

63.3.3 Environmental and Lifestyle Risk Factors

Ionizing radiations, occupational exposure to heat, and electromagnetic radiation have been considered as possible causal cofactors in the etiology of MBC [12]. Additional clues to a potential importance of other occupational exposures derive from studies showing elevated MBC risks among men exposed to polycyclic aromatic hydrocarbons [18, 44]. Some lifestyle factors have also been involved in the etiology, including alcohol and tobacco exposures, although results have varied across investigations [45].

63.4 Histopathology

63.4.1 Histology

The histology of BC occurring in men is generally similar to that occurring among women although the distribution of the histological types is different. The majority of MBCs are invasive ductal carcinoma (more than 80%) followed by ductal carcinoma in situ (about 10%). Lobular histotype is much less common in men (1.5%) than in women, due to the absence of terminal lobules in male breast tissue [46, 47]. Lobular histotype has been reported in association with Klinefelter's syndrome and, rarely, in men with no previous history of estrogen exposure. The rare tumor types, such as medullary, tubular, mucinous, and squamous carcinomas, are also reported in men although they are rarer than in women. On the other hand, papillary carcinoma is more frequent in men than in women. Both Paget's disease and inflammatory carcinoma are observed with equal frequency (about 1%) in both genders [12]. The majority of MBCs are low histologic grade [46, 47]. Data from the SEER 13 database show that 13% of MBCs are Grade 1 (G1), 50% Grade 2 (G2), and 39% Grade 3 (G3) tumors (Table 63.2) [43].

63.4.2 Biomarkers

The great majority of MBCs are ER+ and PR+ with more than 90% of tumors being positive for ER and about 85% for PR (SEER13, [43]). As reported for FBC, the percentage of men with ER+ BC significantly increases with patient age [1, 8]. Rates of androgen receptor (AR) expression in MBC have been variable in different cohorts, ranging from 39 to 95% [12, 48, 49]. Data about HER2 expression in MBC are inconsistent most likely because of small studies and of not standardized technical approaches. Studies performed by using both immunohistochemical (IHC) and fluorescence in situ

HER2	15

hybridization (FISH) analyses report HER2 overexpression in about 15% of MBCs [50, 51].

Based on immunophenotypic characteristics, MBC can be classified into different molecular subtypes [50, 52]. Luminal A (ER+ and/or PR+, HER2-) subtype has been reported as the most common subtype in MBC (more than 85%), whereas Luminal B (ER+ and/or PR+, HER2+) subtype has been less frequently observed (about 12%). Triple-negative (ER-, PR-, HER2-) subtype and HER2-positive (ER-, PR-, HER2+) subtype have been rarely identified in MBC (about 1%).

63.4.3 BRCA1/2 Male Breast Cancer

Generally MBC presents with lower histologic grade tumors than FBC. In contrast, MBC associated with *BRCA2* mutations presents with higher histologic grade compared both with FBC in *BRCA2* mutation carriers and with MBC in the general population from SEER [53]. In particular, high histologic grade breast tumors are more frequent among male *BRCA2* mutation carriers diagnosed at younger ages (below 50 years) than among those diagnosed at older ages. Thus, the identification of a specific *BRCA2*-associated phenotype suggestive of an aggressive behavior may define a subset of MBC patients (i.e., patients with high-grade breast tumors and with young age at diagnosis) who might particularly benefit from adjuvant chemotherapy. A similar trend is also observed for *BRCA1* mutation carriers. Overall, *BRCA1/2* MBCs display distinct pathologic characteristics compared to *BRCA1/2* FBCs. These findings should lead to the development of gender-specific risk-prediction models and guide clinical strategies appropriate for MBC management.

63.5 Clinical Presentation and Diagnosis

Men with BC are more frequently diagnosed at a more advanced age and with a more severe clinical presentation, with greater tumor size and a more frequent lymph node involvement, than women with BC. In general, this is thought to reflect diagnostic delay in a population unaware of its risk and not appropriately encouraged to undergo routine BC screening. Despite increasing awareness of MBC, there remains an average delay from the onset of symptoms to diagnosis of 6–10 months [54].

The most common symptom of BC in men is a painless lump. The majority of MBC patients present a palpable subareolar mass. Because of the unique anatomy of the male breast, characterized by the presence of the rudimentary breast ducts located directly beneath the nipple, other initial symptoms may include nipple involvement such as retraction, ulceration, discharge, and bleeding [54]. BC primaries in men more often have locoregional metastasis at presentation. More than 40% of MBC patients present with stage III/IV disease, often due to early chest wall spread. Clinically suspected axillary nodes are identified in about 40% of patients at the time of diagnosis [46]. Bilateral involvement is rare, less than 2% of MBC cases [55].

Clinically suspicious lesions identified by palpation are evaluated with mammography and/or ultrasonography scans to select patients who will undergo to further examination generally made by fine-needle aspiration (FNA) or core biopsy. The primary differential diagnosis of a breast mass in a man includes gynecomastia that affects 30% of healthy men [56]. The evaluation of the extension of disease and stage classification follows the guidelines for FBC.

63.6 Prognosis and Survival

Prognosis depends upon tumor size, histologic grade, nodal status, and hormone receptor status. Stage classification of male patients with BC is similar to that of female patients, according to AJCC or UICC guidelines. As postmenopausal FBC, in general MBC have more favorable prognostic factor profile, including low histologic grade and hormonal receptor-positive expression [9]. Despite this, men experience worse prognosis than women, probably due to both an advanced stage and older age at diagnosis. As in FBC, the most important prognostic indicators are tumor size and lymph node status. Men with breast tumor diameter > 2 cm have a 40% higher risk of mortality than men with tumors <2 cm. Similarly, men with lymph node involvement have a 50% higher risk of mortality than men without lymph node involvement. Furthermore, an increasing number of lymph node metastases are positively correlated with a poorer prognosis [1].

Compared with women, overall survival rates are lower in men; however, when adjusted for older age at diagnosis and poor life expectancy, the relative survival rates are quite similar for men and women [9]. This likely reflects the influence of serious comorbidities as result of an older age at diagnosis. The overall 5- and 10-year survival rates of MBC patients are around 60% and 40%, respectively. When grouped by stage at presentation, overall survival rate is 78% and 55% for stage I, 66% and 39% for stage II, and 39% and 21% for stage III disease, at 5 and 10 years, respectively [57]. Overall, survival rates differ significantly according to race/ethnicity. Compared to white men, black men have features of more aggressive disease as higher histologic grade, larger tumor size, and higher rate of nodal involvement. Worse prognosis in black men after

adjustment to clinical, demographic, and treatment factors has been shown [58].

BC mortality and survival rates have improved significantly over time for both male and female BC, but the relative improvement was less significant for men compared with women [7]. Decline in FBC mortality rates are attributed to adjuvant systematic therapy and screening mammography. Decline in MBC mortality would likely reflect just the impact of adjuvant systematic treatment since men do not receive screening mammography. However, the improvement for male is smaller if compared to female BC patients, suggesting underutilization or non-appropriate utilization of adjuvant therapy.

63.7 Oncogenetic Counseling, Screening, and Surveillance

Genetic counseling should be offered to MBC patients based on their increased risk of *BRCA* mutations, particularly in the context of a family history of breast/ovarian cancer. The National Comprehensive Cancer Network (NCCN) recommendation indicates that all MBC patients should be offered genetic counseling and testing based on their risk of carrying a deleterious mutation that might be relevant to their own care or the care of their family members. Risk assessment models to estimate the risk of carrying a *BRCA* mutation, such as BRCAPRO, have been validated for use in male patients [59–61].

Because the age-standardized incidence of MBC is only 1/100,000 person-years with lifetime risk of about 1/1000, there is no role for breast screening in the general male population. On the other hand, screening for BC in men at higher BC risk, including those with *BRCA1/2* mutations, strong family history of BC, such as affected mother and/or sister, Klinefelter's syndrome, or transgenders [62, 63], should be undertaken and should be available preferably in a clinical trial. Extrapolating from FBC, NCCN recommends that men at higher BC risk have a clinical breast exam every 6 to 12 months and consider having a mammogram at age 40. However, as the value of breast imaging remains uncertain in men, mammography and ultrasound should be considered. Men with a *BRCA1/2* gene mutation should also have prostate cancer screening starting at age 40. Men at higher BC risk should also be aware of the warning signs of BC and should be taught for breast self-examination.

The risk of a new BC is higher in MBC survivors. MBC patients had a 30-fold increased risk of developing a contralateral BC, and this risk is greatest in men who were younger than 50 years at BC diagnosis. Thus, male survivors of early stage BC could benefit most from breast screening. MBC survivors are also at risk of certain non-breast second malignancies, prostate and colon cancer being the most common [47]. Thus, MBC survivors should be offered the same screening programs for non-BC as men in the general population, unless they are found to carry deleterious genetic mutations for which specific follow-up is recommended. Overall, there is a clear need for protocols for both screening and surveillance and, more in general, for information and support to men diagnosed with BC.

63.8 Treatment Options

To date, because there have been few evidences supporting a specific therapeutic approach in MBC, the majority of clinicians base their treatment recommendations on their personal experience with this disease and on the data of FBC. Indeed, the small numbers of MBC seen in any unit annually have precluded significant trials being carried out, and treatment of MBC often mirrors that of FBC despite some not negligible differences. Overall, with some minor variations, MBC treatment follows the same indications as female postmenopausal BC, with surgery, radiotherapy, and systemic therapy.

63.8.1 Treatment of Early-Stage Disease

63.8.1.1 Surgical Management

The goals of BC surgery include complete resection of the primary tumor with negative margins to reduce the risk of local recurrences and pathologic staging of the tumor and axillary lymph nodes to provide prognostic and/or predictive information.

In early-stage MBC patients, primary standard treatment is a modified radical mastectomy with axillary dissection [64]. This is primarily due to a paucity of breast tissue in men as well as the fact that in male breast, the tumor usually affects central quadrant. Locoregional disease control to this treatment is generally similar to those seen in women with BC. Conservative breast surgery has produced encouraging results for the treatment of early-stage MBC patients, although in males a larger tumor size and a higher rate of chest wall infiltration are found compared to female patients. Overall, breast conservation has also been used, and results have been similar to those seen in women with BC [65].

Surgical assessment of the axillary lymph nodes is an essential part of primary BC therapy; although men with

early-stage disease typically undergo axillary lymph node dissection, the use of sentinel lymph node biopsies is increasing [66, 67]. If the sentinel lymph node contains cancer, a full axillary lymph node dissection may be needed, depending on the size of the cancer in the lymph node as well as what other treatment is planned. In a recent SEER analysis, 19% of men were treated with lumpectomy [68]. Obviously, if breast-conserving surgery is done, it is usually followed by radiation therapy. External beam radiation is the usual type of radiation therapy for men with BC. This usually includes the chest wall where the breast was removed and, depending on the size and extent of the cancer, may include the underarm area, supraclavicular lymph nodes, and internal mammary lymph nodes.

Rates of contralateral preventive mastectomy in men who received a diagnosis of unilateral invasive BC nearly doubled between 2004 and 2011. In fact, in 2004, about 3% of men had contralateral preventive mastectomy while, in 2011, men who had contralateral preventive mastectomy were 5.6%, with a relative increase of 86.7% [69]. However, this increase has occurred despite the lack of evidence for a survival benefit from bilateral surgery.

Although breast reconstruction is an integral part of BC treatment plan and methods of reconstruction after mastectomy in women are well described, to date, postmastectomy deformity of the male chest has not received sufficient clinical interest. However, body image has emerged as an area of concern for MBC patients, thus deserving gender-specific attention [70].

63.8.1.2 Adjuvant Therapy

Currently, due to the rare occurrence of this disease, no controlled studies have compared adjuvant treatment options in MBC. In this setting, responses are generally similar but not identical to those seen in women with BC, and hormonal therapy has been recommended in all receptor-positive patients. In men with ER+, node-negative BC, endocrine therapy with tamoxifen is usually recommended [71]. In men with node-positive tumors, both chemotherapy and tamoxifen have been used and can increase survival to the same extent as in women with BC. However, there are limited data regarding adjuvant chemotherapy use; to date most clinicians offer either an anthracycline or anthracycline-taxane-based schedules to men who are classified at a high risk of recurrence based on the presence of axillary lymph nodal disease, larger tumors, younger age, and ER-negative tumors [72].

While the data supporting adjuvant chemotherapy in women are strong, there is little information on the effectiveness of adjuvant chemotherapy in men. However, most clinicians use similar guidelines for adjuvant chemotherapy in male and female patients. To date only one study has been performed to determine which male patients would derive benefit from adjuvant treatment as measured by the standardized 21-gene RT-PCR assay [73]. A similar gene expression profile has been found in male compared with female BCs. If these preliminary data will be confirmed by prospective studies, this testing may also be a reasonable help to guide the treatment of early stage, ER+, lymph node-negative MBC (Table 63.3) [74].

63.8.2 Treatment of Metastatic Disease

Advanced-stage disease at BC diagnosis is more frequently observed in men than in women; although a very small selected subset of patients with metastatic BC should be approached with curative intent, it is a generally held belief that once the patient with BC develops clinically detectable metastases beyond the regional lymph nodes, the disease is incurable [64]. The goals of care are to optimize both length and quality of life.

To date, clinical management of metastatic BC is similar in male and female patients. Treatment choice should take into account at least these factors: tumor burden, metastatic de novo or recurrence, hormonal receptors and HER2 status, previous therapies and/or toxicities, and disease-free interval. Given that the vast majority of men have ER+ tumors, hormonal therapy is the upfront approach. Tamoxifen has an established efficacy and toxicity profile in metastatic male BC, with an approximate 50% response rate, and is considered the standard first-line approach.

For male patients with hormone-refractory disease or rapidly progressing visceral metastases, chemotherapy can provide significant palliation. The type of chemotherapy is similar to the one used in the adjuvant setting, with anthracycline and taxanes as the backbone of the chemotherapy regimens. In particular, in the absence of medical contraindications, anthracycline- or taxane-based regimens, preferably as a single agent, would usually be considered as first-line chemotherapy for HER2-negative MBC, in those patients who have not received these regimens as adjuvant treatment and for whom chemotherapy is appropriate (Table 63.3). Similarly to female, in MBC patients pretreated with an anthracycline and a taxane and who do not need combination chemotherapy, single-agent capecitabine, vinorelbine, and eribulin are the preferred choices. The effectiveness of anti-HER2 agents in her2-neu overexpressing male breast cancer is unproven, but certainly it seems reasonable given the strong evidence in support of trastuzumab in women with breast cancer. Finally, no gender-specific trial have been designed so far testing mTor or CDK4/6 inhibitors.

Table 63.3 Drug options

Early stage			Advanced stage		
Chemotherapy regimens[a]:	Hormonal treatments[b]:	Target therapy[c]:	Chemotherapy regimens:	Hormonal treatments[d]:	Target therapy[e]:
AC (doxorubicin and cyclophosphamide)	Tamoxifen	Trastuzumab	Nab-paclitaxel	Tamoxifen	Anti-HER2 agents (trastuzumab, pertuzumab, TDM-1) in her2-neu overexpressing male breast cancer
AC or EC (epirubicin and cyclophosphamide) followed by T (doxorubicin and cyclophosphamide, followed by paclitaxel or docetaxel, or the reverse)	Aromatase inhibitors plus luteinizing hormone-releasing hormone agonist[f]		Doxorubicin	Luteinizing hormone-releasing hormone agonist with or without total androgen blockage (antiandrogen)	Bevacizumab
CAF (cyclophosphamide, doxorubicin, and 5-FU)			Paraplatin	Progesterone	plus LHRHa
CEF (cyclophosphamide, epirubicin, and 5-FU)			Cyclophosphamide	Aromatase inhibitors	CDK4/6 inhibitors
CMF (cyclophosphamide, methotrexate, and 5-FU)			Doxorubicin	Fulvestrant	
EC (epirubicin, cyclophosphamide)			Epirubicin		
TAC (docetaxel, doxorubicin, and cyclophosphamide)			Fluorouracil		
TC (docetaxel and cyclophosphamide)			Gemcitabine		
			Eribulin		
			Ixabepilone		
			Methotrexate		
			Vinorelbine		
			Paclitaxel		
			Docetaxel		
			Vincristine		
			Capecitabine		

[a]The role of taxanes and dose-dense regimen, however, remains to be elucidated
[b]The use of aromatase inhibitors for male BC is controversial; while these have been shown to increase disease-free survival in women, mixed results have been found in men
[c]There is currently few data on the benefits of trastuzumab in male breast cancer
[d]There is currently few data on the benefits of aromatase inhibitors and fulvestrant in male breast cancer
[e]The role of bevacizumab, mTor inhibitors and CDK4/6 inhibitors remains to be studied
[f]The effectiveness of anti-HER2 agents (trastuzumab, pertuzumab, TDM-1) in HER2 overexpressing male breast cancer is unproven but certainly seems reasonable given the strong evidence in support of trastuzumab in women with breast cancer

Treatment of Central Nervous System Involvement

64

E. Munzone, C. Casali, M. Del Bene, and F. Di Meco

64.1 Introduction and Epidemiology

Brain metastases (BMs) are the most common malignancy of the central nervous system (CNS), and their incidence has dramatically increased in recent years, mainly due to the improvements in systemic chemotherapy. This is particularly true for BM from breast cancer whose patients have, even with the best available treatments, a significant mortality and morbidity [1]. Approximately 10–15% of patients with breast primary tumors will develop BM during the course of disease [2], reaching 30% when considering autopsy series [3]. Brain relapse typically occurs within 2 to 3 years after the removal of the breast tumor [4]. The median survival after CNS metastasis in breast cancer patients is approximately 4 months, and the one-year survival rate is about 20% [5].

BMs are of particular interest because of the high mortality resulting from brain lesions and resistance to chemotherapies, mainly due to the inability of many conventional drugs to cross the blood–brain barrier (BBB). The lack of effective treatments for BM represents an important social health problem, and consensus on the therapeutic strategy, sequence of treatments, and combination therapies are still a matter of debate. Several studies have reported some factors associated with the development of BM such as young age, lymph nodal status, high tumor grade, and distant metastases. In addition, patients with metastatic triple-negative breast cancer (ER, PR, HER-2 unamplified) and HER-2-overexpressed subtype tend to develop brain metastasis at a higher rate [1, 6].

In recent years, besides the rise of new promising agents and combination therapies, a crucial role in the care of metastatic breast cancer is being played by the multidisciplinary approach in the development of efficacious treatment strategies, characterized by interaction and active cooperation among radiologists, surgeons, pathologists, radiation oncologists, and medical oncologists. Unfortunately, in routine clinical practice, metastatic breast cancer cases are discussed much less frequently than early breast cancer cases in multidisciplinary meetings. Therefore, the opportunity for a selected local treatment may be not always fully exploited [7].

The primary determinants of outcomes in breast cancer patients with BM are the tumor subtype and performance status of the patient [8, 9].

The most common symptoms experienced in patients with brain metastasis consisted of headache (35%), vomiting (26%), nausea (23%), hemiparesis,(22%), visual changes (13%), and seizures (12%). A majority of the patients had multiple metastases (54.2%). Cerebellum and frontal lobes were the most common sites of metastasis (33 and 16%, respectively).

A recent large retrospective study of 865 patients with BMs reported the median time interval from primary diagnosis to development of BMs, as well as median survival following the diagnosis of BMs, to be shortest in TNBC (27.5 months and 7.3 months, respectively) and HER-2-positive disease (35.8 months and 17.9 months, respectively) and relatively longer in patients with ER-positive/HER-2-negative (54.4 months and 10 months, respectively) and ER-positive/HER-2-positive disease (47.4 months and 22.9 months, respectively) [10]. Therefore, there is a great deal of interest in developing new therapeutic strategies for BMs, particularly in the TNBC and HER-2-positive breast cancer subtypes.

Clinician's arsenal against brain metastases from breast cancer involves supportive care, surgery, radiotherapy, radio-

surgery, and chemotherapy, usually unified in a multidisciplinary cooperative effort. The choice of a treatment or a combination of treatments is dependent on number of lesions, location, size, symptoms, and patient performance status. In this chapter principal treatment options are presented together with a review of the literature.

64.2 Medical Treatment

There are currently no approved systemic chemotherapy regimens for the management of BMs. Traditional systemic chemotherapies included cisplatin, temozolomide, etoposide, capecitabine, epothilone B analogues, and various combinations of these agents. Except in the case of the platinum agents, the reported CNS objective response rates (ORRs) were typically modest, and the duration of benefit was short (<4 months) [11]. Trials of the platinum agents, in which the response rate was higher, are limited in relevance by differences in the patient populations compared with those in the modern era. In particular, patients in those trials tended to be less heavily pretreated in either the adjuvant or metastatic setting. More recently, Anders and colleagues reported results of a phase II trial of irinotecan plus iniparib in pretreated patients with TNBC [12]. Iniparib is a drug initially developed as a poly(ADP-ribose) polymerase (PARP) inhibitor but subsequently shown not to have any PARP inhibitor activity [13]. Nevertheless, clinical activity was observed, with a CNS clinical benefit rate of 30%, albeit with a median overall time to progression of just over 2 months [12]. Given that irinotecan is known to have CNS activity in other tumor types (e.g., glioblastoma), it is reasonable to postulate that most, if not all, of the activity observed in the trial was attributable to this agent. Further analyses are underway to identify factors predictive of response.

64.3 Novel Therapies

Trial design is a major consideration in the evaluation of novel therapies for management of BMs from breast cancer. There has been significant progress in the establishment of standardized guidelines to assess CNS response, progression, neurocognitive function, and quality of life [14, 15]. However, most novel agents evaluated for treatment of BMs are being assessed in the setting of disease that is refractory to systemic therapy and most often in patients who have received local therapies such as radiation. The majority of studies of BMs include small patient cohorts and lack a control arm, as there are no systemic therapies approved for use in this setting. Development of new systemic therapies for breast cancer—coupled with improvements in trial design, in imaging modalities, and in the definition and measurement of clinical endpoints—has led to a renewed interest in developing novel therapeutic approaches for BMs. Despite the increasing number of trials of systemic therapies specific for BMs, however, local therapy options remain the current standard of care for these patients.

64.4 Current Local Care Approach

In general, the initial management of patients with brain metastases depends on (a) the number, size, and location of brain lesions; (b) the presence or absence of neurological symptoms; (c) the patient's performance status and medical comorbidities; (d) the status of systemic metastases; (e) the availability of systemic treatment options; and (f) the patient preference. Initial management will include some combination of surgical resection, radiosurgery, and/or WBRT, depending on the above factors. Systemic therapy could be a consideration either on a clinical trial, in the context of minimal CNS disease burden with rapidly progressive extracranial disease, or in select, well-informed patients as an alternative to localized therapies with close follow-up (i.e., a patient with small, asymptomatic CNS lesions). Among patients who have developed subsequent CNS progression after initial standard therapy, options include surgical resection, WBRT, stereotactic radiosurgery (SRS), off-label use of systemic therapy, consideration of a clinical trial, or best supportive care. Options will vary based on prior treatments received, response to prior treatments, location and number of the new or progressive CNS lesions, and the other patient- and disease-related factors as listed above.

64.5 Surgery

Surgical resection has the potential to immediately resolve focal deficits or intracranial hypertension and to obtain a histological diagnosis. Surgery is particularly indicated in case of large solitary mass (>3–4 cm), if important perilesional edema is present, in case of relevant mass effect/midline shift, and in symptomatic patients [16].

One of the first studies on the role of resection was a randomized trial, in which surgery plus whole-brain radiotherapy (WBRT) was compared to WBRT alone demonstrating an improvement of overall survival from 15 to 40 weeks in patients with a single metastasis [17]. A successive trial randomized patients with a single brain metastasis to surgery plus WBRT or to WBRT alone. The combination (surgery + WBRT) obtained a longer overall survival (12 vs 7 months) and longer functional independency (9 vs 4 months) in patients with controlled extracranial disease [18]. Notwithstanding, patients with progressive extracranial disease had the same prognosis regardless of the treatment, as

subsequently confirmed by another group [19]. In case of multiple metastases, surgery can be considered, in particular if there is a principal lesion determining edema or neurological deficits [20]. Two dated studies have demonstrated that surgical resection of multiple metastases is not able to improve patient survival if compared to WBRT alone [21, 22]. In a more recent publication by Bindal et al., resection of all metastases has proven to increase patient survival if compared to incomplete resection (14 vs 6 months) [23].

Another relevant indication to surgery is the need to obtain a histological diagnosis, for example, in those patients who have no known primitive or if the time from primitive breast cancer diagnosis is excessive.

In regard to surgical technique, several neurosurgeons defend the use of "en bloc" instead of piecemeal resection. Rationale of en bloc removal is to prevent malignant cells seeding, thus reducing the risk of leptomeningeal dissemination and of tumor recurrence [22, 24, 25]. Another technical aspect involves the margin of the tumor. It has been demonstrated that metastases determine some amount of infiltration, usually not exceeding 5 mm from the solid tumor [26, 27]. Taking into account these considerations, actual gold standard for surgery should obtain en bloc removal of solid mass together with 5 mm margins when possible. In this effort, surgery can be guided by images, preoperative acquired (neuro-navigation) or intraoperative (ultrasound, magnetic resonance, fluorescence), that help in the identification of solid mass and its margin, also permitting to assess the degree of removal.

64.5.1 Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) is a form of radiotherapy based on delivering high dose of radiation focally to the tumor, thus spearing the healthy brain parenchyma. The principal advantage of this approach is to avoid the neurocognitive decline consequence of whole-brain radiotherapy while delivering a higher intensity of photon radiation to the volume target [28–30]. RTOG 90-05, in a prospective study, has identified the proper SRS doses depending on lesion size. The dose varies from 15 to 18 and 24 Gy for lesions of 31–40, 21–30, and 20 mm or less, respectively [31]. Numerous studies have reported that SRS alone or in combination with WBRT can achieve a high rate of local control [28, 32–34]. In a recent trial from EORTC (22952), SRS has demonstrated a local control rate at 1 year of 69%, while surgery of 41%, and SRS combined with WBRT of 81%. [35]. Kondziolka demonstrated that SRS can improve local control in multiple brain metastases (two to four) from 6 months with WBRT to 36 months with the addition of SRS. However, the overall survival was unchanged, depending mainly on extracranial disease [28]. The RTOG corroborated the effectiveness of combining SRS and WBRT in patients with one to three metastases and demonstrated an improvement of 1.6 months in overall survival in patients with one unresectable lesion [36].

Another active area of research is the use of SRS after surgical resection, in order to enhance local control. Soltys et al. observed 1-year control rate of 94% adding 2 mm margin to the surgical bed and 78% if no margin is added [37].

Whether SRS can substitute surgery in metastases treatment is still uncertain in terms of level 1 evidence. In routine practice most of institution decides the treatment plan on the basis of tumor size, location, clinical presentation, and patient comorbidity. Metastases greater than 3–4 cm and localized superficially are almost invariably treated with surgery, while those of 1–2 cm deep seated are treated with SRS. In case of lesions susceptible of both treatments, patient's symptoms are determining. Asymptomatic lesions can be treated with SRS, otherwise surgery is preferred. In case of patient with augmented surgical risk because of specific comorbidities, SRS could be favored [38].

64.5.2 Whole-Brain Radiotherapy

Over the years the mainstay of treatment has been WBRT, especially in case of multiple metastases. The first description of WBRT is from Chao in 1954 [39]; henceforward radiotherapy has gained a pivotal role in the palliation of brain metastases. WBRT has two main aims: destruction of the microscopic seeding of the brain and the control of macroscopic metastases. Over the years, a number of publications have studied WBRT application, fractionation schemes, and its influence on patient outcome [38]. Actually the treatment consists in opposed lateral fields that shield the nasopharynx, oropharynx, throat, and anterior orbits with doses and fractionation schemes that vary from 20 Gy to 40 Gy, delivered over 1 to 4 weeks. The scheme with the highest rate of local control (up to 70%) is from the control arm of RTOG 9508 [36] and provides 37,5 Gy in 15 fractions.

The combination of WBRT and surgery has proven to improve local control, also reducing distance failures within the brain. Patchell et al., in his randomized study, demonstrated that the addition of WBRT, after complete resection, could decrease intracranial failure from 70% to 18% and local recurrence from 46% to 10%; however survival was not increased [40]. In view of this, WBRT is advisable as adjuvant therapy after surgery in order to reduce intracranial recurrences.

On the other hand, side effects of WBRT have to be considered. Typically they include hair loss, headache, erythema, serous otitis media, fatigue, and neurocognitive dysfunction. Whereas most of them have little relevance, neurocognitive symptoms could be gravely debilitating. In

order to mitigate this effect, two solutions have been studied. One consists in administrating memantine, an N-methyl-D-aspartate (NMDA) receptor agonist that has demonstrated to significantly prolong the time needed for cognitive decline [41]. The other solution implicates an intensity-modulated radiotherapy in order to avoid the hippocampus, thus preventing the neural stem cell injury [42].

64.6 Supportive Care

Principal endpoints are to reduce perilesional edema, decreasing intracranial pressure, thus stabilizing acute neurological deficits and control seizures.

Dexamethasone is generally preferred because of the marginal mineral-corticoid effect and prolonged half-life. Starting dose is 4–8 mg/day [43], and in the majority of cases, it leads to relevant neurological improvement in 24–72 h. On the other hand, side effects from protracted steroid administration are common and are causes of further disability. Cairncross and Posner have reported that dexamethasone if used as single therapy produces approximately 1 month of remission of symptoms and an increase of the median survival if compared to patient not treated at all [44].

Anticonvulsant therapy is obviously indicated in patients who have experienced seizures, but there is still no evidence supporting prophylaxis in patients harboring brain metastases. Selection of antiepileptic drug must take into account potential drug interactions with steroids and chemotherapeutic agents. Phenytoin, carbamazepine, oxcarbazepine, and phenobarbital induce the cytochrome P450 reducing the half-life of corticosteroids and some chemotherapeutic agents, thus decreasing their efficacy. Furthermore steroids and chemotherapy could lead to subtherapeutic levels of anticonvulsants because of enzymatic induction and inhibition.

64.7 Summary

The treatment of central nervous system involvement by metastatic breast cancer is often a cooperative effort between neurosurgeon, radiation oncologist, and oncologist.

Relying on the actual literature, this synergistic management should contemplate the following points:

In case of a single brain metastasis, surgery can increase survival, especially if extracranial disease is controlled and the patient is symptomatic. Adjuvant SRS or WBRT can decrease local recurrence. If the solitary metastasis is near an eloquent area, SRS or WBRT alone can be suggested.

In case of multiple metastases (1–4), SRS with or without WBRT could enhance local control. WBRT should be delayed as much as possible to retard neurocognitive symptoms. Surgery can be used for the larger lesions.

In all other cases, WBRT remains the only solution in order to palliate symptoms and to improve local control.

The challenge ahead is to move some of the promising therapies from early-phase trials into a randomized phase II or III setting, to advance the standard of care for patients with BCBMs. To decrease the heterogeneity of responses, specific consideration will need to be given to the specific breast cancer subtype and to the identification of novel predictive biomarkers of response.

New markers for predicting BM occurrence in the primary tumor setting are urgently needed for the early detection of high-risk patients and to effectively prevent the formation of BM in those patients. To what extent "liquid biopsies" (i.e., analysis of CTCs or circulating nucleic acids) may contribute to this goal remains under investigation [45].

Follow-Up of Patients with Breast Cancer

65

Lorenzo Gianni, Alessandra Affatato, and Davide Tassinari

Breast cancer (BC) is the most frequently diagnosed cancer and the leading cause of cancer death among females in the world. Thanks to the advances of screening, diagnosis and treatment, the number of BC survivors will continue to increase [1, 2]: according to GLOBOCAN worldwide estimates, 1.7 million new BC cases and 521,900 BC deaths were expected in 2012 [1], and this translated in a 5-year BC prevalence of 6.232.100 [3]. It is a huge population, with a significant number of older survivors and comorbidities, requiring prolonged clinical monitoring over time after primary treatment [4]. Therefore, for healthcare organizations, to provide facilities able to respond to this increased demand, focusing on multiple objectives, avoiding fragmentation and lack of coordination in care, is a major challenge.

65.1 Patterns of Relapse of BC

Risk of recurrence is function of time and clinical-biological factors. Familiarity about BC natural history and knowledge of diagnostic accuracy of available investigative tools are essential elements for proper management of BC follow-up. In a seminal paper, Saphner et al. [5] presented a retrospective joint analysis of seven adjuvant clinical trials conducted by the Eastern Cooperative Oncology Group from 1978 to 1988 including 3585 patients with a median follow-up of 8.1 years. In the whole population the hazard of recurrence peaked between years 1 and 2 after surgery, declined steadily until the interval between years 5 and 6, and afterward a slow reduction of the hazard occurred, but never reached zero even by year 12. Analysis according the estrogen receptor (ER) status showed that even if the hazard rate was higher for the ER-negative patients, the hazards for ER-negative and ER-positive patients crossed and were higher for the ER-positive group beyond 5 years. Indeed data from a study of International Breast Cancer Study Group with a very long follow-up confirm that patients with ER-positive BC maintain a significant recurrence rate even after more than 10 years of follow-up [6]. In a study comparing different temporal cohorts of patients, a similar pattern of disease relapse over time according to ER status persisted, even if the hazard rate of relapse improved significantly for both populations, possibly due to evolving adjuvant treatment [7]. Breast cancer is likely to metastasize to the local soft tissue, lymph nodes, bone, lungs, liver, and brain, but metastases can be observed in a variety of other organs, even unusual, and often in multiple sites at presentation. It has also been recognized that BC subtypes are associated with distinct patterns of metastatic spread and significant differences in survival after relapse. While the bone is the most common metastatic site in almost all subtypes, luminal/HER2 and HER2-enriched tumors are associated with a significantly higher rate of brain, liver, and lung metastases. Basal-like tumors have a higher rate of brain, lung, and distant nodal metastases, but a significantly lower rate of liver and bone metastases [8]. In case of late relapse, the bone and lung seem the most frequent sites of metastases, often detected after an unscheduled visit due to symptom emergence [9]. It's probably important to remember that infiltrating lobular carcinoma may exhibit a tendency to spread to unusual sites for BC, such as the gastrointestinal tract, genitourinary tract, peritoneum, retroperitoneum, and leptomeninges, making sometimes quite difficult differential diagnosis from primary cancers [10].

65.2 Surveillance After Primary Treatment

Even if there are no randomized data supporting intensive surveillance or any particular follow-up protocol, regular evaluation of patients with early BC after surgery and adjuvant treatment is recommended [11–14], according to patient needs and costs. The aims of follow-up are manifold [13, 15]:

- Early detection of cancer recurrence and early diagnosis of contralateral BC

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_65

- Recognition, prevention, and management of disease or treatment-related complication, with quality-of-life (QOL) improvement
- Monitoring and supporting hormonal treatment adherence
- Promotion of general healthy lifestyles and attention to survivorship issues, with psychological support and information for relief of anxiety and fear of disease recurrence
- Update of cancer family history

65.3 Screening for Locoregional Disease Recurrence

Definition of locoregional recurrence (LRR) is not always consistent and clear in BC studies, sometimes making it difficult to compare study outcomes. Just recently the Maastricht Delphi Consensus addressed this issue providing with a clear definition of all types of recurrence in BC [16].

About 5% of patients develops LRR within 5 years with a local failure rate of approximately 1–2.5%/year [17]. A systematic review on 5045 patients showed that about 58% of isolated LRR after primary treatment for early BC were diagnosed during routine visits or routine tests, while 41% were discovered outside scheduled controls [18]. Patients with isolated LRR have substantial worse prognosis [19], and efforts for an early detection should be maximized, as it influences survival, with an estimated absolute reduction in mortality of 17–28% [20]. Risk factors for LRR after breast-conserving therapy or mastectomy are young age, pathological tumor status or nodal status, boost radiotherapy, and surgical margins. These factors, combined in a simple prognostic index, could help to identify patients with low (<7.5%), intermediate (7.5–12.5%), or high (>12.5%) risk of LRR at 10 years [21]. Molecular subtyping of BC can give further information to identify patients at increased risk of LRR [22], even if target therapy with trastuzumab may reduce also the risk of LRR in HER-2-positive disease [23].

65.4 Screening of Recurrence After Breast Conservative Surgery

Current guidelines suggest annual surveillance mammography after breast conservative treatment, even if a more frequent evaluation, albeit in the first years of follow-up, is also reported. Mammography detection rate of ipsilateral breast tumor recurrence is about 50%, equally detected by the patient or on physical examination [17]. Surveillance mammography sensitivity ranges 64–67% and specificity 85–97% [24]. Recurrent tumors detected by surveillance mammography are often smaller and have better prognosis [20]. Unfortunately, depending on previous surgery and radiotherapy, physical examination and imaging interpretation may be more complex and misled by false-positive results. Even if magnetic resonance imaging (MRI) has the highest sensitivity (86–100%) and specificity (93%) for routine ipsilateral BC detection [24], current guidelines recommend it mainly for patient at high risk of contralateral BC or in case of originally mammographically occult primary BC [17]. When mammographic, and/or sonographic findings are inconclusive in differentiating scar tissue from tumor recurrence, MRI is very useful as absence of enhancement was associated to an 88% negative predictive value for cancer [25]. The role of postoperative breast ultrasounds (US) in BC patients remains unclear and it's advised regularly only by the ESMO guidelines [13]. Annual supplemental US screening in intermediate and high-risk women with mammographically dense breasts resulted in an additional 3.7 cancers detected per 1000 screened women [26].

Accelerated partial-breast irradiation such as intraoperative radiotherapy (IORT) is now an option, both as anticipated boost radiotherapy and as the sole treatment modality in selected patients. Radiologist should be aware of imaging alterations possibly related to these treatment modalities such as seroma, architectural distortion, and cytosteatonecrosis with calcifications [27, 28]. Fat necroses and scar calcifications appear to be more frequent and larger after IORT than following external radiotherapy [28]. Multiple, relatively scattered, round calcifications at the lumpectomy site were described early after IORT delivery in relation to small tungsten particles from shielding devices and granulomatous reaction [27].

Similarly fat necrosis and oil cyst occur in about 75% of patients undergoing autologous fat grafting for breast reconstruction and augmentation. At mammography they generally manifest as round lucencies, and the thin walls of these oil cysts can calcify over time; US appearance may vary, but generally shows avascularity and circumscribed margins; breast biopsy and MRI may confirm diagnosis [29].

65.5 Screening of Postmastectomy LRR

Local-regional recurrence after mastectomy is generally discovered during routine clinical examination or by the patient. In case of mastectomy without reconstruction surveillance, physical examination is easier and targeted US scan of any palpable area may help [17]. Imaging surveillance of the reconstructed breast is generally not recommended. Mammography is very limited in women that have undergone a mastectomy with implant reconstruction, because there is minimal tissue between the pectoralis major muscle and skin to image. Moreover local recurrences are generally superficial to the reconstruction and easily detectable on physical examination [30].

Patients with breast implant can benefit of US for it has high sensitivity and specificity particularly in case of extracapsular rupture [31]. However, MRI represents the gold standard to evaluate capsule integrity, silicone extrusion in soft tissue, and local disease recurrence. The Food and Drug Administration (FDA) recommends MRI imaging screening for "silent" implant rupture 3 years after implantation and every 2 years thereafter [32]. Finally an additional reason for monitoring women with breast implants is related to the infrequent development of a primary breast anaplastic large cell lymphoma (ALCL) in the scar capsule adjacent to the implant [33]. Advances in reconstruction techniques have led to an increased use of autologous breast reconstruction; as autologous tissue is placed over the pectoralis major, concern may arise that physical examination is less sensitive to reveal chest wall recurrence. In the absence of clinical randomized trials or indication from available guidelines, uncertainty for follow-up of these patients exists. Locoregional recurrences after autologous reconstruction have been reported in 3.8%, located in the skin flap in 50% and in the chest wall in 50% [34]. They generally present as a palpable mass, irregularity, skin changes, or pain, but data on surveillance imaging are extremely limited [30, 34]. In a recent retrospective study on 541 patients who had mastectomy and autologous reconstruction and a median follow-up of 7 years, LRR was reported in 27 patients (5%), after a median time of 2.6 years. Clinical exam was regularly performed and detected LRR in 24 of 27 patients (88.9%). Additional mammography screening of the reconstructed breast added minimal benefit, detecting two recurrences on 25 biopsies that also were palpable [35].

A last point is that surgical management of the axilla has undergone to major changes in recent years. Preoperative accurate evaluation of the axilla with US and fine-needle aspiration cytology is cost-effective and mandatory [36] with a negative predictive value for axillary metastases of 79% and overall accuracy of 84% [37]. On the other side it's more difficult to recommend US axillary follow-up for patients who have had a negative sentinel node biopsy: axillary recurrence rate from pooled analysis is only 0.3% (median time interval 20 months, range 4–63 months) [38], and it's unlikely that monitoring of such patients with repeated US examinations is cost-effective in the absence of palpable nodes.

65.6 Screening of Contralateral BC

Different histologies from the primary tumor and the coexistence of an in situ component may corroborate the diagnosis of contralateral breast cancer (CLBC), while new techniques may help to distinguish it from metastatic disease with important prognostic implication [39]. Women with a personal history of breast cancer have a 1.5-fold to twofold increased risk for developing a CLBC compared with the general population [40]. In a large study with long-term follow-up, the annual risk of CLBC remained constant at approximately 0.75% per year after treatment, and cumulative risk at 20 years was 15.4%, without difference between primary ductal in situ or infiltrating carcinoma. The median time to any CLBC was 8.2 years (range 0.5–26.5 years) with the majority being infiltrating disease (83%) [41].

The incidence of CLBC decreased by approximately 30% since the early 1980s [42], mainly for ER-positive CLBC due to increasing use of adjuvant endocrine therapy [43]. The effect on prognosis resulting from the occurrence of a metachronous CLBC is probably limited, even if young patients and those diagnosed within 2–5 years from primary breast cancer could be at higher risk [40, 42]. Risk factors for occurrence of CLBC are, among others, strong family history of BC, BRCA mutations, young age, ER-negative disease, lobular histology, race/and or ethnicity, previous chest radiotherapy especially in young age, ataxia telangiectasia gene mutation, lifestyle, and reproductive factors [44, 45]. In a recent systematic review, a cumulative 5-year risk of CLBC for BRCA1 and BRCA2 mutation carriers was 15% and 9%, respectively, and the 10-year risk increased up to 27% and 19%, respectively, a remarkably greater risk than non-BRCA carriers (3% and 5%, respectively, at 5 and 10 years) [46]. Despite the current trend of increasing prevalence of contralateral prophylactic mastectomy, outside the subset of patients bearing BRCA mutation, risk-reducing surgery seems to have limited effect on survival [47].

Current guidelines suggest monthly self-examination and yearly mammographic evaluation for screening of CLBC, while breast MRI is generally regarded as an option for patients at high risk of bilateral BC, particularly BRCA mutated [11–14]. Data from nonrandomized study suggest that mammography detects approximately 45–90% of CLBC, with evidence of a potential survival benefit for asymptomatic/early-detected diseases [48–50].

Surveillance mammography has shown to reduce mortality in older patients (>65 years), after diagnosis of early-stage disease [51]. Unfortunately younger women tend to have CLBC more frequently detected by physical examinations or by self-diagnosis than older patients [52]. A recent health technology assessment concludes that surveillance with mammography every 12–24 months is likely to improve survival, with the need for stratification of patients to ensure maximum benefit and optimal use of resources being considered [53]. Better imaging techniques and tailored strategy are probably required beyond current recommendations to detect new CLBC cancer, mostly in younger patients and according to risk factors. We have limited information on MRI surveillance of women previously treated for BC, all from retrospective studies [54, 55], and inappropriate use

may result in low yield [55]. Detection rate ranges 9–12%. Sensitivity is high (91–100%) with a moderate specificity (about 80%) and positive predictive value (PPV) of 28–55%. In patient with personal and familiar history of BC, detection rate was 15% with a positive predictive value (PPV) of 50%; cancer detected with MRI was more likely to be DCIS or minimal cancer [56]. Outside BRCA mutation carriers, selective posttreatment MRI surveillance may have a place in patients at higher risk of recurrence, strong familiar history, or with anticipation of difficult detection such as young women, dense breasts, and mammographically occult primary cancer [54].

65.7 Screening for Distant Disease

Even if prolonged and long-term survival is described after treatment for MBC, particularly in case of oligometastatic disease [57], MBC is generally an incurable disease, and hence the main treatment goals are palliating, maintaining/improving quality of life, and possibly prolonging survival.

Two large prospective Italian trials investigating the impact of more intensive vs. a symptom-based follow-up strategy were published in 1994 [58–60], and both failed to detect an improvement in overall survival and QoL despite a greater number of metastases detected and a small diagnostic anticipation. In an additional Finnish study with a smaller sample size [61], 472 patients were randomly assigned to four arm exploring both frequency of follow-up visits (every 3 vs. every 6 months) and different follow-up tests (routine diagnostic tests including blood count, calcium, sedimentation rate, liver enzymes, and CA 15-3 at every visit, chest X-ray every 6 months, liver ultrasound, and bone scan every 2 years vs. no routine testing). Neither the frequency of visits nor the intensity of diagnostic examinations had any effect on disease-free or overall survival of patients and doubled the costs per detected recurrence from 4166€ to 9149€. A 2005 Cochrane Collaboration-sponsored meta-analysis confirmed these results both in the whole population and in subgroup analysis according to patient age, tumor size, and nodal status [62].

These data, however, refer to an era of less sophisticated diagnostic procedures and less efficacious treatment for advanced disease, and new trials urgently need to reassess this question [13].

The aforementioned guidelines and the 2007 update of recommendations for the use of tumor markers in breast cancer [63] claimed against their use during BC follow-up. Even if increasing level of CEA, CA 15-3, and, to a minor extent, alkaline phosphatase may announce breast cancer recurrence before a clinical or radiological evidence of disease, their definitive significance remains unknown [63, 64]. Fluorodeoxyglucose positron emission tomography-computed tomography (PET-CT) has high sensitivity (81%–97%) and specificity (52%–100%) in the assessment of women with suspected BC recurrence [65]. In a recent study PET-CT was coupled to CEA, CA 15-3, and CA 125 in case of elevated tumor markers as an intensified aftercare algorithm. Metastases were detected in 65.9% of patients, 13.6% had secondary malignancies besides BC, and 20.5% had no detectable malignancy. Limited disease was found in 24.1% of patients [66]. Thus, while FDG-PET scanning appears to be useful in case of suspected BC recurrence, no data support its role in routine breast cancer surveillance in asymptomatic patients.

65.8 Follow-Up in Special Populations

Older age does not seem a good reason for skipping surveillance mammography after primary treatment of early BC. Indeed in a US study, any additional surveillance mammogram was associated with a 0.69-fold decrease in the odds of breast cancer mortality. The protective association was strongest among women with stage I disease, those who received mastectomy, and those in the oldest age group [51]. Identifying frailty or pre-frailty may have prognostic significance, and providers should be aware of this [67].

Breast cancer under 40 years accounts for approximately 7% of all BC diagnoses. Routine mammography follow-up does not guarantee early detection of local recurrence or CLBC in young women with BC [68]. These young women have a number of particular issues specifically related to fertility and future pregnancies, menopausal, and psychosocial problems [69].

As far as male BC is concerned, there is limited information about the benefit of the contralateral breast screening mammography, MRI, or US [70], due to the relative rarity of the disease. A subset of men at higher risk of CLBC that could possibly benefit from screening mammography are younger men (<50 years at diagnosis), with strong family history of BC, BRCA carriers, Jewish ancestry, Klinefelter's or testicular disease, local exposure to radiation, liver disease, and estrogen treatment [70, 71]. Clinical and self-examination should be adequate in most patients as male BC generally presents as a palpable nodule [17, 47].

65.9 Second Non-breast Cancer

An increased risk of new non-breast malignancies has been reported among breast cancer survivors. Analysis of SEER data [72] indicates a 17.6% cumulative incidence of any second primary after BC at 25 years (including a 6.9% incidence of CLBC) and higher risk for black and younger women. Salivary gland, esophagus, stomach, colon, uterine

corpus, ovary, thyroid, and soft tissue sarcomas; cutaneous melanoma and acute nonlymphocytic leukemia (ANLL) were cancer types whose hazard was significantly increased. An individual predisposition or possible carcinogenic effects of adjuvant treatments may be factors involved in this often late-onset event.

A recent meta-analysis confirms that adjuvant radiotherapy is associated to a small but significantly increased risk of second non-breast cancer. After 5 or more years, relative risk (RR) was 1.12 overall, 2.53 for sarcomas, 1.53 for esophageal cancer, and 1.39 for lung cancer, while no association was seen for thyroid carcinoma [73]. However, the benefit of adjuvant RT on local control and OS far outweighs the risk of getting a radiation-induced second cancer 10–15 years after treatment [74].

Clinical studies seem not to find an increased risk of CLBC after adjuvant RT in BRCA mutation carrier, even if concern remains, particularly in young patients [75].

Noteworthy is the postradiation breast angiosarcoma, a rare but very aggressive complication with a latency of several years after treatment and generally exhibiting c-myc amplification [76]. The tumor presents as a cutaneous red-blue-colored lesion, whose appearance on the irradiated breast may be confused with the benign skin changes of radiation [77].

Perhaps the most feared adverse effect after adjuvant treatment is the acute myeloid leukemia (AML) or myelodysplasia (MDS). Two types of AML have been described: the first one is generally observed after exposure to alkylating agents, a mean latency period of 5–7 years, and is frequently preceded by a MDS phase. Chromosome 13 deletions or complete or partial loss of chromosome 5 or 7 is reported. A second type of AML, related to exposure to anthracycline-topoisomerase inhibitors, generally shows no latency period or MDS phase and different chromosomal alterations. Risk of AML after adjuvant treatment ranges 0.2–1.7%, in different studies [78]. In a recent large study on 20,063 stages I–III BC, most of which had received four cycles of an anthracycline and cyclophosphamide as part of adjuvant chemotherapy regimen with a median follow-up of 5.1 years, a marrow neoplasm (MN) was diagnosed in 50 patients (0.25%). Compared to no adjuvant treatment, hazard ratio for MN was 2.6 for radiotherapy only, 6.8 after surgery plus chemotherapy, and 7.6 after surgery, chemotherapy, and radiation. Cumulative incidence of MN increased with time being 0.24% at 5 years and 0.48% at 10 years [79]. Patients exposed to tamoxifen (TAM) have an increased risk of endometrial proliferation, hyperplasia, polyp formation, invasive carcinoma, and uterine sarcoma. The increased risk of endometrial cancer is limited to postmenopausal women. No risk increase or possibly a decreased risk has been observed with aromatase inhibitors (AI), and switching to an AI reduces TAM risk [80]. In the Early Breast Cancer Trialists' Collaborative Group meta-analysis of AIs vs. TAM [81], the 10-year risk was 0.4% in the AIs vs. 1.2% in the TAM group (absolute difference 0.8%, 95% CI 0.6–1.0; $p < 0.0001$). Continuing TAM after 5 years further increases risk: in the ATLAS trial, the cumulative risk of endometrial cancer during years 5–14 was 3.1% (mortality 0.4%) for women allocated to continue TAM vs. 1.6% (mortality 0.2%) for controls [82].

Even if uterine endometrial cancers after TAM treatment are often considered to be tumors with a good prognosis, data from a Dutch study shows that TAM-associated tumors may have less favorable histological features and a poorer survival, with a worsening prognosis in long-term users [83].

Premenopausal women have no known increased risk of uterine cancer and require no additional monitoring beyond routine gynecologic care. Postmenopausal women should be closely monitored for symptoms of endometrial hyperplasia or cancer, but routine transvaginal ultrasonography, endometrial biopsy, or both are not indicated in asymptomatic women. Pretreatment evaluation may identify patients at higher risk: the risk of incidence of atypical hyperplasia was 11.7% in the group with initial benign polyps vs. 0.7% in the group without lesions ($P < 0.0001$) [84].

65.10 Organizational Health Issues

A Canadian randomized clinical study was reassuring in showing similar outcome for patients allocated to receive, approximately 1 year after diagnosis, routine specialist follow-up in the clinic or from their own primary care physician (GP). Recurrence, deaths, recurrence-related serious clinical events, and health-related quality of life were similar in the two groups. However, only 58% of the screened patients accepted to participate in the study, and median follow-up was of only 3.5 years from randomization (4.5 years from diagnosis) [85]. In a cross-sectional study conducted on 145 patients, 73% of women were extremely satisfied of the follow-up provided by their GP [86], and in general GP showed willingness to assume exclusive responsibility for routine follow-up of patients [87].

65.11 Guidelines and Recommendations

Table 65.1 summarizes recommendation from some of the more recently updated follow-up guidelines. In general, guidelines are consistent in recommending to avoid surveillance radiographs, blood tests, and radionuclide scans in the asymptomatic patient and to prefer a symptom-directed assessment.

Table 65.1 Guidelines and recommendations for surveillance after primary treatment of breast cancer

Items	ASCO (2012 update) [11]	NCCN version 1.2016 [12]	ESMO 2015 [13]	AIOM 2015 [14]
Interval history and physical exam	Every 3–6 months for the first 3 years, every 6–12 months for 2 years, and annually thereafter	1–4 times per year as clinically appropriate for 5 years and then every 12 months	Every 3–4 months for 2 years, every 6 months from years 3–5, and annually thereafter	Every 3–6 months for the first 3 years. Every 6–12 months for years 4 and 5; annually thereafter
Mammography	Every 12 months (first posttreatment mammogram no earlier than 6 months after RT)	Every 12 months (wait 6–12 months after RT) Routine imaging of reconstructed breast not indicated	Annual mammography plus US recommended	Annual mammography (first 1 year after diagnosis or at least 6 months after RT)
Breast MRI	Not recommended for routine surveillance	Option in patients at high risk of bilateral BC (e.g., carriers of BRCA1/BRC2 mutations)	May be indicated for young patients, especially with dense breast tissue and genetic or familial predispositions	Not recommended except for BRCA mutation carriers
Laboratory and imaging tests	Not recommended	Not indicated. For women on AIs and treatment-related amenorrhea, estradiol and gonadotropin monitoring	Not recommended. Ultrasound can be considered in lobular invasive carcinomas	Not recommended in the absence of clinical indications
Breast self-examination	Monthly breast self-examination recommended			Monthly self-examination "could be performed"
Pelvic examination	Regular gynecologic follow-up recommended for all women; patients on tamoxifen should be advised to report any vaginal bleeding to their physicians	Annual gynecologic assessment for women on tamoxifen if uterus is present (routine US or biopsy not recommended)	Annual gynecological examination, possibly with a gynecological ultrasound, recommended for patients on tamoxifen	Regular gynecologic evaluation, including pelvic ultrasound and PAP smear, advisable
Bone health assessment		Bone mineral density at the baseline and periodically thereafter in women on an AI or with ovarian failure secondary to treatment	Regular bone density evaluation is recommended for patients on AIs	Periodic bone mineral density examination should be considered for patients on AIs
Blood cholesterol and triglyceride monitoring			Indicated for patients on ET	Periodic monitoring in case of treatment with AIs
Follow-up duration				No clear indication for interruption of yearly mammography. Referral to PCP at the end of follow-up in the specialist clinic
Coordination of care	By a physician experienced in the surveillance of patients with cancer and in breast examination. Possibility of transfer of care to a PCP 1 year after diagnosis in patients with early-stage BC. Continuity of care should be ensured			

Table 65.1 (continued)

Items	ASCO (2012 update) [11]	NCCN version 1.2016 [12]	ESMO 2015 [13]	AIOM 2015 [14]
Patient education	Counseling about the symptoms of recurrence	Educate, monitor, and refer for lymphedema management. Assess and encourage adherence to ET. Active lifestyle, healthy diet, limited alcohol intake, maintaining an ideal body weight Breastfeeding not contraindicated in case of pregnancy	Regular exercise and nutritional counseling for obese patients recommended Hormone replacement discouraged	
Symptom management and concomitant drugs		Warning about concomitant use of TAM and certain SSRIs. Use of hormones for birth control or osteoporosis discouraged (bisphosphonates or denosumab preferred)	Patients should have unlimited access to specialized rehabilitation facilities and services, to decrease the physical, psychological, and social "sequela" of breast cancer treatment	
Genetic counseling	Women at high risk for familial breast cancer syndromes should be referred for genetic counseling	Periodic screening for changes in family history		

MRI magnetic resonance imaging, *US* ultrasonography, *RT* radiotherapy, *AI* aromatase inhibitor, *ET* endocrine therapy, *PCP* primary care physician, *SSRIs* serotonin reuptake inhibitors

Compliance of physician with current guidelines has not been precisely evaluated, although some reports indicate a variable grade of discrepancy [88–94]. As pointed out by the recent 2015 ESMO guidelines, most available data for follow-up recommendations come from an era of less sophisticated diagnostic procedures and less effective treatments for advanced disease [13]. Different authors have evaluated the issue of follow-up personalization according to locoregional risk of recurrence [95, 96] or contralateral cancer [97], and a feasibility study showed that implementation of a tailored follow-up program according to risk of recurrence may permit to decrease the number of visits for low-risk patients [98]. Moreover current guidelines do not take into account that BC is a heterogeneous disease and that different molecular subtypes behave differently, and this could challenge also the "one-size-fits-all" follow-up strategy. New trials are urgently needed to reassess this question [99, 100], but we are aware of only one ongoing study from Japan exploring if intensive postoperative surveillance could be worthy in high-risk EBC [101].

Meanwhile the scenario could be quickly modified by advance in imaging [102] and laboratory diagnostic monitoring for minimal residual disease [103, 104].

Part X

Investigating New Drugs and Immunological Agents in Breast Cancer

Targeting Immune Checkpoint

66

Angela Esposito and Giuseppe Curigliano

66.1 Introduction

Tumor cell transformation prompts to activation of adaptive and innate immune responses, which had a crucial role in eliminating and controlling early cancer growth. Over the past 10 years, there has been a greater understanding of the immune response to tumors which has led to the development of a huge number of immunotherapeutic strategies [1, 2]. The immune system plays a dual role in cancer: it not only can suppress tumor growth by destroying cancer cells or inhibiting their outgrowth but also promotes tumor progression either by selecting for tumor cells that are more fit to survive in an immunocompetent host or by establishing conditions within the tumor microenvironment that facilitate tumor outgrowth. The conceptual framework called "cancer immunoediting" integrates the immune system's dual host-protective and tumor-promoting roles. Nonetheless, numerous studies have shown that tumors can be recognized and contained for extended periods of time by the immune response through the concerted action of the innate and adaptive immune responses [3]. Agents such as the immune checkpoint inhibitors have demonstrated to induce a response in a number of solid malignancies [4], but their therapeutic benefit has not been seen in all cancer types. The initial enthusiasm for immune checkpoint inhibitors is mainly based on results obtained in melanoma, lung cancer, bladder cancer, and renal cell carcinoma [5]. But also in breast cancer (BC), preliminary data from the first clinical studies is encouraging.

66.2 Role of Immunotherapy in Breast Cancer Treatment

Evading immune destruction should be considered an emerging hallmark of cancer. The knowledge of the underlying principles of tumor biology and immunology, enhanced by recent insights into the mechanisms of immune recognition, regulation, and tumor escape, has provided new approaches for cancer immunotherapy [6]. Highly immunogenic cancer cells can be eliminated in immunocompetent hosts as a result of the "immunoediting" process. Weakly immunogenic variants can grow and generate solid tumors [7]. A variety of tumor-infiltrating cells, including regulatory T cells (Tregs), myeloid-derived suppressor cells (MDSC), and activated (type 2) macrophages (M2), are involved in the modulation of immune responses in cancer patients [8]. For example, an increased number of Tregs was found in blood and in the tumor microenvironment of patients affected by different tumors: it was demonstrated that Tregs suppress T-cell response and natural killer (NK) cell proliferation and function, thus interfering both with acquired and innate immunity [9]. In BC, recent evidence has demonstrated that immune-related factors play an important role in defining patient prognosis and their response to treatment. These include the extent of lymphocyte infiltration in tumor tissue [10] and a class of gene expression signatures [11], both of which have the potential to more precisely define patients' clinical evolution and identify patient subgroups with different sensitivities to standard treatments.

BC has not been traditionally considered immunogenic, as it does not occur at a higher incidence in the immunosuppressed populations who have been treated with immunosuppressive therapies [12]. However, it seems that, despite a weak influence on primary tumor growth, the immune system is effective in preventing BC metastases [13, 14]. The heterogeneous expression of tumor antigens within the primary tumor or its metastases, the modification of antigenic

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_66

profile during the tumor progression, and the low levels of the antigen, major histocompatibility complex proteins, and other costimulatory proteins necessary to generate a strong immune response can explain this low immunogenicity. Moreover, the tumor microenvironment releases immunosuppressive factors that make the antigen presentation difficult and that have a negative impact on the immune response [15]. The interaction of the immune system with tumor cells in breast cancer seems to be breast cancer subtype specific. Triple-negative BC (TNBC) and HER2-positive BC harbor higher genomic instability compared to luminal A and B subtypes, leading to increased DNA damage or mutational load [16, 17]. Recent data shows that a higher mutational load elicits production of higher tumor-specific antigen levels and can produce stronger immune responses [18, 19]. When the immune system fails to eliminate all cancer cells, the less immunogenic cells survive and tumors can evade the immune system [20]. T-cell-inhibiting immune checkpoints have an important role in this escape. The binding of programmed death protein 1 (PD-1) and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) on T cells with programmed death ligand 1 (PD-L1) and CD80, respectively, on tumor cells can strongly decrease T-cell activity. In addition aberrant expression of major histocompatibility complex II (MHC II) has been correlated to weak tumor immunity [21]. This demonstrates the tumor MHC II antigen presentation pathway is a crucial component of tumor immunity. The TNBC and HER2-positive BC subtype produce stronger immune responses and are hypothesized to be more dependent on these resistance mechanisms [19].

66.3 Immune Checkpoint Blockade

In recent years, the better knowledge of BC biology has provided an opportunity to develop some types of immunotherapy to overcome the relative non-immunogenic property of BC and improve immune response. Some molecules such as PD-1 and its ligand PDL-1, CTLA-4, and immune cells such as regulatory T (Treg) cells are involved in the induction of tolerance to antigens, and their upregulation is associated with increased risk of developing BC [22]. Recently, agents which stimulate T-cell function, by blocking immune checkpoints, have an emerging clinical interest. Checkpoint receptors, including CTLA-4 and PD-1, are upregulated on activated T cells and transmit inhibitory signals, which suppress T-cell proliferation and function [23]. CTLA-4 is a member of the CD28:B7 immunoglobulin superfamily, and it is normally expressed at low levels on the surface of naive effector T cells and Tregs [24]. After stimulation of a naive T cells, CTLA-4 is upregulated and competes with CD28 for B7 and, finally, leads to suppression of T-cell activity. Anti-CTLA-4 mAb facilitates T-cell proliferation and activation and abrogates the suppressive function of Tregs [25]. In addition to CTLA-4, PD-1 is a key immune checkpoint protein expressed on chronically stimulated T cells, which leads to the suppression of T-cell activity through interaction with its ligands, PD-L1 and PD-L2 [26]. Antibodies targeting PD-L1 or PD-1 have been shown to promote cytotoxic T-lymphocyte expansion [27] and tumor regression in many mouse tumor models [28–30]. Only two studies with CTLA-4 blocking agents in breast cancer patients have been performed. An exploratory study in 18 patients with predominantly hormonal receptor-positive early-stage breast cancer demonstrated a lowly increased ratio of CD8+ to Treg cells in tumor sample of patients who underwent mastectomy after pretreatment with ipilimumab and cryotherapy, while pretreatment with cryotherapy or ipilimumab alone did not increase this ratio. Cryotherapy causes a release of tumor antigen. It was therefore supposed that ipilimumab might augment the response against these antigens [31]. In another phase I study, the combination of tremelimumab and exemestane was explored in 26 postmenopausal metastatic breast cancer patients. Treatment was well tolerated. The best overall response rate (ORR) was stable disease for 12 weeks or more in 11 of 26 patients (42%). Treatment was associated with increased levels of peripheral CD4+ and CD8+ T cells that expressed the protein inducible costimulator (ICOS) of T-cell activation, a potential biomarker of immune activation resulting from blockade of CTLA-4 [32]. Two agents targeting the PD-1 and PD-L1 have been studied in breast cancer. Pembrolizumab (also known as MK-3475 and lambrolizumab) is a humanized monoclonal IgG4-kappa antibody that blocks PD-1 signaling [33]. In a phase Ib study, pembrolizumab was evaluated in 32 patients with PD-L1-positive metastatic TNBC. The overall response rate for 27 evaluable patients was 18.5% and the 6-month PFS rate was 23.3% [34]. 17.2% of the patients had at least one serious adverse event, and one patient died due to disseminated intravascular coagulation. MPDL3280A, a human IgG1 anti-PD-L1 monoclonal antibody with an engineered Fc receptor, preventing it from causing ADCC, has been evaluated in a phase I study in 27 pretreated patients with PD-L1-positive metastatic TNBC [35]. Among 21 efficacy-evaluable patients with a PD-L1 IHC 2 or 3 score (13 IHC 2 and 8 IHC 3), the unconfirmed RECIST response rate was 24% (95% CI, 8% to 47%). Response duration ranged from 0.1+ to 41.6+weeks. A phase III study in 350 metastatic breast cancer patients researching combination treatment with MPDL3280A and nab-paclitaxel is currently recruiting patients (NCT02425891). Anti-PD-1/PD-L1 agents are more effective in tumor types with higher mutational load, such as NSCLC and melanoma [36]. TNBC express high genomic instability due to double-strand DNA-repair deficiencies [16]. This subtype also has highest levels of PD-L1 in all breast cancer types [37]. The presence of pro-

grammed death 1 (PD-1)-positive tumor-infiltrating lymphocytes is associated with poor prognosis in human breast cancer [38]. According to present thinking, this might increase effectiveness of checkpoint inhibitors in this subtype.

66.4 The Combination of Immunotherapy with Radiotherapy

Greater understanding of radiation therapy's effect on tumor cells and components of the tumor microenvironment has in turn evidenced the central role of the immune system, as highlighted by Lee et al., who described that in a mouse model, radiotherapy (RT) needs the presence of CD8+ T cells for post-RT tumor control [39]. The interaction of host immune system and proper antitumor activity can lead to immune-mediated rejection of non-irradiated metastatic lesions after irradiation of the primary lesion in a process known as the abscopal effect. The abscopal effect of radiation therapy is an event by which a primary tumor is irradiated and a response is observed at distant metastatic sites externally of the field of the radiation [40]. Preclinical evidence supported the hypothesis that the abscopal effect is mediated by the immune system [41], but the effect of radiation appears to be relatively weak and is rarely seen in clinical practice. Recently, there have been an increasing number of case reports showing the appearance of abscopal effects when radiotherapy is concomitantly administered with immune checkpoint inhibitors [42, 43], underlining that the radiotherapy treatment can lead to an immune response which is augmented by the immune-modulating agents [44]. The critical role of radiation is to induce the release of tumor immunogenic antigens responsible of the augmented pool of intracellular peptides for cross presentation; in this way the radiation creates an "in situ vaccination" [45]. During combinatorial treatment between RT and immunotherapy, the tumor-specific immune response is elicited and intensified subsequently. Preclinical models showed that radiation can augment tumor-specific antigen–MHC complexes, upregulate antigen cross presentation in the draining lymph node, and increase T-cell infiltration into tumors [46]. Of particular interest is the combination of anti-PD-1 antibodies with radiotherapy. Supporting data of the efficacy of this combination has been demonstrated in a murine model of breast and colorectal carcinomas, where augmented tumor control was showed [43]. Actually, many early-phase clinical trials combining immune checkpoint inhibitors with radiotherapy are ongoing. A number of these studies are examining the combination of stereotactic radiotherapy with PD-1 or PD-L1 inhibitors in patients with oligometastatic disease [47, 48]. The optimal timing of administration, the duration, the sequence of the immune-modulating agents with RT, and the appropriate patient populations are still not elucidated.

66.5 Immune-Related Toxicity of Immune Checkpoint Inhibitors

Toxicity is a major issue for the new cancer immunotherapy. Ipilimumab and other immunomodulatory drugs have been associated with several immune-related adverse events (irAEs), most of them related to the infiltration of highly activated CD4 and CD8 T cells and the increased production of inflammatory cytokines in normal tissues [49]. The most common irAEs related to the use of anti-CTLA-4 antibody involve the gastrointestinal tract, skin, liver, and endocrine system [50]. These effects are reported in up to 60% of patients treated with ipilimumab, with severe toxicities (grades 3 or 4) in about 10%–15% of patients [51]. They can appear at various times after anti-CTLA-4 treatment. The average timelines for irAEs are 2–3 weeks for dermatologic events, 6–7 weeks for gastrointestinal and hepatic events, and 9 weeks for endocrine events [52]. The presentation of irAEs can vary from insidious to sudden and can be confused with other known autoimmune conditions. Usually, irAEs were reversible, but in rare cases, they may be severe and life-threatening. The most common dermatologic toxicities include maculopapular, erythematous rash, or pruritus. Vitiligo can also be seen and is considered a positive prognostic factor in patients with melanoma, as it signals an immune attack on melanocytes. Frequently, irAEs involved gastrointestinal tract. Grade 3/4 diarrhea/colitis was the most frequently observed serious adverse event in clinical trials. Compared to anti-CTLA-4, agents targeting the PD-1/PD-L1 pathway seem to be better tolerated, with a more favorable toxicity profile, emphasizing the distinct biologic features of the two pathways. One reason that could explain the reduced toxicity could be that the PD1/PD-L1 checkpoint interaction takes place peripherally, i.e., at the tumor site, whereas the CTLA4/B7 interaction occurs mostly centrally, i.e., in the lymphoid organs [53]. Most of the toxicity associated with anti-PD-1/PD-L1 was immune related, as well as with anti-CTLA-4 therapy [54]. The most frequent adverse events recorded, regardless of causality, were fatigue, decreased appetite, diarrhea, nausea, dyspnea, constipation, vomiting, rash, pyrexia, and headache [54]. The grade 3/4 adverse event rate was 14% in patients receiving nivolumab. Interestingly, one unique and potentially life-threatening toxicity for these agents is pneumonitis, which occurred in 3% of patients, but only 1%–3% developed a grade 3 or 4 pneumonitis [54, 55]. No clear relationship was reported between the incidence of this side effect and tumor type, the dose level, or the number of doses received. In the majority of cases, it was reversible with treatment discontinuation and/or glucocorticoid administration, but three patients died despite the use of infliximab and mycophenolate [54]. Mild infusion reactions were observed in patients receiving

anti-PD-L1 treatment, whereas severe adverse effects were infrequently noted [56]. Indeed, irAEs were observed in 39% of patients and included rash, hypothyroidism, hepatitis and, less frequently, sarcoidosis, diabetes mellitus, and myasthenia gravis. These adverse events were predominantly of grade 1 or 2 and were managed with treatment interruption or discontinuation. The grade 3/4 adverse event rate was 9% in patients receiving BMS-936559 [57] and was managed with glucocorticoids.

66.6 Future Perspectives

At present, knowledge about the interaction between carcinogenesis, immunity, and tumor biology is rapidly expanding. The first clinical data from new immune-mediated therapies in breast cancer are mainly promising for TNBC and HER2-positive breast cancer, possibly due to higher immunogenicity of these subtypes [16]. Biomarkers to select patients who will benefit from immunotherapy are needed, as shown by the large differences in immunogenicity between breast cancer subtypes. This is underlined by the prognostic value of TILs and PD-1 and PD-L1 in selected subgroups only. The highly dynamic nature of PD-L1 complicates the validation of this target as a relevant marker. Multiple clinical trials are now underway to evaluate breast cancer immunotherapy, including vaccines, adjuvants, and checkpoint blockade, alone or as multimodality therapy. The synergy of RT and immunotherapy represents a rising strategy with the potential to better target local irradiated/viable tumor cells and to give higher control of distant systemic disease. The future is bright, as the most effective immunotherapies may not only affect objective tumor responses acutely but also establish durable responses that promote the long-term control, and ultimately the cure, of breast cancer.

Targeting PI3K/AKT/mTOR Pathway

67

Carmen Criscitiello and Giuseppe Curigliano

67.1 Introduction

Breast cancer is the principal cause of new cancer diagnosis and the second principal cause of cancer death in women in Europe and the United States [1, 2]. Our understanding of the biology of breast cancer has increased dramatically in the recent past, and progresses in molecular biology have uncovered a vast number of genomic aberrations. It is becoming more and more evident that a lot of these aberrations converge on a few key pathways involved in cancer cell signal transduction, including the phosphatidylinositol 3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) cascade [3]. This pathway plays an important role in normal cellular physiology; the carcinogenic process involves and uses this same pathway to communicate constitutively active survival signals to the nucleus. Here we discuss why the PI3K/AKT/mTOR signaling pathway is potentially highly relevant to all three major subtypes of breast cancer (i.e., estrogen receptor (ER) positive/human epidermal growth factor receptor 2 (HER2) negative, HER2 positive, and ER negative/HER2 negative) and the rationale for inhibition of this pathway in breast cancer.

67.2 Biology of the PI3K/AKT/mTOR Pathway in Breast Cancer

Initially, it was determined that the transforming gene product of the Rous sarcoma virus phosphorylates phosphatidylinositol using PI3K as a catalyst [4]. Then, it was observed that the PI3K enzyme was a heterodimer consisting of a catalytic domain (p110) and a regulatory domain (p85). The PI3K pathway is crucial in controlling the normal physiological environment within the cell, and knockout of either α or β subunit of p110 leads to embryonic lethality in mice [5, 6]. Also, the PI3K pathway plays a paramount role in metabolism, growth, and survival of cancer cells in a number of human cancers, including breast cancer [7].

PI3K pathway signaling may be activated by G protein-coupled receptors (GPCRs) and via cell surface receptor tyrosine kinases (RTK) like epidermal growth factor receptor (EGFR, also called human epidermal growth factor receptor 1 or HER1), HER2, insulin-like growth factor 1 receptor (IGF-1R), and fibroblast growth factor receptor (FGFR) [3]. PI3K phosphorylates phosphatidylinositol diphosphate (PIP2) to form phosphatidylinositol triphosphate (PIP3) which eases the activation of the oncogene AKT. The tumor suppressor gene phosphatase and tensin homolog (PTEN) acts as the main negative regulator of the PI3K pathway by dephosphorylating PIP3 to PIP2. Inositol polyphosphate 4-phosphatase type II (INPP4B) is a newly described lipid phosphatase that switches PIP2 to phosphatidylinositol monophosphate (PIP) and could be a potential tumor suppressor, as well as a regulator of AKT activity [8, 9]. AKT is a serine-/threonine-specific protein kinase which phosphorylates effectors within cell survival, proliferation, and metabolic pathways [10]. Inhibition of tuberous sclerosis complex 2 (TSC2) by AKT stimulates the mammalian target of rapamycin (mTOR) leading to increased protein synthesis via its effector's eukaryotic translation initiation factor eIF4E-binding protein 1 (4EBP1) and p70S6 kinase (S6 K). Hence, AKT is a nodal point linking cell growth, apoptosis, and cellular metabolism. mTOR is an evolutionarily conserved serine/threonine kinase made of two distinct protein complexes, mTORC1 and mTORC2. Both complexes may be necessarily inhibited for optimally controlling cancer growth [11]. mTOR inhibitors like rapamycin and its analogs preferentially inhibit mTORC1. mTORC1 exerts negative feedback on the PI3K pathway (via S6K1 and IRS-1), and thus a selective blockade of mTORC1 alone may in fact improve cell growth by reflex activation of AKT mediated by mTORC2 [12]. Conversely, selective mTORC1 blockade using allosteric inhibitors is extremely efficient in cancer cell lines with PIK3CA mutations [13–15]. In addition, the BOLERO-2 study showed remarkable benefit of the mTORC1 inhibitor

everolimus in combination with exemestane in postmenopausal hormone-receptor-positive advanced breast cancer patients who were resistant to anastrozole or letrozole [16]. Also, the PI3K pathway is important for normal glucose homeostasis, protein synthesis, and metabolism. Insulin and IGF-1 signaling through the PI3K pathway is a key mechanism for metabolism control, and the high incidence of its deregulation in breast and other cancers highlights the link between metabolism regulation and the oncogenic process [17]. PIK3CA mutations have been shown to activate the PI3K pathway and to be transforming in preclinical models [18, 19]. In humans, mutations of the PIK3CA gene are seen in about 25% of patients with breast cancer and are predominantly associated with the ER-positive and HER2-positive subtypes [20–23]. The PI3K pathway is often dysregulated in breast cancer [24]. PI3K pathway may become hyperactivated in breast cancer as a result of overexpression of upstream activators like HER2 or IGF-1, PTEN loss (which appears to predominate in triple-negative breast cancer [TNBC]), and gain-of-function mutations of the PIK3CA gene that codes for PI3K catalytic subunit (mostly seen in luminal and HER2-positive breast cancer) [25]. A report from the Cancer Genome Atlas Network involving 825 patients showed that there is substantial difference in the frequency of molecular alterations in the PI3K/AKT/mTOR pathway among the different clinical subtypes of cancer [23]. Another publication reported that PIK3CA point mutations were found in 27 of 79 ER-positive and 3 of 21 ER-negative BC tumor samples analyzed [26]. Loss of PTEN is a common means of activating PI3K signaling in human cancers [27]. However, PTEN mutation is only seen in about 3% of breast cancer cases, thus suggesting other mechanisms of regulation at the epigenetic, transcriptional, and posttranscriptional level, limiting the utility of simple protein or gene-expression-based assays to determine PTEN status [3, 26, 28–30]. Techniques for detection of PTEN loss are still evolving and not yet standardized. Epithelial cells have been demonstrated to be sensitive to decrease in PTEN abundance; in addition, microRNAs produced by the PTEN tumor suppressor gene and its pseudogene (called PTENP1) could play an important role in carcinogenesis [31]. PTEN-deficient tumors could be preferentially reliant on the p110β isoforms of PI3K [32]. Notably, some recent reports have failed to demonstrate a correlation between expression of PTEN and clinical outcome, both in early and advanced breast cancer [33, 34]. In a phase II study (n = 31 patients with pretreated breast cancer) using single-agent temsirolimus 25 mg weekly, the authors found no correlation between clinical benefit and PTEN loss or PIK3CA mutations [35]. Genetic alterations and constitutive activation of the PI3K pathway are likely to contribute to the pathogenesis of all three major breast cancer subtypes [28]. The classic example is that of HER2-positive breast cancer, where overexpression of the HER2 protein has long been associated with a poor prognosis [36]. HER2-amplified cell lines display profound sensitivity to PI3K, AKT, and/or mTORC1/mTORC2 inhibition, suggesting that HER2-overexpressing breast cancers are more dependent on dysfunctional PI3K/AKT/mTOR signaling [13, 15, 37–39]. While the prognostic influence of PIK3CA mutations is unclear in humans (particularly in ER-positive disease), increased sensitivity to tamoxifen in PIK3CA mutant versus wild-type cell lines has been observed [21, 40]. The biological mechanism for this is presently unidentified, and differences probably exist for the site-specific mutations. The increased sensitivity of the ER-positive/PI3K-mutant genotype to inhibitors of PI3K and mTOR in cell lines is interesting and raises the possibility that this group may represent an ideal population for clinical evaluation of these agents [41]. Reverse phase protein arrays (RPPA) studies are emerging as a useful tool for the functional analysis of kinases and steroid proteins. One study found that an 82-protein functional proteomic "fingerprint" was technically reproducible and able to classify 128 non-microdissected breast cancer surgical specimens into six prognostic subgroups that demonstrated a significant correlation with breast cancer subtypes identified by transcriptional profiling [42]. Creighton et al. used RPPA-based proteomic studies to show that the luminal B subtype of human breast cancer had hyperactivated PI3K signaling associated with lower ER levels. They were able to increase the ER level in cell lines by PI3K blockade and concluded that dual targeting of the PI3K and ER signaling pathways may be useful in a subset of patients with aggressive ER-positive breast cancers [43]. The potential use of PI3K/AKT/mTOR blockade in luminal cancers was reviewed recently [44]. The frequency of PIK3CA mutations in TNBC is quite low, but these tumors frequently display a loss of expression of PTEN (ranging from 35% to 50%) [23, 45–48]. Preclinical data suggest a strong contribution from the PI3K signaling pathways to TNBC tumor biology. Given the strong scientific rationale for PI3K pathway inhibition in breast cancer, results from clinical trials evaluating these agents are eagerly awaited by the breast cancer community.

67.3 PI3K/AKT/mTOR Pathway Inhibitors in Clinical Development

Traditionally, the earliest compounds used to block the PI3K pathway were mTOR inhibitors. The prototype mTOR inhibitor is rapamycin (also called sirolimus), a macrolide antibiotic first discovered in a soil sample from Rapa Nui (Easter Island). Rapamycin is an allosteric inhibitor of mTORC1 that has little effect on mTORC2 and seems to merely partially inhibit 4EBP1 [49]. Other analogs ("rapalogs") of rapamycin have been developed, including temsirolimus (CCI-779), everolimus (RAD001), and ridaforolimus (MK-8669/AP23573), which function via a kinase-independent mechanism. In breast cancer, single-agent temsirolimus showed promising preclinical activity [50]; however, its clinical

benefit has been modest [51, 52]. Wolff and colleagues reported results from a phase III trial in which 1112 patients with aromatase inhibitor-naive, hormone-receptor-positive advanced disease received letrozole plus oral temsirolimus/placebo [52]. There was no overall improvement in the primary endpoint progression-free survival (PFS), and the independent data monitoring committee recommended early closure of the study for futility at a preplanned interim analysis. In contrast, when everolimus plus exemestane and exemestane plus placebo were randomly assigned to 724 patients with hormone-receptor-positive advanced breast cancer with prior exposure to aromatase inhibitors in the phase III BOLERO-2 trial, the combination was found to have a significantly better PFS than exemestane alone (6.9 versus 2.8 months, HR 0.43, 95% CI 0.35–0.54, $p < 0.0001$), leading to the early termination of the trial at a preplanned interim analysis [16]. However, the effort to improve clinical efficacy by a more robust blockade of mTOR signaling has led to the development of newer mTOR inhibitors. These are ATP-competitive inhibitors of the catalytic activity of mTOR kinase and efficiently suppress both mTORC1 and mTORC2. The kinase domains of mTOR and PI3K are structurally similar, and this new generation of molecules potently inhibits them both, effectively making them PI3K/mTOR dual inhibitors [11]. Early attempts at PI3K inhibition with nonspecific compounds like quercetin, wortmannin, and LY294002 were useful in understanding the PI3K molecular pathway, but lack of specificity and poor pharmacology limited the clinical application of these agents. More specific and potent PI3K pathway inhibitors currently under development act either on multiple class I PI3K isoforms (e.g., buparlisib or BKM120, XL147, GDC-0941), have dual PI3K/mTOR inhibitor activity (e.g., dactolisib or BEZ235, BGT226, XL765), or inhibit AKT (e.g., MK-2206, GSK2141795) [53]. The clinical development of PI3K and mTOR inhibitors and their use in cancer have been reviewed elsewhere [54–57]. The Breast International Group (BIG), the German Breast Group (GBG), and the Spanish Breast Cancer Study Group (SOLTI) have launched a phase II randomized double-blind study of neoadjuvant trastuzumab versus trastuzumab plus BKM120 in combination with weekly paclitaxel in HER2-positive primary BC patients (NeoPHOEBE study, NCT01816594).

67.4 Toxicity

Since the PI3K/AKT/mTOR pathway plays central roles in normal human cell physiology, its blockade could result in severe or unexpected adverse events. The safety profile of these drugs must therefore be closely monitored over the long term. Results from clinical trials involving different single agents have already begun to reveal toxicity patterns and "class effects." For example, PI3K inhibitors may result in glucose intolerance. Given the role of PI3K in normal glucose metabolic control via IGF-1R, it is not astonishing that inhibition of this pathway leads to hyperinsulinemia and decreased glucose tolerance. Hyperglycemia induced by the pan-PI3K blocker PX-866 has been noted in animal models but is in general mild and reversible [58]. This effect is also apparent in human studies using the mTORC1 inhibitor temsirolimus, the class I selective PI3K inhibitor BKM120, and the AKT inhibitor MK-2206 [51]. The dual PI3K/mTOR inhibitor XL765 caused food-induced increase in plasma insulin, but not glucose, in an exposure-dependent fashion. However, the pan-PI3K inhibitor PX-866 did not show any changes in the insulin or glucose levels in a phase I study. The change from baseline for fasting glucose values may in fact be used as a surrogate pharmacodynamic marker of activity of drugs inhibiting the PI3K/AKT/mTOR pathway. Schedule-dependent, noninfectious pneumonitis is a recognized adverse effect of oral everolimus. In a phase II study, pneumonitis was seen in 46% of patients receiving 10 mg daily and 19% of patients receiving 70 mg weekly everolimus. Although it may initially present as asymptomatic radiological signs or with cough, it may be severe and dose limiting. It is not clear whether pneumonitis is a class- or pathway-specific toxicity. Management may require close monitoring of patients and effective and early intervention through dose modifications, interruptions, or supportive interventions. Apart from pneumonitis, the long-term use of mTOR inhibitors in renal transplant recipients has been associated with infection, proteinuria, edema, dermal eruption, and hyperlipidemia. In the BOLERO-2 study, the most common grade 3 or 4 adverse events included stomatitis (8% in the everolimus-plus-exemestane group versus 1% in the placebo-plus-exemestane group), anemia (6% vs. <1%), dyspnea (4% vs. 1%), hyperglycemia (4% vs. <1%), fatigue (4% vs. 1%), and pneumonitis (3% vs. 0%) [16]. Mood disorders have been associated with the use of BKM120 [59]. mTOR-associated enteritis has been reported in two patients enrolled in a phase II clinical trial of everolimus plus rituximab in advanced B-cell lymphoma and one patient on a phase II study of temsirolimus and bevacizumab for metastatic renal cell carcinoma [60]. Fatigue, infection, and mucositis were the main non-hematological toxicities in 47 patients with HER2-positive metastatic breast cancer receiving everolimus plus trastuzumab [61].

67.5 Future Perspectives

Prognosis of patients with breast cancer has improved significantly over the past few decades, mainly as a result of routine screening for breast cancer, improvements in surgery, radiation techniques, and systemic therapy. The only remarkable success of modern targeted therapy in improving breast

cancer outcome has been the advent of anti-HER2 agents. Although several genomic aberrations are seen in HER2-positive breast cancers, yet these tumors remain critically dependent on HER2 signaling for survival and growth, and anti-HER2 therapies exploit this phenomenon of "oncogene addiction" to deliver significant clinical benefit [62]. Similar improvement in clinical outcome by blockade of other targets is proving to be notoriously difficult to replicate, mainly because of cross talk and redundant signaling pathways [63]. Thus there is a need to characterize in greater detail the biology of the canonical PI3K/AKT cascade, one of the most frequently dysregulated signal transduction pathway in breast cancer. This will help identify critical dependencies on particular components and escape mechanisms. Furthermore, we need to understand more accurately the cross talk between the PI3K/AKT/mTOR pathway and other pathways. As most solid tumors are the result of multiple accumulated genetic aberrations that cause perturbations in several signaling pathways, it seems improbable that targeting any one of these anomalous pathways will lead to sustained tumor response. Hence, future strategies are likely to use the combination of two or even more targeted agents in order to avoid or significantly slow the traffic of signals down these pathways and thus achieve optimal and sustained clinical benefit. In general, targeted agents are very expensive, and the simultaneous use of multiple such drugs is likely to impose a significant financial burden on the healthcare system. In recent decades, the rational design of molecules against these targets has dominated the oncology drug development process, replacing previous methods of empirical screening of drug libraries. There is a need to further refine and improve the drug-designing process, in order to produce specific and potent targeted agents with fewer off-target effects. Once suitable candidates are identified, collaboration between different pharmaceutical companies will be necessary for optimal development of rational drug combinations. Targeted drugs need to be tested in smartly designed clinical trials incorporating optimal endpoints and innovative statistical design in order to minimize drug development "costs"—money, time, and number of patients required [64]. The optimal duration of targeted therapy and how to best incorporate it into standard treatment protocols also need to be determined [65]. Since the effects of some targeted drugs may be modest, and thus obscured by high tumor burden or development of resistance, it is likely that the neoadjuvant setting, including presurgical or window-of-opportunity design, may be a better paradigm for testing these new molecules as compared to the metastatic setting [66, 67]. The neoadjuvant setting may also provide an ideal opportunity to identify predictive and prognostic biomarkers, including imaging biomarkers. In future randomized trials, molecular screening could be used to select patients with specific genomic features and could yield substantially improved clinical response rates to targeted agents than patient selection based on traditional histopathological and clinical criteria [68]. Additionally, the combined use of biomarkers such as genotype (e.g., PIK3CA mutation), gene signatures, and sequencing-based approaches may help better define a responsive population [9, 21, 69, 70]. The promise of personalized oncology remains substantially unfulfilled to date. While there has been some progress in tailoring therapies according to breast cancer biomarkers (e.g., we have moved from viewing breast cancer as a single monolithic disease a couple of decades ago to two entities based on hormonal status to four clinicopathological entities currently—luminal A, luminal B, HER2-positive, and TNBC), truly personalizing therapy according to the complex molecular features of the individual patients is not yet a reality [71]. Despite the early hopes raised by microarray-based technologies, gene signatures still remain largely a research tool and with some exceptions like Oncotype DX and MammaPrint are not widely used in the clinic [72–74]. A systems biology approach to comprehensively assess DNA, RNA, protein, and metabolites could help identify key breast cancer molecular drivers and biomarkers [75, 76]. The huge amounts of data generated by sequencing and other "-omics" technologies present a formidable challenge—in terms of storage, handling, analysis, interpretation, and application. Strong technologies for dynamic in vivo assessment of response using functional imaging biomarkers or receptor imaging with newer PET radiotracers are needed to allow real-time readout of effects of individual targeted drugs. Significant efforts are already underway; examples include the development of zirconium-labeled trastuzumab, copper-labeled DOTA-trastuzumab, carbon-labeled GSK1120212, and carbon-labeled GSK2118436 (NCT01081600, NCT01093612, NCT01387204, and NCT01340833, respectively) [77]. In the future, this may allow clinicians to quickly adapt targeted therapy combinations based on tumor response and thus deliver truly personalized care to breast cancer patients.

Conclusions

Advances in molecular research have resulted in an improved understanding of breast cancer biology. Several targets of critical importance to breast cancer cells have been identified, such as ER, HER2, other RTKs, and components of the PI3K/AKT/mTOR pathway. As we unravel the molecular circuits of breast cancer in greater detail, we have begun to recognize the terrific complexity of carcinogenic mechanisms. Based on strong preclinical rationale, it is logical to envisage that the inhibition of the PI3K/AKT/mTOR pathway in selected breast cancer patients may lead to clinically significant benefit; however, this hypothesis needs to be tested further in clinical trials. Successful development of combinations will require determining the preferred

drug targets, doses and schedules, and supportive interventions that maximize therapeutic index (i.e., effective inhibition of target pathways in tumors for maximal anticancer effects with acceptable normal tissue sparing). Several such clinical trials are underway and results are eagerly awaited. By using biomarker-driven patient selection, serial pharmacodynamic evaluation, optimal treatment schedules, and rational combinations of therapies, the modern generation of cancer researchers and clinicians should be able to meet the great challenge of developing more effective breast cancer therapies in the near future.

Targeting Genome Instability and DNA Repair

68

Marzia Locatelli and Giuseppe Curigliano

68.1 Introduction

Genomic instability is a characteristic of most human cancers and plays critical roles in both cancer development and progression.

Genomic stability is dependent on faithful DNA repair and chromosome segregation during cell division [1].

To maintain genomic integrity, eukaryotes have evolved a system called the DNA damage response (DDR). DDR is a complex signal transduction pathway that allows cells to sense DNA damage and transduce this information to the cell to arrange the appropriate cellular responses to DNA damage [2, 3]. The failure to respond to DNA damage is a characteristic associated with genomic instability. This instability can manifest itself genetically on several different levels, ranging from simple DNA sequence changes to structural and numerical abnormalities at the chromosomal level. During S phase, the centrosome and genomic material are replicated concurrently, and replication errors are repaired prior to mitotic entry. During mitosis, equal segregation of chromosomes requires a bipolar mitotic spindle, telomeric preservation, and completion of the spindle assembly checkpoint. Ectopic amplification of centrosomes, telomerase dysfunction, and failure of the spindle assembly checkpoint may result in aborted mitosis. The majority of cancers exhibit chromosomal instability (CIN), which refers to the high rate by which chromosome structure and number changes over time in cancer cells compared with normal cells [4]. Although CIN is the major form of genomic instability in human cancers, other forms of genomic instability have also been described. These include accumulation of DNA base mutations and microsatellite instability (MIN), a form of genomic instability that is characterized by the expansion or contraction of the number of oligonucleotide repeats present in microsatellite sequences [4–6], and forms of genomic instability that are characterized by increased frequencies of base pair mutations [7].

68.2 Hereditary Versus Sporadic Cancers

Familial breast cancer (BC) accounts for approximately 5–10% of BC cases. The most prevalent mutations leading to hereditary breast and ovarian cancer affect the homologous recombination (HR) genes BRCA1 and BRCA2. Heterozygous individuals carrying mutations of the BRCA1 or BRCA2 genes have a 40–80% risk of developing BC [8].

Patients (pts) with BRCA2 mutations have increased incidence of male breast, pancreas, and prostate cancer [3]. Tumors with BRCA1 or BRCA2 mutations are significantly associated with low level of 53BP1, indicating that 53BP1 mutation might confer a survival advantage in the absence of BRCA1 and BRCA2 [9]. Moreover, mutations in three additional HR genes, BACH1, PALB2, and RAD51C, have been identified in approximately 3% of familial BC pts and have been associated with a twofold increased risk of BC [10]. Mutations of CHK2, ATM, NBS1, and RAD50 have also been associated with a doubled risk of BC, indicating the importance of the ATM pathway, together with HR, in preventing BC formation. In hereditary cancers that are characterized by the presence of CIN, the genomic instability can also be attributed to mutations in DNA repair genes. The identification of mutations in DNA repair genes in hereditary cancers provides strong support for the *mutator hypothesis*, which states that genomic instability is present in precancerous lesions and drives tumor initiation by increasing the spontaneous mutation rate [4, 11, 12]. According to mutator hypothesis, the genomic instability in precancerous lesions results from mutations in caretaker genes, that is, genes that primarily function to maintain genomic stability [4, 11, 12]. Indeed, in inherited cancers, germline mutations targeting DNA repair genes are

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_68

present in every cell of the patient's body. Thus, a single event—loss of the remaining wild-type allele—would lead to genomic instability and drive tumor development, as predicted by the mutator hypothesis. The classical caretaker genes are DNA repair genes and mitotic checkpoint genes [4]. Germline mutations in caretaker genes can explain the presence of genomic instability in inherited cancers. However, efforts to identify caretaker genes, the inactivation of which leads to genomic instability in sporadic (nonhereditary) cancers, have met with limited success [4, 13]. Thus, unlike hereditary cancers, the molecular basis of genomic instability in sporadic cancers remains unclear. A second hypothesis could explain the presence of CIN in sporadic cancers. That is *the oncogene-induced DNA replication stress model for cancer development* [14–18]. According to the second model, CIN in sporadic cancers results from the oncogene-induced collapse of DNA replication forks, which in turn leads to DNA double-strand breaks (DSBs) and genomic instability [4].

68.3 Cellular Mechanisms that Prevent or Promote Genomic Instability

68.3.1 Telomere Damage

Telomeres, which are located at the ends of each chromosome, consist of approximately 5–10 kbp of specialized, tandem repeat, noncoding DNA complexed with a variety of telomere-associated proteins [1, 19, 20]. These elements create a protective cap that prevents the recognition of the chromosomal termini as DSBs and their consequent aberrant repair via nonhomologous end joining (NHEJ) or HR [1, 21–24]. Due to the inability of DNA polymerase to fully replicate the ends of linear DNA molecules, in the absence of compensatory mechanisms, telomeric DNA is lost at the rate of approximately 100 base pairs (bp) per telomere per cell division [1, 25–27]. In normal somatic cells, this telomere erosion is used by the cell to monitor its division history, with moderate telomere shortening triggering either irreversible cell-cycle arrest, termed replicative senescence, or apoptosis [1]. This block to continued proliferation is thought to have evolved to prevent the development of cancer in long-lived organisms by restricting the uncontrolled outgrowth of transformed cell clones and also by preventing further telomere erosion which would accompany such abnormal growth and eventually destabilize the telomeres leading to CIN [1, 25, 28].

68.3.2 Centrosomes

Centrosome amplification, the presence of greater than two centrosomes during mitosis, is a common characteristic of most solid and hematological tumors that may induce multipolar mitoses, chromosome missegregation, and subsequent genetic imbalances that promote tumorigenesis [1, 29].

The centrosome is the primary microtubule organizing center in dividing mammalian cells [1]. The centrosome is duplicated in a semiconservative fashion with one daughter centriole formed next to a preexisting mother centriole, and this process only occurs once in every cell cycle [1, 30, 31].

Centrosome amplification arises from many different mechanisms, including centrosome over duplication [1, 31, 32], de novo assembly [1, 33], and mitotic failure downstream from mono- [34] or multipolar division [35]. Given that centrosome clustering may be advantageous for cancer cell survival, this process may be an attractive and specific therapeutic target [36–38]. Bipolar chromosome attachment during mitosis is ensured by a quality control mechanism known as the spindle assembly checkpoint [1]. The assembly checkpoint relies upon kinase signaling to delay cell-cycle progression and correct attachment errors. Aurora kinase B, for example, detects misattached chromosomes [1], and overexpression of the kinase is sufficient to disrupt the checkpoint and promote tetraploidy [1]. Moreover, mutations or expression changes in other checkpoint gene products may compromise the checkpoint and favor tumorigenesis [39].

68.3.3 DNA Methylation and Chromatin Remodeling

A vast array of epigenetic mechanisms contribute to the genomic instability in cancer cells [40]. One of them is the DNA methylation, which consists of the addition of a methyl group at the carbon 5 position of the cytosine pyrimidine ring or the number 6 nitrogen of the adenine purine ring [41]. Most cytosine methylation occurs in the context of cytosine-phosphate-guanine (CpG) dinucleotides and occurs via a group of DNA methyltransferase enzymes resulting in silencing of gene transcription [1]. A prominent example is the aberrant methylation of CpG islands in the promoter regions of DNA mismatch repair (MMR) genes that result in cancer cells with a "mutator phenotype" [1, 42]. In addition to DNA methylation, histone molecules that form the primary protein component of chromatin also regulate genome stability as well as gene transcription [43]. A number of posttranslational modifications such as acetylation, deacetylation, methylation, phosphorylation, and ubiquitination have been identified that alter the function of histones [1]. Various combinations of these posttranslational histone modifications have been hypothesized to form a "histone code" that dictate distinct chromatin structures that can affect genome stability pathways and transcription [1]. Therefore, in most cases, histone acetylation enhances transcription while histone deacetylation represses transcription.

In addition, histone acetylation can affect DNA repair. Similarly, histone ubiquitination can also modify DNA repair capacity [1, 44]. Finally, histone phosphorylation is an early event following DNA damage and required for efficient DNA repair [1].

68.3.4 Mitochondrial DNA Alteration in Human Cancers

Mitochondria are the key component of the oxidative phosphorylation system to generate cellular adenosine triphosphate. Mitochondrial genetic reprogramming and energy balance within cancer cells play a pivotal role in tumorigenesis [1]. Most human cells contain hundreds of nearly identical copies of mt-DNA, which are maternally inherited. A substantial number of studies identified somatic mt-DNA mutations involving coding and noncoding mt-DNA regions in various cancers [1].

Table 68.1 DNA lesions generated by endogenous and exogenous DNA damage [3]

Exogenous DNA damage	Dose exposure (mSV)	DNA lesions generated
Peak hr. sunlight	–	Pyrimidine dimers (6-4) photoproducts
Cigarette smoke	–	DSBs
Chest-X-ray	0.02	DSBs
Mammography	0.4	DSBs
Body CT scan	7	DSBs
Tumor PET scan	10	DSBs
Airline travel	0.005/h	DSBs
Endogenous DNA damage	*Dose lesions generated*	*Number lesions/cell/day*
Depurination	AP site	10,000
Cytosine deamination	Base transition	100–500 s
SAM-induced methylation	3 meA	600
	7 meA	4000
	O^6 meG	10–30
Oxidation	8oxoG	400–1500

68.4 DNA Repair Pathways

Repeated exposure to both exogenous and endogenous insults challenges the integrity of cellular genomic material. To maintain genomic integrity, DNA must be protected from damage induced by environmental agents or generated spontaneously during DNA metabolism.

Environmental DNA damage can be produced by physical or chemical sources. For example, the ultraviolet (UV) component of sunlight can cause up to 1 × 105 DNA lesions per cell per day, many of which are pyrimidine dimers. If left unrepaired, dimers that contain cytosine residues are prone to deamination, which can ultimately result in cytosine being replaced with thymine in the DNA sequence. Likewise, ionizing radiation (e.g., from sunlight or cosmic radiation) can cause single-strand breaks (SSBs) and DSBs in the DNA double helix backbone. If misrepaired—for example, the inaccurate rejoining of broken DNA ends at DSBs—these breaks can induce mutations and lead to widespread structural rearrangement of the genome [45]. Table 68.1 [46, 47] showed environmental agents that cause DNA damage and mutations.

Spontaneous DNA alterations can be due to dNTP misincorporation during DNA replication, interconversion between DNA bases caused by deamination, loss of DNA bases following DNA depurination, and modification of DNA bases by alkylation. Additionally, DNA breaks and oxidized DNA bases can be generated by reactive oxygen species (ROS) derived from normal cellular metabolism.

Organisms respond to chromosomal insults by activating a complex damage response pathway. This pathway regulates known responses such as cell-cycle arrest and apoptosis (programmed cell death) and has been shown to control additional processes including direct activation of DNA repair mechanisms. Most of the subtle changes to DNA, such as oxidative lesions, alkylation products, and SSBs, are repaired through a series of mechanisms that is termed base excision repair (BER). In BER, damaged bases are first removed from the double helix, and the "injured" section of the DNA backbone is then excised and replaced with newly synthesized DNA [48]. Key to this process are members of the poly(ADP-ribose) polymerase (PARP) family. The PARP family has 16 members, but only PARP1 and PARP2 have been implicated in the DDR [49]. PARP1 and PARP2 are activated by SSBs and DSBs and catalyze the addition of poly (ADP-ribose) chains on proteins to recruit DDR factors to chromatin at breaks [3]. Mispaired DNA bases are replaced with correct bases by MMR [50]. In addition to BER, the pool of deoxynucleotides (deoxyadenosine triphosphate (dATP), deoxythymidine triphosphate (dTTP), deoxyguanosine triphosphate (dGTP), and deoxycytidine triphosphate (dCTP)) that provide the building blocks of DNA can be chemically modified before they are incorporated into the double helix. The nucleotide pool is, therefore, continually "sanitized" by enzymes such as nudix-type motif 5 (NUDT5). Whereas small base adducts are repaired by BER, some of the bulkier single-strand lesions that distort the DNA helical structure, such as those caused by ultraviolet light, are processed by nucleotide excision repair (NER) through the removal of an oligonucleotide of approximately 30 bp containing the damaged bases. NER is often subclassified into transcription-coupled NER, which occurs where the lesion blocks and is detected by elongating RNA polymerase, and global-genome NER, in which the lesion is detected not as part of a blocked transcription process but because it disrupts

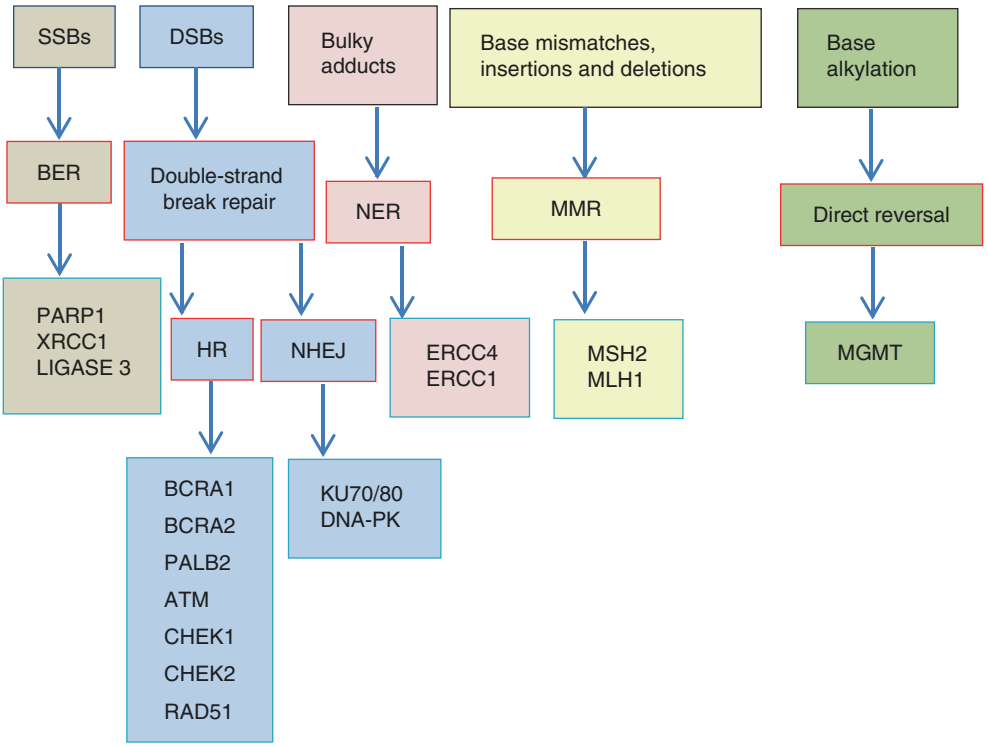

Fig. 68.1 DNA Repair Mechanisms maintain genomic stability. *SSBS* single-strand break, *DSBs* double-strand break, *HR* homologous recombination, *NHEJ* nonhomologous and joining, *MMR* mismatch repair

base pairing and distorts the DNA helix. Although these processes detect lesions using different mechanisms, they repair them in a similar way: DNA surrounding the lesion is excised and then replaced using the normal DNA replication machinery. Excision repair cross-complementing protein 1 (ERCC1) is key to this excision step. The major mechanisms that cope with DSBs are HR [51] and NHEJ [52]. HR acts mainly in the S and G2 phases of the cell cycle and is a conservative process in that it tends to restore the original DNA sequence to the site of damage. Part of the DNA sequence around the DSB is removed (known as resection), and the DNA sequence on a homologous sister chromatid is used as a template for the synthesis of new DNA at the DSB site. Crucial proteins involved in mediating HR include those encoded by the BRCA1, BRCA2, RAD51, and PALB2 genes. In contrast to HR, NHEJ occurs throughout the cell cycle. Rather than using a homologous DNA sequence to guide DNA repair, NHEJ mediates repair by directly ligating the ends of a DSB together. Sometimes this process can cause the deletion or mutation of DNA sequences at or around the DSB site. Therefore, compared with HR, NHEJ, although mechanistically simpler, can often be mutagenic.

SSBs repaired by single-strand break repair (SSBR), whereas DSBs are processed either by NHEJ or HR [3]. DNA repair is carried out by a plethora of enzymatic activities that chemically modify DNA to repair DNA damage, including nucleases, helicases, polymerases, topoisomerases, recombinases, ligases, glycosylases, demethylases, kinases, and phosphatases.

In summary DDR can be divided into a series of distinct, but functionally interwoven, pathways, which are defined largely by the type of DNA lesion they process (Fig. 68.1). DDR pathways encompass a similar set of tightly coordinated processes: namely, the detection of DNA damage, the accumulation of DNA repair factors at the site of damage, and finally the physical repair of the lesion.

MMR [50] is crucial to the DDR. Key to the process of MMR are proteins encoded by the mutS and mutL homologue genes, such as MSH2 and MLH1.

Finally, translesion synthesis and template switching allow DNA to continue to replicate in the presence of DNA lesions that would otherwise halt the process. Translesion synthesis and template switching are therefore usually considered to be part of the DDR. In translesion synthesis, relatively high-fidelity DNA replication polymerases are transiently replaced with low-fidelity "translesion" polymerases that are able to synthesize DNA using a template strand encompassing a DNA lesion. Once the replication fork passes the site of the lesion, the low-fidelity DNA polymerases are normally replaced with the usual high-fidelity enzyme, which allows DNA synthesis to continue as normal. In template switching, the DNA lesion is bypassed at the replication fork by simply leaving a gap in DNA synthesis opposite the lesion. After the lesion has passed the replication

fork, the single-strand gap is repaired using template DNA on a sister chromatid, similar to the process used during HR.

Although sometimes considered distinct from the DDR, the mechanisms that control the integrity of telomeric DNA at the end of each human chromosome also act as a barrier against genomic instability and mutation [53].

The core DDR machinery does not work alone but is coordinated with a set of complementary mechanisms that are also crucial to maintaining the integrity of the genome. For example, chromatin-remodeling proteins allow the DNA repair apparatus to gain access to the damaged DNA [54]. DDR core components interact with the cell-cycle checkpoint and chromosome segregation machinery. These interactions allow DNA repair to occur before mitosis takes place and ensure that the correct complement of genetic material is passed on to daughter cells [55].

68.5 Therapeutic Targeting of Genomic Instability in BC

When as CIN, and as changes to the structure of DNA, such as nucleotide substitutions, insertions, and deletions, they occur in crucial "driver" genes (of which there are probably fewer than ten per tumor), these mutations can alter cell behavior, confer a selective advantage, and drive the development of the disease. Importantly, these mutations can also influence how the tumor will respond to therapy. Alongside key driver mutations, emerging data from cancer genome sequencing suggests that a typical tumor may contain many thousands of other genetic changes. These "passenger" mutations do not contribute directly to the disease but are probably collateral damage from exposure to various environmental factors or defects in the molecular mechanisms that maintain the integrity of the genome. DNA damage causes cell-cycle arrest and cell death either directly or following DNA replication during the S phase of the cell cycle. Cellular attempts to replicate damaged DNA can cause increased cell killing, thus making DNA-damaging treatments more toxic to replicating cells than to non-replicating cells. However, the toxicity of DNA-damaging drugs can be reduced by the activities of several DNA repair pathways that remove lesions before they become toxic. The efficacy of DNA damage-based cancer therapy can thus be modulated by DNA repair pathways. In addition, some of these pathways are inactivated in some cancer types. These two features make DNA repair mechanisms a promising target for novel cancer treatments. Increasing knowledge of DNA repair permits rational combination of cytotoxic agents and inhibitors of DNA repair to enhance tumor cell killing. Thus, DNA repair inhibitors can be used in combination with a DNA-damaging anticancer agent. This will increase the efficiency of the cancer treatment by inhibiting DNA repair-mediated removal of toxic DNA lesions.

Moreover DNA repair inhibitors can be used as monotherapy to selectively kill cancer cells with a defect in the DNA damage response or DNA repair. Synthetic lethal interactions between a tumor defect and DNA repair pathway can be used to identify novel treatment strategies.

High levels of DNA damage cause cell-cycle arrest and cell death. Furthermore, DNA lesions that persist into the S phase of the cell cycle can obstruct replication fork progression, resulting in the formation of replication-associated DSBs. Evidence is also building that the DDR is not only invoked but also dysfunctional at an early stage in the development of neoplasia. Markers of DSBs, such as nuclear γH2AX foci (a histone phosphorylation event that occurs on chromatin surrounding a DSB), are markedly elevated in some precancerous lesions [14, 17]. The activation of oncogenes such as MYC and RAS stimulates the firing of multiple replication forks as part of a proliferative program. These forks rapidly stall, collapse, and form DSBs because they exhaust the available dNTP pool or because multiple forks collide on the same chromosome. Regardless of the mechanism, stalled and collapsed forks normally invoke the DDR and cell-cycle checkpoints that enable DNA lesions to be repaired before mitosis takes place. For precancerous lesions to progress to mature tumors, it is thought that critical DSB signal transduction and cell-cycle checkpoint proteins, such as ataxia telangiectasia (ATM) and ATM-Rad3 related (ATR), and the master "gatekeeper" protein p53 become inactivated. With these DDR components rendered dysfunctional, collapsed forks are not effectively repaired, and cells proceed through the cell cycle with DNA lesions intact, increasing the chance of mutagenesis [14, 17].

Common types of DNA damage that interfere with replication fork progression are chemical modifications (adducts) of DNA bases, which are created by reactive drugs that covalently bind DNA either directly or after being metabolized in the body. These *alkylating agents* are grouped in two categories: *monofunctional alkylating agents* with one active moiety that modifies single bases and *bifunctional alkylating agents* that have two reactive sites and cross-link DNA with proteins or, alternatively, cross-link two DNA bases within the same DNA strand (intrastrand cross-links) or on opposite DNA strands (interstrand cross-links). Interstrand cross-links pose a severe block to replication forks.

Despite the adverse side effects caused by alkylating agents on the bone marrow and other normal tissues, drugs such as cyclophosphamide, ifosfamide, chlorambucil, melphalan, and dacarbazine remain some of the most commonly prescribed chemotherapies in adults and children with various solid and hematological malignancies, particularly in combination with anthracyclines and steroids in multi-agent

regimens. The repair of alkylated lesions is thought to be quick, with the majority of lesions probably being repaired within 1 h. If the lesions are removed before the initiation of replication, the efficiency of alkylating agents in killing the tumor is significantly reduced. Thus, modulation of DNA repair that clearly influences the efficacy of alkylating agents is often explained by increased expression and/or activity of DNA repair proteins.

Antimetabolites, such as 5-fluorouracil (5FU) and thiopurines, resemble nucleotides, nucleotide precursors, or cofactors required for nucleotide biosynthesis and act by inhibiting nucleotide metabolism pathways, thus depleting cells of dNTPs. They can also impair replication fork progression by becoming incorporated into the DNA [56].

An alternative approach of interfering with replication is to target specific DDR components. Topoisomerase inhibitors, such as irinotecan (a topoisomerase I inhibitor) and etoposide (a topoisomerase II inhibitor), could be considered as the first generation of DDR targeted agents [45]. Topoisomerases are a group of enzymes that resolve torsional strains imposed on the double helix during DNA transcription and replication. They induce transient DNA breaks to relax supercoiled DNA or allow DNA strands to pass through each other [57]. Etoposide and irinotecan that inhibit this function leave DNA breaks across the genome. Topoisomerase II poisons cause DSBs, and topoisomerase I poisons cause positive supercoils in advance of replication forks and replication-associated DSBs [57].

PARP inhibitors as targeted therapy: PARP inhibitors are the next generation of DDR inhibitors.

It has been reported that expression levels of DNA repair genes are frequently associated with chemotherapy sensitivity and prognosis in BC subtypes. The poly(ADP-ribose) polymerase-1 (PARP1), one of the best characterized nuclear enzymes of the 17-member PARP family, participates in the repair of DNA SSB via the base excision repair pathway.

PARP1 and PARP2 catalyze the polymerization of ADP-ribose moieties onto target proteins (PARsylation) using NAD^+ as a substrate, releasing nicotinamide in the process. This modification often modulates the conformation, stability, or activity of the target protein [45]. The best understood role of PARP1 is in SSBR, a form of BER. PARP1 initiates this process by detecting and binding SSBs through a zinc finger in the PARP protein. Catalytic activity of PARP1 results in the PARsylation of PARP1 itself and the PARsylation of a series of additional proteins, such as XRCC1 and the histone H1 and H2B; when PARP activity is inhibited, SSBR is compromised [45].

The PARP inhibitors have been shown a substantial efficacy for hereditary BRCA1/2-related and triple-negative BC (TNBC) therapy [58–60]. Meanwhile, there are reports demonstrating that PARP inhibitors might be also active in non-hereditary BC cells lacking mutations in BRCA1 or BRCA2 [60, 61]. From a historical perspective, PARP-1 inhibitors entered the arena as promising co-adjuvant components of standard chemo-and radiotherapy regimens. Later, the discovery that tumor cell lines bearing deficiencies or mutation in DNA-repair genes (e.g., BRCA1 or BRCA2) do not tolerate PARP-1 inhibition fuelled the application of PARP inhibitors as single agent therapies in breast and ovarian BRCA-mutated cancer settings. More recently, the discovery of new potential combinative synergisms (e.g., PI3K, NAMPT, and EFR inhibitors) as well as the broadening of "synthetic lethality" context (e.g., PTEN and ATM mutations, MSI colorectal cancer phenotypes and Ewing's sarcomas) in which the inhibition of PARP-1 can be therapeutically valuable has further raised interest in this target.

PARP inhibitors were designed to imitate the nicotinamide portion of NAD^+ with which they compete for the corresponding PARP-1 binding site. PARP inhibition probably works by allowing the persistence of spontaneously occurring SSBs or by inhibiting PARP release from a DNA lesion. Whichever is the case, both of these DNA lesion types could credibly stall and collapse replication forks, potentially creating lethal DSBs [45]. Recent data propose an indirect mechanism, according to which PARP1 activity would be dispensable for BER sheer execution and would be rather engaged to seize potentially detrimental SSB intermediates and to promote their resolution. Recently, PARP1 contribution to SSB repair has also been extended to MMR and NER. In normal cells, the effects of PARP inhibition are protected by HR, which repairs the resultant DSB. However, effective HR is reliant on functioning BRCA1 and BRCA2, so when these genes are defective—as they are in tumors of germline BRCA-mutant carriers—DSBs are left unrepaired, and potent PARP inhibitors can cause cell death. BRCA1 plays a role in both the G1/S and G2/M cell-cycle checkpoint regulation in response to DNA damage, again preserving genomic integrity. Moreover, the sensitivity to PARP inhibitors seems to be defined more by the BRCA genotype of a cancer cell than by its tissue of origin. Breast, ovarian, and prostate cancers with BRCA mutations all seem to be profoundly sensitive to these drugs.

As early as in 1980, Durkacz and colleagues used the still immature, low-potency PARP inhibitor 3-aminobenzamide (3-AB) to derail DNA damage repair and enhance the cytotoxicity of dimethyl sulfate, a DNA alkylating agent [62].

The first clinical trial in pts was initiated in 2003 and allowed safety, pharmacokinetic, and pharmacodynamic evaluation of the PARP inhibitor AG014699 (*rucaparib* [63]) in combination with temozolomide (TMZ), a DNA alkylator and methylator, in advanced solid tumors [64]. However, the subsequent phase II study in melanoma [65], as well as additional independent clinical trials, featured a common (albeit not universal) shortcoming of combinatorial strategies with PARP inhibitors, namely, enhanced toxicity. Myelotoxicity was the main dose-limiting concern in the face of variable

Table 68.2 PARP Inhibitors under investigation

PARP inhibitor	Cancer type
Veliparib	Ovarian, breast, gastric, colorectal, and pancreatic tumors and a range of other solid tumors
Niraparib (Nira, MK4827)	Ovarian cancer and BRCA+ breast cancer
Olaparib (Ola, AZD2281)	Ovarian, breast, gastric, colorectal, and pancreatic tumors and a range of other solid tumors
Iniparib (BSI-201)	Breast cancer, ovarian cancer, lung cancer, glioma, glioblastoma
Rucaparib (AG014699)	Breast and other solid tumors
BMN-673	Ovarian, breast, gastric, colorectal, and pancreatic tumors and a range of other solid tumors
CEP9722	Lymphoma, breast, ovarian cancer
E7016	Melanoma
AZD-2641	Solid tumors
INO-1001	Melanoma, breast cancer
E7449	Melanoma, breast cancer, ovarian, B-cell malignancies

response rates. The need to reduce the dosage of either chemotherapy or PARP inhibitor (or both) to overcome excessive toxicity raises obvious questions about the real contribution of PARP inactivation to combinatorial regimens.

Currently, almost eight PARP inhibitors are at different stages of clinical investigation, targeting several tumor types either as single agents or in combination (Table 68.2).

Veliparib (Veli, ABT-888) is a potent, oral inhibitor of PARP-1 and PARP-2 [66]. It is orally bioavailable and crosses the blood-brain barrier. Veli potentiated the cytotoxic effect of TMZ in several human tumor models. ABT-888 was investigated in an innovative phase 0 trial, the first such study in oncology [67]. The primary study endpoint was target modulation by the PARPi. There is an extensive clinical trial program associated with this agent with 32 ongoing clinical trials of Veli in combination with cytotoxics in ovarian, breast, colorectal, prostate, liver cancers, neurologic malignancies, and leukemias. In a phase II study [68], combined ABT-888 and TMZ is active in metastatic BC (MBC). Exploratory correlative studies including BRCA mutation analysis are underway to determine predictors of response. The dose and schedule of Veli suggest the clinical activity seen is not likely due to Veli alone but rather to the combination. Promising antitumor activity was observed in pts with BRCA mutations.

Olaparib (Ola, AZD2281) also inhibits PARP-1 and PARP-2 at nanomolar concentrations. Preclinical studies have largely concentrated on investigations of synthetic lethality in BRCA1 or BRCA2 defective models or combinations with platinum in these models. The first clinical study of PARP inhibition in BRCA-mutant cancers was with this agent. In this phase I study which enrolled 60 pts, Ola doses were escalated from 10 mg daily for 2 of every 3 weeks to 600 mg twice daily [69]. Olaparib is one of the most investigated PARP inhibitors through clinical trials either as monotherapy [70, 71] or in combination with other anticancer drugs [72–77]. There is general agreement that 400 mg b.i.d. is the maximum tolerable dose of Ola. At this dose, Ola exhibited an acceptable safety profile. Most common adverse effects reported are of Grade 1/2 type, such as procedural pain, nausea, and other gastrointestinal symptoms of mild to moderate intensity, and thus are manageable. An important outcome of combination phase I trials results is the general tolerance of Ola when given in combination with bevacizumab [74], cediranib [75] and liposomal doxorubicin [77]. Ola-paclitaxel combination against TNBC [76], as well as the Ola-CDDP combination against breast or ovarian cancer in pts carrying germline BRCA1/BRCA2 also report partial efficacy. In both studies, dose-limiting hematological toxicities were neutropenia and thrombocytopenia.

Five phase II trials were conducted with Ola alone. As with the phase I clinical trials for Ola, despite inherent differences in the study design, cancer types, patient variability, and evaluation protocols, important similarities are evident in the outcomes of these phase II clinical trials. A study in pts with confirmed BRCA1 or BRCA2 mutations and recurrent ovarian cancer [78] yielded the objective response rate (ORR) of 33% for Ola 400 mg b.i.d. In pts with BRCA1 or BRCA2 mutations and advanced BC, ORRs were significantly higher (41%) for the 400 mg dose [79]. In another study conducted at this dose level [80], TNBC pts with or without BRCA mutations failed to show any objective response (OR). Interestingly, in the same study, a very strong ORR of 41% was obtained for ovarian cancer pts with BRCA1 or BRCA2 mutations; pts without the BRCA1 or BRCA2 mutations also responded at a robust ORR of 11% [80]. In summary in phase II clinical studies, 40% of pts with breast or ovarian cancer with germline BRCA mutations had a favorable response to the drug. This is a particularly high response given that the pts in these trials had been heavily pretreated and had become resistant to a range of chemotherapies [45, 64].

INO-1001 is an isoindolinone derivative and is being developed for both oncological and cardiovascular indications. Preclinical studies demonstrate its protective effect in models of cardiac dysfunction and reversal of TMZ resistance in MMR-defective xenografts. This agent is being developed in oncology in melanoma and glioma and as a single agent in cancer for BRCA1- and BRCA2-deficient tumors. In phase I trials, INO-001was tested alone or in combination with TMZ [83]. Pharmacokinetic analyses indicate lack of interactions between TMZ with INO1001 and establish a “safe to administer” dose of the combination for further evaluation of the efficacy of INO1001 against

advanced melanoma. However, outcomes of some clinical trials are less encouraging.

CEP9722 in phase I trials was tested alone or in combination with TMZ [84]. These dose escalation phase I trials established what the authors call an "adequately tolerated" dose for these compounds. Thus, while no neutropenia and other hematological toxicities were noticed, dose-dependent PARP inhibition was also not observed, with only limited clinical activity.

Niraparib (Nira, MK4827) is a potent inhibitor of PARP-1 and PARP-2 that is currently in phase III clinical trials for ovarian cancer and BRCA+ BC. In a phase III, randomized, open-label, multicenter, controlled trial, Nira was compared versus physician's choice in previously treated, HER2-negative, germline BRCA mutation-positive BC pts. MK4827 (in a 2:1 ratio) is administered once daily continuously during a 21-day cycle. Physician's choice will be administered on a 21-day cycle. Health-related quality of life will be measured. The safety and tolerability will be assessed by clinical review of adverse events (AEs), physical examinations, electrocardiograms (ECGs), and safety laboratory values.

Iniparib (BSI-201) is an anticancer agent with PARP inhibitory activity in preclinical models. Although the full mechanism of its antitumor activity is still under investigation, iniparib enhances the antiproliferative and cytotoxic effects of carboplatin and gemcitabine in vitro models of TNBC. Phase I–Ib studies of iniparib alone and iniparib in combination with chemotherapy in pts with advanced solid tumors have shown iniparib to have mild toxicity, with no maximal dose reached in terms of side effects. O'Shaughnessy et al. [59], in a phase II trial, evaluate whether iniparib could potentiate the antitumor effects of gemcitabine and carboplatin with acceptable toxicity levels. A total of 123 pts were randomly assigned to receive gemcitabine (1000 mg per square meter of body-surface area) and carboplatin (at a dose equivalent to an area under the concentration-time curve of 2) on days 1 and 8—with or without iniparib (at a dose of 5.6 mg per kilogram of body weight) on days 1, 4, 8, and 11—every 21 days. Primary end points were the rate of clinical benefit (CB) (i.e., the rate of OR [complete or partial response] plus the rate of stable disease (SD) for ≥6 months) and safety. Additional end points included the ORR, progression-free survival (PFS), and overall survival (OS). The addition of iniparib to chemotherapy improved the CB and OS of pts with metastatic TNBC without significantly increased toxic effects. On the basis of these results, a phase III trial adequately powered to evaluate overall survival, and progression-free survival is being conducted.

In summary, there are many differences in the studies evaluating anticancer activity of PARP inhibitors used alone or in combination with one or more anticancer agents. While there are many differences in the studies, some common observations should be noted with particular emphasis on various enzymatic activities associated with this multi-domain group of proteins as it applies to developing new anticancer agents and/or regimens. Specifically, the discovery of activation of PARP-2 and PARP-3 by phosphorylated DNA ends mimicking substrates or intermediates in various DNA repair pathways is quite important. These observations shed new light on the molecular functions of different PARPs. Additionally, better understanding of the substrate specificity of individual members of the PARP family will allow researchers to further refine inhibitor chemistry and minimize adverse effects of drugs currently under evaluation. Another area of considerable potential for research and development of PARP inhibitors as first-line anticancer drugs is their application to personalized medicine. Targeted therapy is rapidly becoming a hallmark of a number of anticancer drugs.

Platinum chemotherapies: Cisplatin, carboplatin, and oxaliplatin have become three of the most commonly prescribed chemotherapeutic drugs used to treat solid cancers in pts [57]. Platinum resistance, either intrinsic or acquired during cyclical treatment, is a major clinical problem as additional agents that can be added to therapy in order to circumvent tumor resistance do not currently exist. Platinum chemotherapy is now being tested with PARP inhibition clinical trials. The rationale for combining PARP inhibition with platinum chemotherapy is based on preclinical observations that PARP inhibitors preferentially kill neoplastic cells and induce complete or partial regression of a wide variety of human tumor xenografts in nude mice treated with platinum chemotherapy [57]. For example, Veli has been shown to potentiate the regression of established tumors induced by cisplatin, carboplatin therapy in rodent orthotopic, and xenografts models [57]. However, the biological mechanisms of chemo-sensitization of cancer cells to platinum chemotherapy by PARP inhibition remain to be resolved.

Ionizing radiation and radiomimetic agents such as bleomycin cause replication-independent DSBs that can kill non-replicating cells. In addition, such treatments can also rapidly prevent DNA replication by activation of cell-cycle checkpoints to avoid formation of toxic DNA replication lesions [57].

Targeting microsatellite instability (MSI): MSI is a marker of defective MMR. The predictive value of MMR status as a marker of response to 5fluorouracil, irinotecan, and other drugs is still controversial. Two large retrospective analyses from several randomized trials confirmed the detrimental effect of a 5 fluorouracil-based adjuvant therapy in stage II colorectal patients [81–83], not applicable to stage III patients [84]. These latter authors, however, reported that MSI stage III tumors harboring genetic mutation in the MMR genes seem to benefit from the 5 fluorouracil adjuvant therapy. These data imply that molecular differences within the MSI subgroup influence the response to 5 fluorouracil. Combination therapy with methotrexate (MTX) and PARP inhibitors may be effective against tumors with MMR mutations. MTX elevates ROS and DSBs and the combination of

MMR mutation and PARP inhibition may attenuate repair and induce growth arrest or apoptosis [85–87].

Targeting gene expression of cell cycle and DNA repair components: Resveratrol, a phytoalexin produced by plants such as the Japanese knotweed, prevents hypermethylation of the BRCA1 promoter [88] and may be effective for TNBC or basal subtype BC. Other natural compounds, like genistein and lycopene, can alter DNA methylation of the glutathione S transferase p1 (GSTP1) tumor suppressor gene.

Targeting centrosome abnormalities: Griseofulvin, an antifungal drug that suppresses proliferation in tumor cells without affecting non-transformed cells, declusters centrosome, although the precise mechanisms behind the drug's action remain unknown [36]. In a similar fashion, depletion of a kinesin-like motor protein can selectively kill tumor cells with supernumerary centrosomes [36]. Finally, the PARP inhibitor PJ34 also declusters super numerary centrosomes without deleterious effects on spindle morphology, centrosome integrity, mitosis, or cell viability in normal cells [89–90].

Conclusion

Genomic instability plays a critical role in cancer initiation and progression. The fidelity of the genome is protected at every stage of the cell cycle. In cancer, the presence of aneuploid or tetraploid cells indicates the failure of one or many of these safety nets. The resultant genomic heterogeneity may offer the cancer "tissue" a selection advantage against standard of care and emerging therapies. Understanding these safety nets, and how they are bypassed in cancer cells, may highlight new and more specific mechanisms for cancer prevention or therapeutic attack. The therapeutic targeting of genomic instability may check and inhibit other enabling characteristic of tumors cells, such as replicative immortality, evasion of antigrowth signaling, and tumor promoting inflammation. To this end, vitamins, minerals, and antioxidants, such as vitamin B, vitamin D, carotenoids, and selenium, as well as nutraceuticals, such as resveratrol, have shown remarkable plasticity in elucidating antitumor responses. In addition to alleviating genomic instability, these compounds are known to inhibit proliferative signaling, attenuate oncogenic metabolism, and block inflammation.

Targeting the CDK4/6 Pathway in Breast Cancer

69

Luca Malorni, Ilenia Migliaccio, Cristina Guarducci, Martina Bonechi, and Angelo Di Leo

69.1 Introduction

Uncontrolled chronic proliferation is a fundamental hallmark of cancer [1]. In mammalian cells, the control over cell cycle entry and the progression from Gap 1 (G1) to Synthesis (S) is a particularly critical checkpoint. A key effector of this checkpoint is the retinoblastoma susceptibility gene product (Rb) which, like other Rb family members (such as p107 and p130), functions by binding and inactivating E2F transcription factors [2]. Rb activity is mainly regulated through phosphorylation by cyclin-dependent kinases (CDK), a group of serine/threonine kinases whose activity depends on binding of regulatory proteins known as cyclins. CDK4 and 6, which bind preferentially to D-type cyclins [3, 4], are the initial CDK to phosphorylate Rb, followed by other complexes such as cyclin E–CDK2. Fully phosphorylated Rb then induces the release of E2F transcription factors with consequent transcription of genes required for S-phase entry. CDK activity and progression of the cell cycle through G1-S checkpoint are negatively modulated by the universal CDK inhibitors of the Cip-Kip family, including p21Cip1 and p27Kip1, and the specific CDK4 and CDK6 inhibitors of the INK4 family, typified by p16 INK4a [5–9]. The p16 gene product inhibits formation of active D cyclin-CDK complexes through specific binding interactions with CDK4 or CDK6 that prevent D cyclin-CDK association [10–12] Fig. 69.1.

Homeostasis of adult healthy tissue requires that cells enter the cell cycle in a highly regulated manner. Tight regulation of the cyclin D-CDK4/6 axis is obtained by control of different steps including transcription of the Cyclin D1 gene, assembly of the Cyclin D1-CDK4/6 complex, and its nuclear transport and stability. All these processes are regulated via complex biochemical mechanisms whose description in detail is beyond the scope of this chapter. However, to appreciate the role of D-type cyclins in cancer, these should be viewed as major drivers of cell cycle progression under mitogenic stimuli [13]. Indeed, the CDK4/6 axis physiologically responds to a variety of extracellular stimuli including those activated by growth factors and receptors (e.g., RAS, mitogen-activated protein kinase (MAPK), and mammalian target of rapamycin (mTOR)), cytokines, cell adhesion machinery, and nuclear receptors (e.g., the estrogen receptor (ER)). Most of these stimuli also represent well-known oncogenic drivers in many cancer types, including breast cancer, thus highlighting one of the layers of involvement of the Cyclin D-CDK4/6 axis in cancer development, i.e., its role in mediating proliferation signals from oncogenic pathways.

An additional layer of involvement resides in the fact that genetic alterations, including mutations, amplification, and deletions in members of the Cyclin D-CDK4/6 axis, are frequently detected in many cancer types (recently reviewed in [14]). In physiologic conditions, some degree of functional redundancy exists among members of the Cyclin D1-CDK4/6 axis. This has been elegantly demonstrated by studies in transgenic mice where abrogation of the function of individual genes *Ccnd1*, *Cdk4/6*, and *Cdkn2a* (encoding for p16 protein), while resulting in focal developmental defects, still permitted the generation of viable mice. These observations generated the notion that individual members of this pathway are nonessential for the cell cycle itself [15, 16]. In contrast, as suggested by models of oncogene-induced cancer, members of the CyclinD-CDK4/6 axis might be essential for the development of some cancer types under specific oncogenic insult and might therefore represent unique therapeutic targets in these settings. As an example, studies using mouse tumor models where oncogenes such as Erbb2 and ras are under

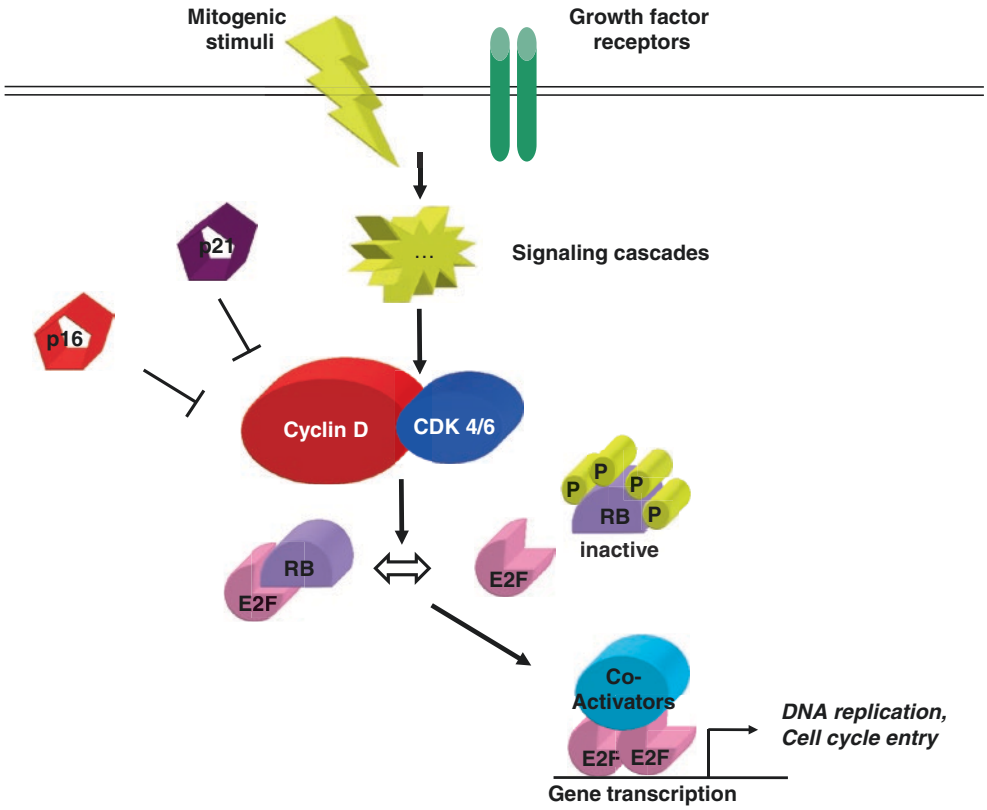

Fig. 69.1 Schematic representation of the CDK4/6 pathway

the control of the mouse mammary tumor virus (MMTV) promoter have indeed shown that breast tumor formation is impeded in the absence of CDK4 or CyclinD1 [17, 18]. However, the absence of cyclin D1 has no effect on breast tumor development induced by other oncogenes such as c-myc or Wnt-1 [19, 20]. Of note, the expression of neither CDK4 or Cyclin D1 is essential for mammary gland development [21]. These observations suggest that perturbations in the Cyclin D-CDK4/6 axis may represent crucial targets for cancer treatment in specific oncogenic contexts.

69.2 CDK4/6 Inhibitors as Anticancer Agents: Early Clinical Experiences and Phase I Studies

Given the central role of CDK in cancer, it is not surprising that several CDK inhibitors have been developed as potential antitumor drugs [22]. The first generation of CDK inhibitors included nonselective pan-CDK inhibitors, such as flavopiridol and roscovitine [14]. These compounds have been tested in numerous solid tumor types, but their clinical development has been hampered by their limited clinical activity and their unfavorable toxicity profile [14, 22]. Therefore, next-generation CDK inhibitors have subsequently been developed with specific activity toward individual CDK, including CDK4/6.

Three selective ATP-competitive, orally administered inhibitors of CDK4 and CDK6 have been synthesized, PD0332991 (palbociclib), LY2835219 (abemaciclib), and LEE011 (ribociclib), and are currently in different stages of clinical development.

Palbociclib, a highly specific inhibitor of CDK4 (IC50, 0.011 Mmol/L) and CDK6 (IC50, 0.016 Mmol/L), was the first compound to be developed and tested in clinical trials. It exerts G1 arrest with consequent antiproliferative activity in vitro and prevents tumor growth in vivo in a variety of Rb-positive tumor cells [23–27]. Palbociclib was first studied in two phase I dose-escalation trials in patients with advanced solid tumors or non-Hodgkin's lymphoma with histologically proven Rb tumor expression [28, 29]. In the first study, a total of 33 patients were enrolled across four cohorts receiving oral palbociclib at 100 mg ($n = 3$), 150 mg ($n = 4$), 200 mg ($n = 20$), and 225 mg ($n = 6$) daily doses [28]. A total of six patients experienced dose-limiting toxicities (DLT) consisting exclusively of myelosuppression (neutropenia with or without thrombocytopenia). Of these, two received a dose of 225 mg and four received 200 mg, which was identified as the maximum tolerated dose (MTD). Hematological toxicity in general was common. Grade 3 or 4 hematological adverse events consisted of lymphopenia (36%), neutropenia (24%), leukopenia (21%), thrombocytopenia (9%), and anemia seen in a single patient (3%). The most common non-hematological adverse events were

fatigue, nausea, and diarrhea. Treatment was generally well tolerated, and no patient discontinued treatment permanently because of treatment-related adverse events [28]. Of 31 patients evaluable for response, one patient with non-seminomatous germ cell testicular tumor had a partial response (PR), and nine patients (29%) experienced stable disease (SD). Stable disease was observed in four liposarcomas, one thyroid tumor, one melanoma, one cholangiosarcoma, and one angiomyxoma. Stable disease lasting ten cycles or more was observed in two patients with liposarcoma. In the second phase I trial, 41 patients were enrolled to receive palbociclib in six cohorts at doses ranging from 25 to 150 mg once daily on a 3 weeks on and 1 week off schedule [29]. DLT were observed in five patients (12%) at 75, 125, and 150 mg doses. MTD was 125 mg once daily. On the basis of these data, recommended phase II dose of palbociclib was 125 mg once daily. As in the other trial, hematological toxicity was common, and non-hematological adverse events consisted mostly of fatigue and nausea [29]. Of the 37 patients evaluable for response, none had PR and 13 (35%) maintained SD for at least two cycles, including 3 patients with liposarcoma and 2 with testicular tumors. Palbociclib subsequently moved into phase II and III clinical trials in different tumors, including breast cancer (see below).

As stated previously, hematological toxicities, especially neutropenia, were the most frequently reported adverse events for palbociclib. A recent work investigated the mechanism of palbociclib-induced bone marrow suppression and compared it to that induced by cytotoxic chemotherapeutic agents [30]. The authors demonstrated that, in contrast to chemotherapeutic agents which caused DNA damage and apoptotic cell death in human bone marrow mononuclear cells (hBMNCs), palbociclib did not induce senescence, with hBMNCs resuming proliferation following palbociclib withdrawal.

Abemaciclib is another orally available CDK4/6 inhibitor. In biochemical assays, abemaciclib inhibits CDK4/cyclinD1 and CDK6/cyclin D1 with IC50 = 2 nmol/L and 10 nmol/L, respectively, and inhibits Rb phosphorylation resulting in a G1 arrest and inhibition of proliferation in vitro and in vivo [31, 32]. Similar to palbociclib, its activity is specific for Rb-proficient cells [31]. In addition, preclinical studies in mice showed that abemaciclib crosses the blood-brain barrier and that brain levels are reached more efficiently at presumably lower doses and are potentially on target for a longer period of time than palbociclib [33]. The phase I trial of abemaciclib monotherapy included 132 patients with advanced solid malignancies. Results of this trial have so far been reported only in abstract form. Patients received abemaciclib 150–200 mg every 12 h continuously dosed, and a different toxicity profile was observed. Like palbociclib, neutropenia and fatigue were reported frequently; however, in contrast, the most common adverse events included gastrointestinal disorders such as diarrhea, nausea, and vomiting. In this trial, abemaciclib demonstrated activity in patients with breast cancer and non-small cell lung cancer (NSCLC) [34, 35].

Ribociclib is another CDK4/6 inhibitor. Its activity has been evaluated in vitro and in vivo. It has been shown to cause cell cycle arrest and cellular senescence in neuroblastoma-derived cell lines and growth delay in neuroblastoma xenografts [36] and to exert antiproliferative effects in CDK4-amplified human liposarcoma [37] and dermatofibrosarcoma protuberans in vitro and in vivo [38]. A total of 132 patients with advanced solid tumors and lymphomas were treated in a phase I trial with escalating doses of LEE011 on a 21-of-28-days or continuous schedule. DLT were observed in ten patients: neutropenia (3 pts), asymptomatic thrombocytopenia (2 pts), mucositis, pulmonary embolism, hyponatremia, QTcF prolongation (>500 ms), and increased creatinine (1 pt each). The MTD and the recommended phase II dose were declared as 900 and 600 mg/d on 21-of-28-d schedules, respectively. The most common study drug-related adverse events were neutropenia (40%), leukopenia (36%), nausea (35%), and fatigue (27%) [39].

69.3 CDK4/6 Inhibitors in Breast Cancer

In breast cancer, continuous cell proliferation is maintained by different mechanisms, including alterations involving the Rb pathway [40]. Cyclin D1 overexpression/amplification and CDK4 gains are frequent events, particularly in luminal breast cancer, while loss of RB1 and overexpression of $p16^{INK4A}$ occur mostly in basal-like carcinomas. Given the well-known lack of efficacy of CDK4/6 inhibitors in the context of RB1-negative models and the very high frequency of RB1 loss in basal-like and triple-negative breast cancers, the clinical development of CDK4/6 inhibitors has not been prioritized in these breast cancer subtypes. Conversely, given the high frequency of Cyclin D1 amplification or CDK4 gains in luminal breast cancers, most of the resources in terms of clinical development of CDK4/6 inhibitors have been invested in this subtype.

Accordingly, the majority of clinical trials have enrolled and are currently focusing on patients with hormone receptor (HR)-positive, HER2-negative tumors, often investigating associations of CDK4/6 inhibitors with endocrine therapy. However, new data on the role of CDK4/6 inhibitors in different breast cancer subtypes have accumulated in recent times. Here, we will review recent molecular and clinical advances on the role of CDK4/6 inhibitors in breast cancer therapy. In particular we will underline current progresses on the understanding of the role of CDK4/6 inhibitors in the context of the different breast cancer subtypes.

69.4 CDK4/6 Inhibitors in HR-Positive Breast Cancer

69.4.1 Preclinical Data

About three quarters of breast cancer cases express HRs (estrogen receptor—ER—and progesterone receptor (PR)) and are molecularly classified as luminal A or B. Among breast cancer subtypes, these tumors show the highest rate of cyclin D1 amplification and CDK4 gains and commonly retain Rb. The ER pathway and the Cyclin D-CDK4/6 axis are connected by extensive molecular cross talk. Indeed, ER directly controls Cyclin D1 expression at the transcriptional level [41], and estrogen modulation of E2F is critical for hormone regulation of the proliferative program of breast cancer cells [42]. However, the prognostic role of cyclin D1 amplification or overexpression in breast cancer is still controversial [43–47]. Recently, an integrated analysis of copy number and gene expression data in a large clinical annotated dataset of breast cancer patients has revealed a new, high-risk, ER-positive 11q13/14 cis-acting subgroup (IntClust 2). This subgroup includes both luminal A and B tumors and displays enrichment for Cyclin D1 amplification. However, other potential driver genes in the 11q13/14 amplicons are also amplified in this subgroup, including PAK1, RSF1, and EMSY, therefore suggesting that the particularly adverse outcome of this luminal population might be driven by a cassette of amplified genes rather than Cyclin D1 alone [48]. HR-positive breast cancers are preferentially treated with endocrine therapy, comprising drugs which target ER including tamoxifen, fulvestrant, and aromatase inhibitors (AI) (anastrozole, letrozole, and exemestane). Interestingly, endocrine therapy has been shown to act by restoring in part cell cycle control [49–51]. Although endocrine therapy is very efficacious, resistance commonly develops, representing a major clinical problem. The biology of resistance to endocrine therapy is complex and has not been completely elucidated, being underlain by deregulation of several different pathways [52]. Cyclin D1 overexpression and amplification in human breast tumors have been associated with resistance to tamoxifen [53, 54]. Interestingly, recent data has shown that breast cancer cells that have developed resistance to estrogen deprivation rely on an ER/CDK4/E2F axis for survival and that an E2F activation gene signature correlated with a lesser response to AI in breast cancer patients [55], therefore suggesting CDK4/6 as a possible target for reversing the resistant phenotype. In vitro and in vivo models demonstrated that breast cancers harboring functional inactivation of Rb overcome hormone deprivation therapy [56], and endocrine-resistant breast tumors maintain cyclin D1 expression [57] and Rb phosphorylation despite effective ER blockade [49]. Fulvestrant resistance has also been associated with CDK6 overexpression [58]. Finally, the transcription factor FOXM1, a well-known transcriptional target and regulator of ER [59] with a critical role in breast cancer endocrine resistance [60], has been shown to be modulated by CDK4/6 [61, 62].

Both preclinical and preliminary clinical studies suggest that CDK4/6 inhibitors are highly effective in HR-positive breast tumors and may have a role in endocrine-resistant breast cancers. In vitro studies demonstrated that ER-positive cell lines are the most sensitive to inhibition by palbociclib, with combination of palbociclib and tamoxifen demonstrating a synergistic effect [63]. Palbociclib was also shown to improve efficacy of fulvestrant and letrozole in ER-positive breast cancer models [64]. Additionally, palbociclib has shown activity in endocrine-resistant cell lines [49] and induced durable cell cycle arrest and partially restored tamoxifen sensitivity in MCF cells resistant to tamoxifen [63].

69.4.2 Clinical Data

Available clinical data confirm the activity of CDK4/6 inhibitors in patients with HR-positive breast cancer. Although palbociclib showed modest activity (clinical benefit rate of 21%) when used as a single agent in a phase II trial (NCT01037790) in heavily pretreated advanced breast cancer patients, partial responses and stable disease were observed in patients with ER-positive tumors [65]. Additional clinical data for palbociclib in combination with endocrine therapy in the metastatic setting come from the seminal randomized phase II PALOMA-1/TRIO-18 trial that was recently published. This study evaluated the combination of palbociclib plus letrozole as first-line treatment for postmenopausal patients with ER-positive/HER2-negative metastatic breast cancer as compared to single-agent letrozole. The study was composed of two parts: Part 1 enrolled patients with ER+/HER2-negative disease with no further biomarker assessment, while Part 2 enrolled patients with tumors harboring Cyclin D1 gene amplification and/or loss of p16. The primary endpoint was investigator-assessed PFS. A total of 165 patients were randomized in this study (66 patients in Part 1 and 99 patients in Part 2). Baseline characteristics were well balanced between treatment arms. The majority of the patients enrolled presented with de novo metastatic disease (52% in the palbociclib + letrozole arm and 46% in the letrozole arm) or recurred more than 12 months from the end of adjuvant treatment (30 and 37% in the combination arm and the letrozole arm, respectively). Roughly half of the patients in both arms had not received any systemic adjuvant/neoadjuvant treatment prior to study entry, while less than a third of patients had received prior endocrine therapy, of which almost half had received an aromatase inhibitor. Therefore, the patient population in this

trial represents mostly a population with predictably high benefit from first-line endocrine therapy in the metastatic setting. However, 44% of the patients in the combination arm and 53% in the letrozole arm presented with visceral disease, therefore representing a population enriched with patients with a poorer outcome. The final analysis of primary endpoint showed a statistically significant improvement in PFS for the combination arm (20.2 months) compared to the letrozole arm (10.2 months) with hazard ratio (HR) = 0.488 (95% CI: 0.319, 0.748, 1-sided $p = 0.0004$) [66]. Significant improvements in PFS were also seen in both Part 1 and Part 2 when analyzed separately (HR = 0.299 [95% CI: 0.156, 0.572]; 1-sided $p = 0.0001$ for Part 1 and HR = 0.508 [95% CI: 0.303, 0.853]; 1-sided $p = 0.0046$ for Part 2). The OS analysis with only 61 events was still immature and demonstrated a trend favoring the palbociclib plus letrozole combination vs. letrozole (37.5 months with 30 events vs. 33.3 months with 31 events, respectively; HR = 0.813; $p = 0.2105$).

The toxicity profile of palbociclib appears very favorable. In the abovementioned single-agent study, side effects were mainly hematological, in line with data from the phase I trials. Grade 3/4 toxicities were limited to transient neutropenia (50%) and thrombocytopenia (21%), and all other toxicities were grade 1/2. Treatment was interrupted in 25% and dose reduced in 46% of patients for cytopenia [65]. Similarly, in the PALOMA-1 study, the most common adverse events in the combination arm were neutropenia, leukopenia, fatigue, and anemia [66]. In particular, grade 3–4 neutropenia was reported in 54% of the patients in the combination arm and versus 1% of the patients in the letrozole arm. Of note, no cases of febrile neutropenia or neutropenia-related infections were reported, and discontinuation rates due to adverse events were 13% in the combination arm versus 2% in the letrozole arm. Comparable safety data deriving from the US Expanded Access Program for palbociclib that enrolled 242 patients were recently communicated in abstract form [67]. The results of the PALOMA-1 trial led to the approval of palbociclib by the Food and Drug Administration for the treatment of patients with HR-positive and HER2-negative advanced breast cancer in combination with letrozole. An ongoing phase III trial reproducing the same design of PALOMA-1 (PALOMA-2) is ongoing.

In the setting of endocrine-pretreated metastatic breast cancer, results from the phase III PALOMA-3 trial have recently been published [68]. This study involved patients with ER-positive/HER2-negative metastatic breast cancer that had relapsed or progressed during prior endocrine therapy. Patients were randomized in a 2:1 ratio favoring the combination arm, to receive palbociclib and fulvestrant or placebo and fulvestrant. Premenopausal or perimenopausal women were eligible and also received goserelin. Patients who had received one line of prior chemotherapy for the treatment of metastatic disease were eligible for this trial. A total of 521 patients were randomized in this study, 347 in the palbociclib and fulvestrant arm and 174 in the palbociclib and placebo arm. The majority of the patients were postmenopausal (79.3% in both arms) and had received one or more prior lines of therapy for metastatic disease (patients who had received no prior treatment for metastatic disease represented 24.2% and 25.9% of the trial population in the palbociclib + fulvestrant and the placebo + fulvestrant arms, respectively). The study met its primary endpoint of progression-free survival. Median progression-free survival was 9.2 months with palbociclib and fulvestrant and 3.8 months with placebo and fulvestrant (HR) = 0.42 (95% CI, 0.32–0.56) and $p < 0.001$ [68]. Toxicities were mostly in line with previous data. The rate of discontinuation due to adverse events was 2.6% with palbociclib and 1.7% with placebo. To date, overall survival data are still immature and require longer follow-up [68].

Additional data with other CDK4/6 inhibitors in the context of breast cancer come from a phase I clinical trial in which abemaciclib was given as a single agent to 47 patients with metastatic breast cancer who had received a median of seven prior systemic regimens (NCT01394016). Among 36 patients with HR-positive tumors, nine confirmed partial responses were observed, for an overall response rate of 25%, a disease control rate (complete response + partial response + stable disease) of 81%, and a median PFS of 9.1 months [34]. Based on these encouraging results, abemaciclib has been granted FDA breakthrough therapy designation for patients with refractory HR+ metastatic breast cancer. Another phase Ib trial investigating the safety and tolerability of abemaciclib in combination with endocrine or HER2 target therapies for pre- or postmenopausal patients with metastatic breast cancer was recently communicated in abstract form (NCT02057133). In this study, patients with HR+ and HER2-negative disease received abemaciclib in combination with either letrozole ($n = 20$), anastrozole ($n = 16$), tamoxifen ($n = 16$), exemestane ($n = 15$), or exemestane plus everolimus ($n = 17$). HR+/HER2-negative patients included in this study had not received any prior systemic chemotherapy for metastatic disease but had received a median number of prior systemic treatments that varied among the different cohorts between 2 and 4. This study did not show any evidence for pharmacokinetic drug-drug interactions between abemaciclib, tamoxifen, exemestane, and trastuzumab and therefore showed the potential for abemaciclib to be safely combined with other targeted and endocrine treatments. The toxicity profile of the combinations confirmed what had been seen with abemaciclib monotherapy, with diarrhea, nausea, vomiting, neutropenia, and fatigue being the most frequently reported adverse events. Activity was seen in all cohorts, with partial responses ranging from

10 to 27% with a disease control rate (complete response + partial response + stable disease) ranging from 54 to 88% and a PFS at 6 months ranging from 86.7 to 73.3% [69].

Ribociclib is also in advanced stage of clinical development. However, clinical data in patients with breast cancer have not been fully published yet. Available data come from the phase Ib part of a phase Ib/II trial of ribociclib in association with either letrozole, the alpha-isoform selective PI3K inhibitor alpelisib (BYL719), or both and have been communicated in abstract form (NCT01872260). Regarding the combination of ribociclib and letrozole, ten patients were treated showing no signs of pharmacokinetic interaction, a fairly acceptable toxicity profile with the more common adverse event reported being neutropenia (all grades 90%, G3–G4 50%) and nausea (all grades 40%, G3–G4 0%), and preliminary signs of efficacy with 1 PR and 2 SD out of six evaluable patients [70].

Many studies are currently investigating CDK4/6 inhibitors in combination with endocrine therapy in patients with HR-positive breast cancer, which will give a definitive answer on the efficacy and safety of the use of CDK4/6 inhibitors in this patient population. We are currently running a phase II, open-label, multicenter, randomized clinical trial of palbociclib monotherapy versus palbociclib in combination with the endocrine therapy to which the patient has progressed in the previous line for ER-positive, HER2-negative postmenopausal advanced breast cancer patients [To Reverse ENDocrine resistance (TREnd) trial] (NCT02549430). This trial has been designed primarily to address the open question of whether palbociclib is able to restore endocrine sensitivity in patients previously treated with endocrine therapy.

Clinical data for the triple combination of ribociclib, letrozole, and the alpha-isoform selective PI3K inhibitor alpelisib (BYL719) have been recently communicated in abstract form (NCT01872260) [73]. Within this trial (NCT01872260), 36 postmenopausal women with HR+ HER2-negative advanced breast cancer received the triple combination. Fifteen patients discontinued treatment: seven (19%) due to disease progression and eight (22%) due to adverse events, the most frequent being nausea (all grade, 44%; G3/4, 6%), hyperglycemia (44%; 17%), neutropenia (42%; 22%), and fatigue (36%; 11%). The triple combination showed some preliminary clinical activity. Indeed of 27 evaluable patients, two (7%) had PR, four (15%) had unconfirmed PR, and six (22%) had SD [73].

Another ongoing phase Ib/II clinical trial (NCT01857193) is investigating the combination of the triple combination of ribociclib, everolimus, and exemestane in women with anastrozole- or letrozole-resistant HR+/HER2-negative advanced breast cancer. Preliminary results of this trial have been recently reported in abstract form for 70 patients treated with the triplet [74]. Triple combination permitted lower dosing of everolimus (mostly at 2.5 mg), resulting in better tolerability. Grade 3/4 treatment-related adverse events were neutropenia (45.7%), leukopenia (8.6%), and thrombocytopenia (5.7%), and two (2.9%) patients discontinued due to adverse events. The triplet showed encouraging signs of clinical activity. Among 55 patients evaluable for best overall response, there was (1.8%) complete response (CR), two (3.6%) confirmed and three (5.5%) unconfirmed PR and 26 (47.3%) SD. Of note, clinical activity was also reported in some patients with prior exposure to PI3K/AKT/mTOR or CDK4/6 inhibitors [74].

69.5 Combinations of CDK4/6 Inhibitors and Other Targeted Agents in Breast Cancer

Activating mutations of PIK3CA gene, encoding for the p110 alpha subunit of PI3Kinase, are a common event in HR+ breast cancer, affecting 45% and 29% of luminal A and luminal B breast cancer subtypes, respectively [40]. As a consequence, strategies to target this pathway in combination with hormonal therapies have been developed. Results from clinical trials with the mTOR inhibitor everolimus (BOLERO-2) [71] have been encouraging; however resistance to these drugs eventually develops.

A recent preclinical study revealed, through a combinatorial drug screen on multiple PIK3CA mutant breast cancer cells, that the combination of CDK4/6 inhibitors with PI3K inhibition reduces cell viability [72]. In addition, CDK4/6 inhibitors sensitized cells with acquired and intrinsic resistance to PI3K inhibitors both in vitro and in vivo [72].

69.6 CDK4/6 Inhibitors in HER2-Positive Breast Cancer

HER2-positive breast cancers represent 10–15% of all breast cancers. Women with HER2-positive tumors are currently treated with anti-HER2 therapies including trastuzumab, lapatinib, and pertuzumab, often in combination with chemotherapeutic agents and trastuzumab emtansine (TDM-1). Mouse models demonstrated that cyclin D1-CDK4 complex is critical for (HER2) *neu*-induced tumorigenesis [18, 19, 75]. In addition, analysis of HER2-enriched human tumors showed that cyclin D1 amplification and CDK4 gains are frequent events in this breast cancer subtype [40], supporting the central role of cyclin D1-CDK4-Rb axes in this context.

Preclinical data suggest that HER2-positive tumors might benefit from CDK4/6 inhibition. Indeed, the preclinical work of Finn et al. revealed that HER2-positive breast cancer cells show sensitivity to palbociclib treatment in vitro [63, 76]. Palbociclib activity in HER2-positive tumors has been then

confirmed in primary breast tumor explants and in vivo xenograft models [77]. In addition palbociclib has been shown to act synergistically with trastuzumab in three HER2-amplified breast cancer cell lines [77] and to have highly distinct mechanisms of action compared to TDM-1, which could yield cooperative effects [77]. Interestingly, CDK4/6 inhibition was also effective at blocking proliferation in models of acquired resistance to lapatinib [77]. In a mouse model of HER2-positive breast cancer (MMTV-c-neu), treatment with palbociclib as a single agent caused a decrease in tumor proliferation, a marked reduction in tumor volume (with several tumors showing complete regression), and an increase in median survival [37]. In HER2-amplified cell lines, the combinations of palbociclib and trastuzumab or T-DM1 proved to be synergistic [63, 76]. However, coadministration of palbociclib with carboplatin or doxorubicin in the absence of anti-HER2 therapy showed an antagonistic effect [78].

To date, despite the encouraging preclinical data, clinical data regarding the efficacy of CDK4/6 in patients with HER2-positive breast cancer are lacking. Given the biological rationale and the clinical need for new treatment strategies for patients with HER2-positive breast cancer, this is certainly an open research question.

69.7 CDK4/6 Inhibitors in Triple-Negative Breast Cancer (TNBC)

Approximately 10–15% of all breast cancers do not express HRs or HER2, thus belonging to the TNBC category. TNBC is an aggressive disease characterized by high proliferation rate; therefore targeting the cell cycle might be a potential therapeutic strategy in these patients. Among other molecular characteristics, TNBCs often exhibit loss/mutation of RB and high expression of p16 which are characteristics usually associated with resistance to CDK4/6 inhibition [40]. To date it is still unclear whether patients with TNBC can derive any benefit from CDK4/6 inhibitors; however the majority of preclinical findings suggest that TNBCs do not respond to CDK4/6 inhibition.

Analyzing drug sensitivity in a panel of breast cancer cell lines, it was demonstrated that most of basal-like cell lines (which recapitulate TNBC biology) are resistant to palbociclib [63]. Also, a recent study investigating the regulatory role of Cyclin D1 and CDK4/6 inhibition on migration and stemlike cell activity showed that results vary depending on ER status of tumor cells [79]. Inhibition of cyclin D1 or CDK4/6 led to decreased migration and stemlike activity in ER-positive breast cancer cells but showed opposite effects on ER-negative cell lines. Palbociclib treatment reduced mammosphere formation in ER-positive breast cancer cells, while in ER-negative cells, mammosphere formation was instead increased [79]. Re-expression of ER in two ER-negative cell lines was sufficient to overcome these effects [79]. Additionally, in a basal-like Rb-deficient breast cancer mouse model (C3-Tag model), palbociclib treatment alone did not affect tumor proliferation or growth [78]. On the other hand, it must be mentioned that some of the basal-like cells analyzed by Finn et al. [63] did show moderate sensitivity to palbociclib (HCC-38 and BT-20 with IC50 values of 64 and 177 nM, respectively) and palbociclib was shown to strongly inhibit cell proliferation of some TNBC cell lines [80]. Additionally, in an ex vivo analysis of 13 human tumors, response to palbociclib was demonstrated not to be dependent on ER or HER2 status [81]. TNBC is a heterogeneous disease; therefore response to CDK4/6 inhibitors might depend on intrinsic biological characteristics. Indeed, it has been demonstrated that palbociclib can induce G1 cell cycle arrest in Rb-proficient TNBC cell lines [82, 83] yet is completely ineffective at suppressing proliferation in Rb-deficient TNBC cells [83].

Patients with TNBC are often treated with chemotherapeutic agents including anthracyclines, taxanes, or platinum salts. The efficacy of CDK4/6 inhibition in combination with such agents has therefore recently been tested. Again the effects were shown to be dependent on Rb status [82, 83]. In Rb-proficient TNBC cells, palbociclib antagonized the cytotoxic activity of anthracyclines and taxanes by preventing the induction of DNA damage and consequent cell death and preserved cell viability of doxorubicin-treated cells [82, 83]. In Rb-deficient TNBC cells and mouse models, in which palbociclib alone had no effect, the combination did not alter the therapeutic response to chemotherapeutic agents [78, 82, 83]. Overall, these data do not support the association of CDK4/6 inhibitors with chemotherapy in breast cancer. However, it must be mentioned that a combination of abemaciclib and the chemotherapeutic agent gemcitabine in a xenograft model of lung cancer (calu-6 cells) resulted in additive antitumor activity in comparison to single agents, even though no cell cycle arrest was detected [31].

To date, the only clinical data on the role of CDK4/6 inhibitors in TNBC derive from the abovementioned phase II trial (NCT01037790) in which palbociclib was administered as single agent in patients with refractory tumors. Seven of the eight patients enrolled with TNBC progressed, and only one patient had disease stabilization. Of note all patients enrolled in the trial had Rb-positive tumors [65].

69.8 Potential Biomarkers of Response to CDK4/6 Inhibitors

It is evident that CDK4/6 inhibitors represent a new paradigm for the treatment of metastatic breast cancer patients with HR-positive breast cancer, and available clinical data

suggest that virtually every patient with HR-positive breast cancer should be treated with a combination of endocrine therapy and a CDK inhibitor in the early metastatic setting. However, it must be taken into account that a relevant proportion (±50%) of ER-positive patients undergoing first-line single-agent hormonal treatment can achieve disease responses lasting more than 12 months, with minimal side effects [84, 85]. In this group of patients with high sensitivity to endocrine therapy, any additional benefit given by combinations with a CDK4/6 inhibitor must be carefully weighed, taking into account additional toxicity and costs.

In this context, understanding which subgroup of patients is more likely to benefit from the combination of endocrine therapy and CDK4/6 inhibitors is therefore of critical importance for the future clinical development of these agents.

Recent studies suggest that alterations in the CyclinD/CDK4/Rb pathway might have a predictive role for response to CDK4/6 inhibitors. However, to date, no single biomarker has been developed with any positive or negative predictive value for response to CDK4/6 inhibitors. Palbociclib has been associated with favorable PFS in CDK4-amplified well-differentiated or dedifferentiated liposarcoma [86] and in cyclin D1-overexpressing mantle cell lymphoma [87]. However, CDK4 amplification is not a frequent event in breast cancer. In breast cancer, genetic loss of RB and high expression of p16 protein, which is frequently associated with RB loss, have been linked to resistance to palbociclib [81], while high levels of Rb and cyclin D1 and low levels of p16 have been associated with sensitivity to this compound [63]. Rb expression was an inclusion criterion for the above-mentioned (NCT01037790) trial investigating palbociclib in patients with advanced solid disease [65]. However, despite the presence of functional Rb in tumors, the clinical benefit rate for patients with breast cancer was very modest [65]. Additionally, in the Part 2 of the PALOMA-1 trial, where all included patients were screened for cyclin D1 amplification and/or loss of p16, there was no indication of increased activity of palbociclib compared to Part 1 of the study where no molecular screening was requested [66]. More complex alterations of the pathway are therefore likely to be implicated in resistance to CDK4/6 inhibitors. Indeed, a wider analysis of the Rb/E2F pathway suggested that resistance to palbociclib might be mediated by other components of the pathway, such as E2F2, p107, CDK2, p21, and p27 [80]. Gene expression signatures that analyze the Rb pathway have been developed by different groups [88, 89] and shown to be prognostic in patients with breast cancer and potentially predictive of response to chemotherapy and endocrine therapy [88, 89]. These signatures of Rb functional state show a positive correlation with RB1 mutational status. It is therefore interesting to speculate that such signatures could be also predictive of resistance to CDK4/6 inhibitors.

Conclusion

CDK4/6 inhibitors look very promising for the treatment of patients with hormone receptor-positive HER2-negative breast cancer. Although well tolerated, these drugs are not devoid of side effects. Clearly, biomarker-driven clinical trials are urgently needed to identify subpopulations of breast cancer patients that will derive the greatest benefit from CDK4/6 inhibitors.

Targeting FGFR Pathway in Breast Cancer

70

Carmen Criscitiello, Angela Esposito, and Giuseppe Curigliano

70.1 Introduction

The fibroblast growth factor/fibroblast growth factor receptor (FGF/FGFR) signaling pathway plays a critical role in several cancer types, including breast cancer.

Deregulated FGF signaling is involved in cancer progression in tumors driven by FGF/FGFR oncogenic mutations or amplifications. The FGF/FGFR alterations that occur in cancer may result either in constitutive ligand-independent FGFR activation or in abnormal ligand-dependent signaling.

FGFR pathway activation is generally involved in cancer progression through oncogenesis, neoangiogenesis, and drug resistance. Therefore, there is a strong biologic rationale to support the development of anti-FGF/FGFR agents in breast cancer.

The main activating FGFR genomic alterations found in breast cancer concern FGFR1 and FGFR2.

The amplification of the chromosomal region 8p11–12, which includes the gene encoding

FGFR1, has been identified in 8–10% of breast cancers, mostly in estrogen receptor (ER)-positive tumors. Additionally, this molecular alteration is related to higher FGFR1 mRNA levels [1, 2] and poorer prognosis [3, 4]. Breast cancer cells with FGFR1 amplification are extremely sensitive to FGFR1 tyrosine kinase inhibitors [5]. While FGFR2 amplification has been identified in 4% of triple-negative breast cancers. It has been shown that PD173074 treatment induced apoptosis in FGFR2-amplified cell lines of triple-negative breast cancer, partially owing to inhibited PI3K/AKT signaling [6]. Components of the FGF pathway have been particularly identified in mesenchymal and mesenchymal-like subtypes. Also, cell models of these specific subtypes have been proven to be sensitive to PI3K inhibition. Other interesting information come from genome-wide association studies, which have identified FGFR2 as a breast cancer susceptibility gene; indeed, several single nucleotide polymorphisms (SNP) in FGFR2 are highly associated to breast cancer risk [7]. Having this said, it is easily understandable why there is so much interest in conducting effective trials with FRGF inhibitors in breast cancer.

Here, we present a critical overview of the last year literature focusing on the rationale and potential role of FGFR inhibitors in breast cancer.

70.2 Review

70.2.1 Predictive Factors of Response to FGFR Inhibitors

Identifying the patient population who might derive the greatest benefit from FGFR pathway-targeted therapy is paramount but still challenging and controversial. The first tricky point is the definition of FGFR pathway amplification, as different methods and different threshold copy number have been used across studies. A quantitative gene amplification measurement may not accurately reflect protein expression or activity. Activating mutations may not be relevant if the gene is not expressed. Furthermore, amplicons may not reflect the level of amplification of the component genes, and other potential oncogenes in the amplicon may represent confounding factors. So far it is still unknown which is the best method to test the FGF pathway amplification, if any. Therefore, ongoing clinical trials are using different approaches to detect FGFR alterations. This will ultimately result in potential biases when current data will be analyzed. One of the most demanding but necessary step in this field is to fine-tune the selection of patients more likely to benefit from FGFR-targeted therapies.

JNJ-42756493	1	NCT01962532	Recruiting	JNJ-42756493
Brivanib	1	NCT00798252	Completed	Brivanib + chemotherapy
Orantinib	2	Not available	Completed	Orantinib [9]
Orantinib	2	Not available	Completed	Orantinib + docetaxel [10]
Nintedanib	2	NCT01658462	Recruiting	Docetaxel +/−nintedanib

70.2.2 FGFR Inhibitors Under Investigation in Breast Cancer

A number of FGFR inhibitors are investigated in clinical trials (Table 70.1).

Dovitinib (TKI258) is a potent tyrosine kinase inhibitor that targets FGFR, vascular endothelial growth factor receptor (VEGFR) and platelet-derived growth factor receptor (PDGFR), and other kinases. It has been mainly investigated in patients with metastatic ER+/HER2− breast cancer. After the first evidence of activity [11], trials of dovitinib in combination with endocrine therapies have been designed (NCT01528345, NCT01262027, NCT01484041).

AZD4547 inhibits FGFR1-3 and VEGFR2 [12]. Similarly to dovitinib, this agent is being tested in patients with ER+ breast cancer either alone or in combination with endocrine therapies (NCT01795768, NCT01202591, NCT01791985).

Pan-FGFR inhibitors – such as BGJ398 and JNJ-42756493 – are under clinical investigation in patients with tumors harboring FGFR1/FGFR2 amplifications or FGFR3 mutations (NCT01004224, NCT01962532). These molecules seem to induce reductions in tumor volume, both when used as monotherapy and when combined with the α-selective PI3K inhibitor BYL719 in patients with tumors harboring PIK3CA mutations and FGFR1-3 alterations (NCT01928459, NCT01703481).

A program for the development of lucitanib, – a potent, oral inhibitor of FGFR 1 and 2, VEGFR 1, 2 and 3, and PGFRα/β – is ongoing, but we will discuss this drug in the next paragraph.

Other FGFR inhibitors tested in breast cancer include – but are not limited to – orantinib (TSU-68), which inhibits VEGFR2, PDGFR, and FGFR [9], brivanib alaninate (NCT00798252), and nintedanib (BIBF 1120), which inhibits FGFR1-3, VEGFR1-3, PDGFRα, PDGFRβ, and FLT3 [13].

70.2.3 2014 News and Views

The role of FGFR inhibition on tumor growth and metastasis in breast cancer is well known [14]. Previous studies demonstrated that the FGFR inhibitor PD173074 decreased the viability of numerous human breast cancer cells and 4T1 murine mammary tumor cells [15]. Hence, in a 2014 preclinical paper, it has been shown that PD173074 induces 4T1 cell apoptosis in a concentration-dependent manner [16]. Apoptosis induced by PD173074 was linked to the inhibition of Mcl-1 and survivin. Also, PD173074 considerably increased the Bax/Bcl-2 ratio. In vitro, PD173074 blocked 4T1 cell migration and invasion too. Additionally, in 4T1 tumor-bearing mice, PD173074 significantly inhibited tumor growth, reduced microvessel density and proliferation index, and induced tumor apoptosis. FGFR inhibition induced by PD173074 reduced myeloid-derived suppressor cells in the blood, spleens, and tumors, with increased CD4(+) and CD8(+) T cells infiltration in the spleens and tumors. Furthermore, metastasization to the lung was significantly inhibited by PD173074. Taken together, these findings support the importance of capitalize upon FGFR inhibition as a therapeutic strategy for breast cancer, as it delays tumor

progression, impedes lung metastasization, and cracks immunosuppression.

Moving forward, a clinical phase I/IIa trial evaluated the safety, efficacy, pharmacokinetics, and pharmacodynamics of lucitanib in advanced solid tumors, including breast cancer [8]. Seventy-six patients were included and treated with doses from 5 to 30 mg. The main dose-limiting toxicity was related to the VEGF inhibition. Namely, the most common adverse events were hypertension (91%), asthenia (42%), and proteinuria (57%). Clinical activity was observed at all doses with durable partial responses according to Response Evaluation Criteria In Solid Tumors (RECIST) criteria. In patients with breast cancer and FGF aberration, 50% achieved partial responses with a median progression-free survival of 40.4 weeks. Therefore, lucitanib is a promising drug for FGF+ breast cancer.

Although the majority of data published so far concern the inhibition of FGFR1 and 2, a paper published last year provided insights on the structural analysis of the FGFR4 [17]. Normally, for FGFRs and specifically for FGFR1, there is the phosphorylation of the internal tyrosine 653 first and then the phosphorylation of the external tyrosine 654 [18, 19]. Authors of this preclinical work identified an autoinhibition "dual switch" mechanism for FGFR4 kinase domain. This means that the kinase can be less autoinhibited and achieve a partially active conformation when both the tyrosines of the activation segment are sequentially phosphorylated and stepwise relocated [17]. The identification of these mechanisms shows that FGFR4 behaves differently from other FGFRs. Authors of this paper identified four structures of the kinase domain of FGFR4, in its apo-form and combined with different small-molecule inhibitors [17]. The two apo-FGFR4 kinase domain structures present an activated segment comparable to an autoinhibitory segment observed of the hepatocyte growth factor receptor kinase but different from the other FGFR kinases [17]. The observation of molecular interactions between FGFR4 and different types of kinase inhibitors such as the type I inhibitor dovitinib and the type II inhibitor ponatinib might potentially lead to the design and development of FGFR4 inhibitors for breast cancer [17].

Such an observation may be even more interesting if we consider that resistance to first-generation FGFR kinase inhibitors may occur. Resistance is usually induced by selection for mutant kinases unreceptive to the drug action or by upregulation of compensatory signaling pathways [20–22]. Specifically, resistance to FGFR inhibitors can occur through mutations in the FGFR gatekeeper residue [23–25].

In this context, it is worth mentioning another paper published in 2014 on the development of two selective, next-generation covalent FGFR inhibitors, the FGFR irreversible inhibitors 2 and 3 [26]. These two drugs inhibit the proliferation of cells dependent upon the gatekeeper mutants of FGFR1 or FGFR2, which cause resistance to first-generation FGFR inhibitors [26]. Because of the cocrystal structure of FGFR4 with FGFR irreversible inhibitor 2, a "Asp-Phe-Gly (DFG)-out" covalent binding mode has been displayed. FGFR irreversible inhibitor 3 – due to the conformational flexibility of the reactive acrylamide substituent – covalently inhibits both the EGF receptor (EGFR) and FGFR by targeting two different cysteine residues. Moreover, crystal structures of FGFR irreversible inhibitor 3 bound with FGFR4 V550L and EGFR L858R explain the dual FGFR and EGFR targeting by FGFR irreversible inhibitor 3. Therefore, this study – besides showing the potential of a kinase inhibitor able to covalently target different cysteines within the ATP-binding pocket – highlights the importance of covalent FGFR inhibitors in overcoming resistance to this class of drugs.

Conclusion

The FGFR pathway – besides being involved in several physiologic processes – has a paramount role in many tumor types, including breast cancer. In the era of personalized medicine, it is very important to understand the mechanisms through which the FGFR pathway drives the disease. Also, it is even more important to understand how to capitalize upon the FRGF inhibition in the treatment of breast cancer. Two of the main goals of the next clinical trials with these compounds should be the better identification of patients with FGFR pathway-amplified tumors who are more likely to respond to FGFR inhibitors and the development of new FGFR inhibitors able to overcome resistance to first-generation FGFR inhibitors.

Key Points

1. Aberrant FGFR signaling is known to be involved in the pathogenesis of breast cancer.
2. FGFR targeting has improved over the last years due to the development of novel agents inhibiting FGF or FGFR, especially in breast cancer with FGF aberrations.
3. Right now, there is increasing interest in developing new FGFR inhibitors able to overcome resistance to first-generation FGFR inhibitors.
4. The selection of patients who might derive the greatest benefit from FGFR inhibitors is paramount.

Integrating Next-Generation Sequencing Data in Trial Design

71

Giuseppe Curigliano, Angela Esposito, Marzia Locatelli, and Carmen Criscitiello

71.1 Introduction

The understanding of the central role of the *ERBB2/HER2* gene, amplified in approximately 15–20% of breast cancer, has altered the natural history of this aggressive subtype of breast cancer with the development of therapies directed against the HER2 receptor, such as trastuzumab, lapatinib, pertuzumab, and trastuzumab-DM1. There is an exciting array of experimental breast cancer therapies directed against novel targets that are currently in clinical development. These investigational agents are likely to be effective for small subsets of breast cancers with specific "driver mutations." The ability to perform comprehensive molecular profiling of individual tumors has rapidly expanded over the last few years, as the cost DNA sequencing technologies that allow for targeted multiplex "hotspot" mutation testing or deeper targeted exome and whole genome DNA sequencing has become cheaper than traditional Sanger-based DNA sequencing methods. New DNA sequencing technologies require relatively limited quantities of fresh or archived paraffin-embedded or snap frozen tumor tissue and provide rapid turnaround of sequencing results within a few weeks or less. These technological advances allow for the prospect of point-of-care molecular profiling that can be used to guide the development of personalized breast cancer medicine therapy. For an international collective of academic breast cancer researchers, this provides an unprecedented opportunity to identify patients with rare "driver" molecular alternations that are candidates for proof-of-concept clinical trials with matched targeted therapy. The aim of this report on molecular profiling is to review the known recurrent molecular alterations in breast cancer that are potentially amenable to investigational targeted therapy, to provide an overview of the existing technological platforms for molecular profiling and ongoing or planned institutional/national screening initiatives, and to outline a vision for molecular screening that may be integrated into the future activities of breast cancer research.

71.2 Background and Rationale

Personalized medicine and new drug development. The "oncogene revolution" has led to an explosion of molecularly targeted therapeutics in preclinical and clinical development over the last decade [1]. It is estimated that there are more than 800 targeted anticancer therapies currently in various stages of clinical development. Disappointingly, historical data indicate that only 5% of these investigational therapies will ultimately progress to registration for widespread use. These high attrition rates have multiple causes, including lack of efficacy and excessive toxicity [2]. In particular, when patients are selected for phase III trials based on histopathology alone, a targeted drug with a 5–10% single-agent response rate runs a high risk of failure [3]. Recent efforts to systematically sequence cancer genomes have revealed that individual tumors frequently harbor multiple "driver" somatic mutations that confer growth advantage and positive selection [4].

The increasing identification of specific somatic mutations and other genetic aberrations that drive cancers leaves us on the threshold of a new era of "personalized cancer medicine," in which specific biomarkers will be used to direct targeted agents only to those patients deemed most likely to respond. The potential medical, scientific, and economic benefits of such a personalized approach to cancer therapy are immense and self-evident. Yet despite some important advances, only a limited number of approved targeted agents have had their approvals predicated on specific biomarkers of sensitivity or resistance. The premises behind personalized cancer medicine include the following: (i) genetic aberrations exist in human malignancies; (ii) a subset of these aberrations, often present

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_71

across multiple cancer types, have functional relevance as "drivers" for oncogenesis and tumor progression; (iii) such genetic aberrations are potentially "druggable" targets; and (iv) there are tolerable medicinal compounds that can effectively modulate such targets [5]. A key requirement of this new, personalized approach to anticancer therapy is that specific patients must be matched to a particular drug or combination of drugs. Molecular profiling of tumors to identify somatic mutations and/or other genetic aberrations are examples of enrichment strategies to assist in matching patients to drugs or treatments that have gained increasing interest in the oncology community [6]. The true merits of such personalized medicine strategies remain to be established. However, proof-of-concept clinical trials that establish the value of matching targeted treatments to rare molecular alterations in breast cancer and other malignancies are beyond the scope of any single pharmaceutical sponsor, cancer treatment facility, or national cancer agency and will ultimately require international collaboration. Recent examples demonstrate that sequential testing of infrequent genomic alterations to identify candidates for clinical trials with matched targeted is inefficient, expensive, and wasteful of scarce archived tumor tissue resources. Comprehensive molecular screening programs, which provide simultaneous testing of multiple biomarkers early in the course of a patient's natural history of disease, are most likely to advance personalized cancer medicine.

Genomic alterations in breast cancer. Somatic mutations are responsible for approximately 90% of breast cancers. Although data from comprehensive, large-scale breast cancer DNA sequencing projects are still awaited [7], key features of the genomic breast cancer landscape have begun to emerge. First, although multiple regions of copy gain are observed, none occurs as frequently as 17q12 which harbors *ERBB2/HER2*; second, there are high-frequency somatic point mutations in three "gene mountains" [5]—*TP53* (44%), *PIK3CA* (26%), and *CDH1* (19%)—but low-frequency recurrent point mutations (<5%) are also seen in genes that are validated drug targets in other types of cancer (i.e., *KRAS*, *BRAF*, and *EGFR*); third, genes with somatic point mutations are also frequently regions of copy number gain in independent tumor samples (i.e., *PIK3CA*, *ERBB2*), highlighting their importance as oncogenes; and fourth, point mutations are observed in multiple components of a signaling pathway at a higher rate than expected by chance alone (i.e., *PIK3CA*, *PTEN*, *AKT1*) indicating the relevance of the signaling pathway as a therapeutic target in mutated tumors. Additional data from large-scale sequencing projects, such as The Cancer Genome Atlas (TGCA) and the International Cancer Genome Consortium (ICGC), should provide additional insight with regard to the characteristic genome alterations that define the intrinsic molecular subtypes of breast cancer.

71.3 Molecular Screening Programs

Clinical application of targeted genomic sequencing. Recent advances in DNA sequencing technology allow for rapid testing of multiple hotspot mutations using limited quantities of tumor DNA isolated from archival paraffin-embedded tumor material at an affordable cost [8–10]. Studies by Thomas et al., MacConaill et al., and Dias-Santagata et al. examined between 250 and 1000 individual tumor specimens for 120–400 mutations in 13–33 known oncogenes and tumor suppressor genes. These studies found at least one mutation in 30–37% of tumor samples. Recently, Sequist et al. published their experience at Massachusetts General Hospital (MGH) with molecular screening of 552 non-small cell lung cancer patients using the multiplex PCR-based SNaPshot assays, which detect ~50 mutations and 14 genes, and FISH for ALK translocations [11]. They identified ≥1 mutation in 51% of patients who underwent successful profiling and directed 70 (22%) of 353 patients with advanced disease to a genotype-directed therapy. There are two reported studies that have investigated if therapy matched to molecular profile (MP) improves outcome. Von Hoff et al. conducted a study of matching treatments to MP in 86 patients across nine different centers in the United States [12]. Only 66 patients proceeded to MP, wherein 64 targets were examined using a combination of immunohistochemistry (IHC), FISH, and gene expression microarrays. Each aberration was matched to a predefined treatment. In 18 of 66 patients, they demonstrated progression-free survival (PFS) for matched treatment to be 1.3 times greater than PFS for the treatment patients received immediately prior. Tsimberidou et al. performed molecular analysis on 1283 patients, with success in 1144 (89%) [13]. They used polymerase chain reaction (PCR), fluorescence in situ hybridization (FISH), and immunohistochemistry (IHC) in examining 11 separate molecular aberrations. In their cohort, 40% of patients had at least one aberration. They matched each aberration to a targeted treatment when available and demonstrated that patients who received matched targeted therapy had better response rates and improved time to treatment failure.

Molecular screening platforms. The advantage of multiplex PCR-based platforms such as Sequenom OncoCarta or OncoMap and Applied Biosystems SNaPshot assay is that they provide excellent coverage of frequently mutated "druggable" oncogenes when mutations cluster in a limited number of DNA sequence regions, such as *KRAS* (nine bases account

for >99% of all mutations), *BRAF* (15–18 bases account for >90% of all mutations), and *PIK3CA* (12–15 bases account for >80% of all mutations). However, for clinically relevant tumor suppressor genes, such as *TP53*, *PTEN*, *BRCA1*, or *BRCA2*, where mutations are more widely distributed across a much larger DNA coding region, the ability to detect mutations is limited to a few selected hotspots. In addition, the published molecular screening panels using these platforms are only able to detect known base-pair substitutions and limited deletions or insertions (indels) and gene amplification. They do not include translocations, larger indels, or novel base-pair substitutions. The Sequenom MassARRAY Analyzer has developed methods to evaluate copy number variation (CNV); however, this has not been validated for point-of-care molecular profiling using human tumor samples.

Next-generation sequencing. Sequenom, SNaPshot, and other PCR-based multiplex assays are constrained by bandwidth and throughput. Next-generation sequencing (NGS) refers to technological platforms that allow for massive parallel sequencing of millions of DNA templates. "Second"-generation deep sequencing refers to clonal amplification of DNA templates on a solid support matrix followed by cyclical sequencing with short reads. These instruments are currently used to sequence entire genomes, exomes, transcriptomes, and methylomes that often require weeks for sample template preparation, sequence generation, and data analyses. As a result, their use is largely confined to large genome centers. Since "second-generation" DNA sequencing instruments are not employed in diagnostic settings, additional validation of potential candidate mutations is required using clinical-grade sequencing assays in certified diagnostic laboratories. The advent of "third"-generation sequencers such as Pacific Biosciences PacBio RS and Life Technologies' Ion Torrent Personal Genome Machine (PGM) provides increased speed of sequencing due to their use of sensors that detect nucleotides as they are added to DNA molecules in synthesis, although parallelization and machine throughput currently are much lower than with second-generation technologies. In addition to the Ion Torrent PGM, other so-called "bench sequencing" machines have recently been released by Illumina (MiSeq) and Roche/454 (GS Junior), which are moderate throughput platforms with fast run times, long DNA reads, and automated library preparation that are well suited to clinical applications. The appeal of these low-cost (≤125,000€ per instrument) "bench sequencing" platforms is that they offer the opportunity to comprehensively test a large targeted panel of relevant cancer genes (1000 or more) with 30–50× or greater coverage to identify rare (<5% prevalence) mutations and copy number alterations that are potentially relevant to clinical care with a rapid turnaround time to results of 1 week or less. One of the major obstacles to NGS for cancer diagnostics is the ability to assess DNA extracted from limited formalin-fixed paraffin-embedded (FFPE) material, such as archival tumor blocks or small core tumor biopsies. Preliminary experience suggests that NGS is feasible from FFPE core tumor biopsies, although the quality of DNA isolated from archival tumor material that is routinely stored for >5 years and the robustness of methods of sequence enrichments remain questionable.

Ongoing molecular screening programs. Recognizing that cancer genome sequencing is likely to be integrated in routine clinical decision-making in the near future, many leading cancer research institutions and national cancer agencies have recently launched or are soon to launch broad-scale molecular screening programs for solid tumors, including breast cancer [14]. Massachusetts General Hospital (MGH) has implemented a phased rollout of the SNaPshot testing (which now includes ~120 mutations in 16 oncogenes) using archival tumor tissue in four tumor types: lung, colon, breast, and glioblastoma multiforme (GBM). The Vanderbilt-Ingram Cancer Center (VICC) also initiated a similar program of SNaPshot screening of archival tumor tissue in non-small cell lung cancer and melanoma in 2010 including ~40 mutations in 6–8 genes. They integrated the molecular screening results into the patient's electronic medical record. Their "My Cancer Genome" (www.mycancergenome.org) website includes information about common activating mutations in "druggable" oncogenes and includes links to clinical trials with molecular selection based upon molecular profiling. In July 2011, they expanded their program to include PI3-kinase pathway-specific mutation panel for breast cancer. The Dana-Farber Cancer Institute (DFCI) in partnership with the Brigham and Women's Hospital has recently announced an ambitious USD43 million program (PROFILE) to perform mutation profiling using OncoMap (which includes ~470 mutations in 41 genes) in selected tumors, including colon, lung, breast, and some sarcomas and leukemias. Their project will include patients with early-stage and advanced disease, linking genomic information with clinical outcomes and response to matched targeted therapies. It has been estimated that the program will include up to 10,000 patients annually [14]. In Canada, the Ontario Institute for Cancer Research (OICR) and Princess Margaret Hospital (PMH) opened a pilot feasibility with biopsy of metastatic lesions involving patients with advanced solid tumors for profiling using the Sequenom OncoCarta (v1.0) and the third-generation NGS platform PacBio RS analyzer for the same 19 genes as are included on the OncoCarta v1.0 panel. The initial results for the first 30 patients accrued were presented at the 2011 AACR-NCI-EORTC Molecular Target and Cancer Therapeutics Meetings [15]. PMH will soon launch its own internal program entitled the Integrated

Molecular Profiling in Advanced Cancers Trial (IMPACT) to perform mutation profiling using a customized Sequenom panel that includes ~277 mutations in 25 genes for patients with advanced non-small cell lung cancer, colorectal cancer, ovarian cancer, and breast cancer and patients considered for phase I clinical trials. The IMPACT study will initially include 500 patients annually and will be expanded to include additional disease sites and NGS technology.

Investigators at the University of Michigan also recently published their pilot experience with real-time high-throughput whole-exome sequencing for two patients enrolled in the MI-ONCOSEQ protocol [16]. They successfully performed whole-exome sequencing of fresh tumor biopsies from two patients—with colorectal cancer and melanoma—on the Illumina HiSeq platform and reviewed the results at a sequencing tumor board within 4 weeks from the time of tumor biopsy. There are plans to perform deep whole-exome sequencing of approximately 100 patients with advanced solid tumors per year, with the aim of matching patients to investigational clinical trials with targeted therapies. In Europe, there are also molecular screening programs that are underway. At the Institut Gustave Roussy (IGR) in Paris, the ongoing Molecular Screening for Cancer Treatment Optimization (MOSCATO) clinical trial protocol will perform molecular profiling using array comparative genome hybridization (aCGH) and Sanger sequencing for selected mutation hotspots in 600 patients over 3 years who are candidates for phase I clinical trials. Similarly, the ZAFIR01 clinical trial protocol at IGR will perform aCGH and targeted Sanger sequencing (PIK3CA and AKT1) in 400 patients with advanced breast cancer who undergo tumor biopsies for molecular screening. Cancer Research UK has recently launched the "Stratified Medicine Program" across seven cancer research hospitals in the United Kingdom which will perform molecular profiling for ~20 alterations in eight genes using archival tumor material from 9000 patients with advanced melanoma and breast, prostate, ovarian, colorectal, and non-small cell lung cancer over 2 years. The details of the platform that will be used for molecular profiling have not been publicly disclosed. In the Netherlands, hospitals from Amsterdam, Rotterdam, and Utrecht have launched a molecular screening to perform next-generation sequencing of fresh tumor biopsies from patients who are candidates for phase I clinical trials. Approximately 1200 patients will be enrolled over the next 3 years, with plans to profile approximately 2000 genes per patient using targeted sequencing on the Illumina HiSeq platform. The Breast International Group is also running a molecular screening program in metastatic breast cancer named AURORA project. AURORA has two broad purposes: (1) The first is to analyze breast cancer samples using techniques including but not limited to targeted DNA sequencing and RNA sequencing, in order to better understand the genetic aberrations related to breast cancer. This part of AURORA could help us understand breast cancer disease evolution (this will be done in all patients) and determine why some patients respond well to a certain treatment while others don't (this will only be done in a minority of patients). This may not provide you with any benefit directly, but your participation is likely to help us find answers to questions which could help to improve the treatment and/or quality of life of future breast cancer patients. (2) The second is to identify patients potentially eligible to participate in approved studies testing new therapeutic strategies based on known breast cancer-related molecular aberrations found in the breast cancer samples. Such identification is done when the aberrations of your primary and/or metastatic tumor DNA found by targeted sequencing match an ongoing therapeutic clinical trial testing a drug against the aberration. These trials might not be available at the time being, but your treating physician shall inform you in case they become available. If you are found to be eligible for an ongoing trial, your treating physician will give you more information and an additional informed consent form to sign, specific to that particular trial. Note that enrollment in one of these candidate trials is completely up to you. Please note that aberrations for which therapeutic clinical trials are available may be found only in a minority of patients. To start with, this research project will involve 1300 patients from hospitals mainly located in Europe.

71.3.1 Future Perspectives

It is likely that future clinical trials in breast cancer with targeted therapies will be conducted in molecularly defined subpopulations of disease. Advances in high-throughput DNA sequencing technology allow for screening a large number of genes simultaneously at a relatively low cost to molecularly characterize individual tumors for triage of clinical trials with targeted therapies. These molecular screening programs are rapidly being developed by large cancer research hospitals and national cancer societies in North America and Europe. It is very unlikely that a single pharmaceutical sponsor will be able to support the large-scale molecular screening programs to identify relatively rare subpopulations ($\leq$5%) of breast cancer that are amenable to clinical trials with matched targeted therapies. The existing model of sequential prescreening for individual clinical trials—with separate informed consent forms, processes of tumor material retrieval and shipping, and methods of laboratory testing and reporting—is expensive, inefficient, and not well suited to the current era of molecularly targeted drug development. We need to find new paths to access innovations to clinical research and daily practice. To ensure that continued innovation meets the needs of patients, the therapeutic alliance between patients and academic-led research should be extended to include relevant

pharmaceutical companies and drug regulators with a unique effort to bring innovation into clinical practice. We need to bring together major players from the world of breast cancer research to map out a coordinated strategy on an international scale, to address the disease fragmentation, to share financial resources, and to integrate scientific data. The final goal will be to improve access to an affordable, best standard of care for all patients in each country.

Part XI

Investigational and Miscellaneous Approaches

Lifestyle and Breast Cancer

72

Rowan T. Chlebowski

The potential for lifestyle factors to influence breast cancer incidence, breast cancer recurrence risk, and breast cancer overall survival is being addressed in observational studies and emerging randomized clinical trials. Factors under evaluation include obesity and weight loss/maintenance, physical activity, dietary fat intake, and various dietary patterns. Studies have demonstrated that interventions targeting weight, diet, and physical activity lead to better quality of life and fewer disease and treatment-related side effects in breast cancer survivors [1–3]. While preliminary evidence suggests lifestyle factors can influence breast cancer incidence and outcome, validation studies are needed to support this concept [4, 5]. We summarize below the current evidence linking lifestyle factors and breast cancer incidence and outcome with emphasis on the findings from full-scale randomized trials and the status of ongoing randomized trials in this area.

72.1 Dietary Fat and Breast Cancer Incidence

Hypotheses were first proposed regarding a potential link between high dietary fat intake and obesity with breast cancer incidence and outcome about a half a century ago [6]. Despite the dozens of observational studies addressing the issue of lifestyle influence on breast cancer incidence and outcome, the findings have been mixed [4, 7–9]. In addition, level I evidence from the randomized clinical trial setting is still lacking. The need to obtain such evidence regarding the role of dietary fat intake on breast cancer incidence has been recently addressed in the Women's Health Initiative Dietary Modification (DM) Trial conducted at 40 US clinical centers [10]. Postmenopausal women between the ages of 50 and 79 years were eligible if they had no previous breast cancer, had a dietary fat intake >32% of total energy at baseline assessment, and additionally had a mammogram not suspicious for cancer. Body weight and height were serially measured. Mammogram screening was serially performed [11].

The dietary goal of the low-fat dietary program was to reduce fat intake to 20% of total energy and increase vegetable, fruit, and grain intake [12, 13]. Caloric restriction and weight loss were not targets of the intervention. The intervention was delivered by centrally trained nutritionists using a previously developed low-fat eating plan [13]. In the first year, there were 18 group visits with quarterly visits thereafter.

A total of 48,835 postmenopausal women were randomized. The intervention was successful in that dietary fat significantly decreased from 32% calories from fat to 20%, while fruit, vegetable, and grain intakes were significantly increased. However, the difference in fat intake between dietary and control group participants was somewhat less than called for in the study design. An additional methodology issue was that when the trial was designed in 1992, the time of the definitive analyses was based on a predetermined follow-up period, rather than on a specified number of events as conventionally done today. However, as full accrual took 1 year more than planned, the analyses were subsequently performed with about 1 year less follow-up. Of interest, although not an intervention target, women following a low-fat eating plan can lose weight, and there was a 3.2 pound, statistically significant difference in weight with lower weight seen in the dietary versus control group women and a difference maintained throughout the 8.3 years of dietary intervention [10].

When the study was reported at the end of the 8.3 years of dietary intervention, of the 1727 women diagnosed with invasive breast cancer, there were fewer cases seen in the dietary group (HR 0.91, 95% CI 0.83–1.01), but the difference was not statistically significant ($P = 0.07$) [10]. In subgroup analyses, women in the highest quartile of dietary fat intake at baseline experienced a statistically significant lower breast

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_72

cancer incidence in the dietary comp group. Breast cancer mortality was also somewhat lower for women diagnosed in the dietary group with 27 versus 53 deaths, respectively (HR 0.77, 95% CI 0.48–1.22). However, the difference was not statistically significant. Despite the borderline results, this trial is considered negative and does not establish an influence of a low-fat dietary pattern on breast cancer incidence.

After the dietary intervention period ended, all contact with study nutritionists ended. There was interest to see if a statistically significant reduction in incidence would emerge with longer post intervention follow-up. However, with longer follow-up any signal for dietary effect on breast cancer incidence was lost [14]. Analyses suggesting a differential dietary effect during the dietary intervention period compared to the post intervention period have led to interest in conducting additional, secondary analyses focused on the breast cancer cases in the dietary and control group diagnosed during the dietary intervention period examining dietary influence on deaths from and after breast cancer including all 48,835 participants measured from randomization and breast cancer overall survival (breast cancer diagnosed during the dietary intervention period but followed through 2015) measured from diagnosis. These results, presented in abstract form, were suggestive of a favorable influence of the dietary intervention on breast cancer overall survival for cases diagnosed during the dietary intervention period [15]. These findings are currently undergoing peer review.

A second primary prevention trial entered 4690 women between the ages of 30 and 65 years with mammographic density >50%. Women were randomized to a lifestyle intervention designed to reduce fat intake to 15% of total calories and increase carbohydrates or to a control condition. A significant reduction in fat intake was seen. However, the dietary intervention had no influence on invasive breast cancer incidence (HR 1.19, 95% CI 0.81–1.55) [16].

72.2 Dietary Patterns Including the Mediterranean Diet and Breast Cancer

More recently, observational studies have examined the influence of various dietary patterns on breast cancer incidence and recurrence risk. A general consensus identifies several dietary patterns including western/unhealthy (incorporating high red processed meat, potatoes, sweets, high dairy) or prudent/healthy dietary patterns (high fruit and vegetable intake with poultry, fish, low-fat dairy, and whole grains). A Mediterranean dietary pattern generally follows a prudent guideline with an olive oil emphasis. Dietary quality scores have been developed to facilitate studies of associations with clinical outcome.

Studies examining associations between Mediterranean diets and breast cancer have provided mixed results [17–20]. The European Prospective Investigation into Cancer and Nutrition (EPIC) cohort used the adaptive Mediterranean diet score (arMDS) [21] and found women with high adapted Mediterranean diet score had lower breast cancer risk (P = 0.048) [19], while other observational studies find no such associations [17, 20]. A review citing more recent studies identified five prospective cohort studies and eight case-control studies evaluating Mediterranean diet association with breast cancer risk. Pooled results identified a ten percent lower breast cancer incidence with higher Mediterranean diet intake in the case-control studies, but no association was seen in pooled results from the more reliable prospective cohort studies [22].

Despite such mixed results, interest in the Mediterranean diet and invasive breast cancer association was heightened by the results of secondary analyses performed in the Prevencion con Dieta Mediterranea (PREDIMED) study investigating a Mediterranean diet in a randomized trial in 4282 women aged 60–80 years at high cardiovascular disease risk. Participants were randomized to a Mediterranean diet supplemented with extra-virgin olive oil, a Mediterranean diet supplemented with mixed nuts, or a control diet "advised to reduce dietary fat." After 4.8 years of follow-up, there were 45 incident breast cancer cases with statistically significantly fewer cases seen in the Mediterranean diet with extra-virgin olive oil group (HR 0.32, 95% CI 0.13–0.79) [23]. While the control group was advised to reduce dietary fat, control group counseling was limited, and control group participants did not reduce fat intake substantially. While the numbers are small and this was a secondary analysis, this is the first randomized clinical trial demonstrating an effect of a dietary intervention on breast cancer incidence.

72.3 Comprehensive Lifestyle Behaviors and Breast Cancer

In addition to studies of specific nutrients and dietary patterns, recent studies have examined whether adherence to more comprehensive cancer prevention guidelines is associated with cancer incidence and outcome in prospective cohorts. In the Women's Health Initiative Observational study, the association between the American Cancer Society (ACS) nutrition and physical activity cancer prevention guideline score was associated with risk of incident cancer. The ACS cancer prevention guideline score includes four behavior-associated components: body weight, physical activity, diet, and alcohol consumption [24]. Behaviors least consistent with a recommendation were scored as 0, mid-level concordance were scored as 1, and behaviors that met criteria were scored as 2. While

smoking is not included in the ACS nutrition and physical activity cancer prevention guideline, it was nonetheless considered in a stratified analysis. With 8632 incidence cancers and 2356 cancer deaths, highest ACS guideline scores were associated with a 17% lower risk of any cancer, 22% lower risk of breast cancer, 52% lower risk of colorectal cancer, and 27% lower risk of all-cause mortality with all findings statistically significant [25].

The World Cancer Research Fund/American Association for Cancer Research (WCRF/AACR) published eight nutrition-related recommendations for cancer prevention. Adherence to these recommendations was investigated for association with breast cancer incidence, overall survival, and by hormone receptor subtype in the Swedish Mammogram Cohort of 31,514 primary postmenopausal women [26]. With a score based on adherence to recommendations for body weight, physical activity, energy density, plant foods, animal foods, alcohol drinks, and dietary supplements for a score ranging from 0 to 7, during 15 years of follow-up, women meeting 6–7 recommendations had a 51% lower risk of breast cancer compared to those meeting two or less recommendations (95% CI 0.35–0.70). The association was strongest for estrogen receptor-positive/progestin receptor-positive subtypes, while estrogen receptor-negative/progestin receptor-negative subtypes were associated with adherence to recommendations regarding plant and animal food intakes. Taken together, such reports provide a sound basis for intervention strategies targeting a comprehensive range of recommendations rather than focus on individual nutrients.

72.4 Breast Cancer and Obesity

Obesity is a major health problem with over 68% of adult women in the USA currently being overweight or obese [27]. Obesity has been consistently associated with higher breast cancer risk in systematic reviews and meta-analyses of observational studies with about 20% higher breast cancer incidence in obese women compared to women with normal weight [28]. Despite these strong associations, observational studies have largely failed to establish that adult weight loss of overweight or obese women will reduce breast cancer incidence. In recent analyses in the Women's Health Initiative (WHI), this question was revisited in secondary analyses of over 67,000 postmenopausal women participating in the WHI clinical trials [29]. Women who were overweight and obese had a higher breast cancer risk. For women with obesity class II or III (BMI >35), the hazard ratio for invasive breast cancer was HR 1.58, 95% CI 1.40–1.79. The risk was even higher for hormone receptor-positive breast cancer (HR 1.86, 95% CI 1.60–2.17), but no association with hormone receptor-negative cancers was seen. The effect of weight change during the 13 years of follow-up on breast cancer was examined in women with normal weight (BMI <25.0); those who increased their body weight by more than 5% had increased breast cancer risk compared to women who maintained their body weight (HR 1.36, 95% CI 1.10–1.65). However, in women already overweight or obese, those who decreased their body weight by more than 5% experienced no decrease in their breast cancer risk [29]. While there are other health benefits associated with weight loss for overweight or obese adult women, given current evidence, it is not possible to provide a strong public health message regarding breast cancer risk reduction benefit of weight loss for overweight or obese women.

One issue complicating evaluation of the association between weight loss and breast cancer risk is the issue of voluntary as compared to involuntary weight loss. In postmenopausal women, about one third of weight loss is involuntary. This involuntary weight loss, likely associated with other health problems, may confound analyses attempting to associate weight loss with lower breast cancer risk. Information on voluntary and involuntary weight loss has been captured in over 91,000 postmenopausal women participating in the WHI observational study. In this population, the issue of voluntary weight loss influence on subsequent breast cancer risk is being prospectively addressed.

72.5 Dietary Fat and Breast Cancer Recurrence

There has been ongoing interest in determining whether a low-fat dietary pattern could favorably influence breast cancer clinical outcome (recurrence and overall survival) of postmenopausal women with early-stage disease receiving standard adjuvant therapy. After feasibility of achieving dietary fat intake reduction in the post-diagnosis setting in a six-institution randomized trial involving 300 patients was demonstrated [30], Dr. Ernst Wynder, one of the first scientists to propose the dietary fat hypothesis, led a multicenter, randomized controlled clinical trial to evaluate whether a dietary program designed to reduce fat intake could influence breast cancer recurrence risk. A total of 2427 postmenopausal women entered the study, and during the 5-year median intervention, fat intake was reduced from 38% to 25% calories from fat ($P < 0.0001$), and body weight was reduced as well (−6.0 pounds [mean], $P = 0.005$). Relapse-free survival was the primary study endpoint and was increased by the dietary intervention with fewer relapse-free survival events seen (HR 0.76, 95% CI 0.60–0.98, $P = 0.03$ from the adjusted Cox proportional hazard model) [31].

Funding issues precluded ongoing active follow-up after the intervention ended. A report based on incomplete follow-up found the dietary influence on breast cancer incidence

fading once intervention ended. Of interest was a subgroup analysis (not protocol mandated) that found women with estrogen receptor- and progestin receptor-negative cancers had significantly greater survival in the dietary group (HR 0.36, 95% CI 0.18–0.74, $P = 0.0003$) [32].

A second phase III study evaluating dietary change and breast cancer outcome is the Women's Healthy Eating and Living (WHEL) trial. The study examined a multicomponent dietary intervention targeting increase in vegetable servings, 16 ounces daily vegetable juice, increase in fruit and fiber intake, and a target of reducing fat intake to 15–20% of calories. While fruit and vegetable intake were substantially increased, no sustained decrease in percent energy from fat was seen with intake of fat quite similar at 6 years of follow-up. No suggestion of a dietary effect was seen with breast cancer event-free survival of HR 0.96 (95% CI 0.81–1.14, $P = 0.63$) [33].

While there are several differences between the WINS and WHEL trials in terms of eligibility, study design, and dietary intervention focus [34] (Table 72.1), a hypothesis that emerged from the WINS experience was that a lifestyle change promoting a low-fat dietary pattern which is associated with weight loss could have potential influence on breast cancer recurrence risk. Obviously, such a hypothesis requires verification in a randomized trial. The importance of moving forward with clinical trials providing definitive evidence regarding energy balance interventions to reduce cancer morbidity and mortality has been recently recognized in an American Society of Clinical Oncology statement [35].

72.6 Ongoing Full-Scale Studies of Lifestyle Change and Breast Cancer Outcome

The effect of lifestyle intervention on breast cancer recurrence risk is currently under evaluation in several large randomized prospective clinical trials. The SUCCESS C is a European-based trial evaluating increased physical activity and weight loss/maintenance using a factorial design, implemented in a randomized clinical trial setting where several taxane regimens are under evaluation. As only about 1000 patients are anticipated to be randomized, only relatively large effects of the lifestyle intervention will be detectable

Table 72.1 Completed and ongoing clinical trials evaluating lifestyle interventions as addition to adjuvant breast cancer management

	WINS[a]	WHEL[b]	SUCCESS C	DIANA-5
Eligibility				
Stage	I–III A	I–II A	Node positive, high risk, node negative	High risk[c]
Time from surgery	≤12 months	≤48 months	At diagnosis	<5 years
Age	48–79 years	18–70 years	Pre- and postmenopausal	35–70
Diet at baseline	≥20% calories from fat	Any	Any	Any
Dietary intervention	Individual sessions with dietician	Telephone-based sessions	Telephone calls from lifestyle coach	Cooking classes, conferences, exercise sessions
Number of patients	2437 (3:2 randomization)	3088 (1:1 randomization)	1000 (estimate) (1:1 randomization)	1214 (1:1 randomization)
Intervention targets				
Fat	↓ to 15% calories from fat	↓ to <20% calories from fat	↓ to 20–25% calories from fat	Mediterranean macrobiotic diet
Vegetable	Increase (no target)	Increase to five servings and 16 oz vegetable juice/day	Increase (no target)	See above
Fruit	Increase (no target)	Increase to three servings/day	Increase (no target)	See above
Body weight	N/A	N/A	Weight loss target	Weight loss target
Physical activity	N/A	N/A	↑ to 150–200 min moderate PA/week	↑ to 210 min moderate PA/week
Endpoint	Relapse-free survival	Breast cancer event-free survival	Breast cancer recurrence	Breast cancer events
Primary breast cancer outcome	HR 0.76 (95% CI 0.60–0.98, $P = .63$)	0.96 (95% CI 0.80–1.14, $P = .63$)	Pending	Pending

[36]. The DIANA-5 is another ongoing trial evaluating a lifestyle intervention evaluating a Mediterranean diet and increased physical activity influence on breast cancer recurrence risk compared to a control condition. All participants will receive standard breast cancer therapy as clinically indicated [37]. The study has assigned 1208 breast cancer patients between 35 and 70 years of age with early-stage disease to the lifestyle change or control conditions. Follow-up is anticipated to be completed in 2015. Again, the sample size will only allow a large difference between randomization groups to be detected. The design features and current status of completed and ongoing adjuvant trials evaluating lifestyle interventions are described in Table 72.1.

A full-scale, randomized, controlled clinical trial evaluating a lifestyle intervention in clinical centers in North America is scheduled to begin in 2016 led by Dr. Jennifer Ligibel. The trial will enter 3500 early-stage breast cancer patients who will be randomly assigned to a lifestyle intervention targeting increased physical activity and weight loss/maintenance or a control condition. All will receive standard adjuvant chemotherapy, endocrine therapy, and radiation therapy as indicated by their disease stage and disease characteristics. The centrally mediated, telephone-based intervention has had demonstrated efficacy in a multi-institution feasibility study involving over 300 breast cancer patients where the intervention was successful in increasing physical activity and decreasing/maintaining body weight [38, 39]. A full-scale adjuvant breast cancer trial with similar lifestyle targets is proposed by the Institut Catala d'Oncologia in Spain led by Dr. Antonio Agudo. The plan is to recruit 2000 early-stage patients to a randomized trial evaluating the effects of weight control, diet change, and physical activity intervention on breast cancer recurrence.

72.7 Mechanisms of Action

Several biological models outlining potential mediating factors related to obesity and dietary pattern influence on breast cancer risk include insulin, estrogen, and markers of inflammation [4, 40, 41]. A number of relatively small trials have associated several lifestyle interventions with modest changes in these proposed mediating factors. While such work is important, we have a lesson from the tobacco and cancer experience which perhaps has relevance for study of lifestyle and breast cancer as well. For over a quarter-century, there was a concerted effort to precisely define the mechanism by which tobacco mediated the large increase in lung cancer associated with its use. However, when the focus shifted to the public health setting with development and implementation of policies and procedures designed to reduce smoking in the general population, reductions in tobacco exposure with resultant reduction in cancer risk have been seen. Likewise with lifestyle, wide-scale implementation of programs to influence favorable lifestyle choices based on influence on other diseases could well impact breast cancer incidence and outcome as well.

72.8 Physical Activity

The lifestyle factor most consistently associated with both breast cancer incidence and breast cancer outcome is physical activity [4]. A recent meta-analysis of observational studies found higher physical activity levels associated with lower breast cancer incidence in both pre- and postmenopausal women (RR 0.80, 95% CI 0.78–0.84) [42]. In terms of physical activity and subsequent breast cancer outcome, a meta-analysis from 22 prospective cohort studies was conducted with 123,574 participants and 6898 all-cause deaths [43]. Compared to those who reported low/no physical activity, high post-diagnosis physical activity was associated with fewer all-cause deaths (HR +0.52, 95% CI 0.43–0.64, $P < 0.01$) and fewer breast cancer-related deaths (HR = 0.59, 95% CI 0.45–0.78, $P < 0.05$).

Of most relevance to the management of breast cancer are studies which compare the timing of the physical activity in relation to the cancer diagnosis. Such studies directly address the clinically relevant question of whether a woman with higher physical activity after diagnosis can reduce her recurrence risk regardless of her physical activity before diagnosis. In a report from the Nurses' Health Study, 2987 breast cancer patients with early-stage disease provided self-report of physical activity prior to diagnosis (retrospectively) and about 2 years after diagnosis. Physical activity over 9 MET/h per week was associated with lower recurrence risk [44]. In a report from the Women's Health Initiative, information on physical activity was prospectively collected both before and after breast cancer diagnosis in 2076 early-stage patients. Breast cancer deaths were lower only in women who maintained an active physical activity pattern or who increased physical activity after diagnosis but not in those who are inactive in both periods or who were previously active but decreased their activity post-diagnosis [45–49]. Most recently, a prospective pooling study examined this issue in 6295 estrogen receptor-positive early breast cancer patients. Pooled and harmonized data were available on clinical and lifestyle factors adjusting for clinical factors; post physical activity was inversely associated with 5-year all-cause mortality (HR 0.81, 95% CI 0.71–0.93) (4.92 < 17.4 MET/h/week) [50].

Several moderately sized randomized trials have successfully evaluated a number of strategies to implement physical activity increase in breast cancer survivors [3, 51–53]. The ongoing full-scale trials attempting to confirm the findings from observational study reports are described elsewhere in this report.

72.9 Pragmatic Clinical Trials Evaluating Lifestyle Interventions

Pragmatic trials provide an emerging avenue for evaluation and broad implementation of medical strategies. An example of a pragmatic clinical trial involving a lifestyle intervention is the ongoing Women's Health Initiative Strong and Healthy (WHISH) trial led by Dr. Marcia Stefanick. The trial will evaluate physical activity increase with a goal of 4 h/week walking equivalent compared to a control condition on cardiovascular disease and cancer in postmenopausal women 65 years of age or older. As these women had already been consented for medical outcome follow-up as part of the WHI cohort, the recruitment was done by mail, and, following National Institutes of Health Guidance, the consent was not required from controls. In a 6-month period, the full study complement of 50,000 postmenopausal women has been randomized and the intervention is ongoing. Such studies provide an efficient and cost-effective method of evaluating lifestyle influences on chronic disease in postmenopausal women. In addition, upon determination of favorable influence on chronic disease outcomes, such a strategy provides a cost-effective method of broadly implementing a lifestyle intervention especially in individuals participating in an integrated healthcare system.

72.10 Summary

While there is much evidence from observational studies that lifestyle factors can influence breast cancer incidence and outcome, findings in such studies have limitations. An editorial by Dr. Pamela Goodwin [54] focusing on obesity outlines circumstances which could account for a noncausal association between obesity and increased risk of breast cancer recurrence such as lower compliance to cancer therapy or physician decision to reduce chemotherapy dose in obese women. Even if an effect of obesity is causally related to the adverse outcome, the effect may not be reversible. For example, in the WHI dietary modification trial, there were more progestin receptor-negative cancers in the control compared to the dietary intervention group [10]. Progesterone receptor-negative cancers have a worse prognosis, and it is not clear that changing one's dietary intake after diagnosis could reverse the finding. That is, the higher dietary fat intake may have led to a fixed adverse prognosis that is independent of subsequent lifestyle change. Thus, favorable associations with certain lifestyle practice and breast cancer incidence and outcome must be both causal and reversible to inform medical practice and public policy (Table 72.2).

Table 72.2 Obesity and breast cancer outcome: possible explanations for an association

Type of association	Effect on outcome
Noncausal	Healthy person bias, e.g., normal weight women, are destined to do better, possibly due to greater compliance, treatment tolerance, or adoption of healthy behaviors
	Less aggressive treatment of obese patients
	Presentation of breast cancer at a more advanced stage in obese women
	Other biases or confounders
Causal	Nonreversible: Obesity has affected the type of cancer that has developed, leading to a fixed biologic effect
	Reversible: Obesity affects cancer on an ongoing basis, and this impact can be reversed when weight loss occurs

Note: Weight loss would be postulated to lead to improved cancer outcomes (e.g., decreased risk of recurrence or death) only if the association is both causal and reversible
From Goodwin [54]

While ongoing randomized clinical trials are designed to provide highest level of evidence supporting lifestyle influence on breast cancer outcome, there are established other health benefits for weight loss/maintenance and higher levels of physical activity. Also, the current lifestyle strategies being evaluated, namely, increase/maintenance of 4 hours of walking equivalent per week and maintenance of normal weight or targeting 5% weight loss if overweight or obese, are achievable by many with no/little toxicity and low cost. As current evidence is suggestive of benefit of such lifestyle strategies on breast cancer outcome, while awaiting randomized clinical trial evidence, women with breast cancer should consider incorporating these activities into their daily routine. The recent American Cancer Society/American Society of Clinical Oncology Breast Cancer Survivorship Care Guideline endorses such an approach (Table 72.3) [55]. Physicians managing breast cancer patients should discuss the current level of evidence, including the limitations of such evidence, associating lifestyle decisions with more favorable breast cancer outcome.

Funding/Support

The WHI program is supported by the National Heart, Lung, and Blood Institute, National Institutes of Health, and Department of Health and Human Services through contracts N01WH22110, 24152, 32100-2, 32105-6, 32108-9, 32111-13, 32115, 32118-32119, 32122, 42107-26, 42129-32, and 44221.

The WINS clinical trial was supported by the National Cancer Institute, National Institutes of Health, Department of Health and Human Services, and the American Institute for Cancer Research.

Conflict of Interest Disclosures: Dr. Chlebowski reported being a consultant for AstraZeneca, Novartis, Amgen, Genomic Health, and Novo Nordisk, receiving

Table 72.3 ACS/ASCO Breast Cancer Survivorship Care Guideline recommendations for obesity, physical activity, and nutrition

	Level of evidence
Obesity	
(a) Should counsel survivors to achieve and maintain a healthy weight	0 (maintenance)
(b) Should counsel survivors if overweight or obese to limit consumption of high-calorie foods and beverages and increase physical activity to promote and maintain weight loss	IA, III (weight loss)
Physical activity	
Should counsel survivors to engage in regular physical activity consistent with the ACS guideline and specifically:	
(a) Should avoid inactivity and return to normal daily activities as soon as possible following diagnosis	III (avoid inactivity)
(b) Should aim for at least 150 min of moderate or 75 min of vigorous aerobic exercise per week	I, IA (aerobic exercise)
(c) Should include strength training exercises at least 2 days/week; emphasize strength training for women treated with adjuvant chemotherapy or hormone therapy	IA (strength training)
Nutrition	
Should counsel survivors to achieve a dietary pattern that is high in vegetables, fruits, whole grains, and legumes Low in saturated fats and limited in alcohol consumption	IA, III (nutrition); 0 (alcohol)

Psychological Support in Breast Cancer Patients: A Personalized Approach

73

Chiara Fioretti, Ketti Mazzocco, and Gabriella Pravettoni

It is widely recognized that a breast cancer diagnosis generates a biographic disruption in a woman [1]. The discovery of an insidious disease such as breast cancer is most of the time experienced as a life interruption creating a large gap between the life before and after the diagnosis. In this perspective, the main goal in patient's life, together with fighting the disease, becomes re-establishing the natural life balance.

This process of reconstruction is not exempt from psychological and emotional suffering. The most recent literature on the psychological consequences of cancer disease reveals that one in three patients meets the criteria for mental disorders [2]. Exploring the 4-week prevalence of mental disorders in a total sample of 5889 German patients, Mehnert and colleagues found that the prevalence for any disorder was 31.8%, including anxiety disorder (11.5%), adjustment disorder (11.1%), mood disorder (6.5%), somatoform disorder (5.3%) and others [2].

These results highlight the strong need for a psychological intervention in cancer patients, especially because of the higher 12-month mental disorder prevalence in this population (18.4%) compared to the general population (13.3%) [3], with the highest prevalence (41.6%) in breast cancer [2].

In line with these findings, Arnaboldi et al. [4] investigated the post-traumatic stress disorder (PTSD) symptoms as a consequence of breast cancer disease in the first 30 days after diagnosis and how the symptoms changed over time. Results showed that psychological symptoms in 30 days after diagnosis were anxiety (70.7%), intrusion thoughts (20%) and avoidance thinking and behaviour (19.1%). Particularly, anxiety varied over time, with a pick (76.4%) at the moment of the pre-hospital admission.

Looking at these epidemiologic data, breast cancer has important clinical implications in patients' lives: the diagnosis and the first contact with the hospital context are experienced as a traumatic event by a high percentage of women.

73.1 Supporting the Psychological Distress in Breast Cancer Patients

The psychological distress related to breast cancer is not just a matter of mental disorders. Even the patients who do not experience such disorders can feel a strong distress related to the discovery of being affected by a serious disease.

Cancer-related distress has been defined as "a psychological (cognitive, behavioural, emotional), social, and/or spiritual state that may interfere with the ability to cope effectively with cancer, its physical symptoms, and its treatment" [5]. Supporting patients' distress means to take into account their symptoms from a multifactorial point of view: physical, social and emotional. In breast cancer patients, distress is often related not only to physical symptoms but even to the personal body image perception that, together with treatments, have relational and sexual implications. For example, the hormonal alterations caused by endocrine therapies and chemotherapy direct consequences on the physiology of desire and sexual response [6]. Regarding surgical treatments, mastectomy, quadrantectomy and the more recent nipple-sparing mastectomy importantly affect body image. Thus, even though breast surgery is becoming increasingly conservative with a positive impact on psychological adjustment to disease, body image and sexuality [7], the emotional reactions to cancer, physical signs as scars and the type of treatment can still be detrimental for sexual life. In addition, side effects of medical treatments increase the patient's worries and negative emotional reactions towards her condition. Furthermore, the disruption of ovarian function and menopause due to endocrine modulators are other crucial side effects [8, 9] making pregnancy impossible [10]. The impact of this in young women

cannot always be predicted since it is strongly influenced by individual hormonal profiles and by age. However, even postmenopausal women seem to face sexual difficulties due to the effect of medical therapies, including those involving the adjuvant use of aromatase inhibitors for the treatment of early breast cancer [11].

In general, women tend to feel worries about the sexual encounter with their partner. Any impairment in breast shape and in breast sensitivity demolishes personal certainty and casts the shadow of a doubt over whether the partner will accept these changes.

Nevertheless, in women, the breast is not just part of the sexual life and the relation with the partner, but it acquires meanings due to its generative and nutritional features. The breast, in such a way, is a vehicle of life, the symbol of a femininity which is not only related to a personal image but also to the natural, social and cultural function of generating and feeding. This issue is much more evident in younger women. In fact, the increase in women's awareness of the importance of periodic breast examination, together with the improved accuracy of imaging technology, has considerably increased the number of young women of reproductive age diagnosed with breast cancer. According to these aspects, it is important to understand the specific meanings that each breast cancer woman ascribes to the disease and its consequences in order to uncover the cognitive determinants of emotional reactions and behavioural responses. In this meaning attribution process, to better tailor communication and therapeutic plans, professionals should not ignore partner's meanings associated to the disease.

In a study of Piot-Ziegler and colleagues [12], breast cancer patients described mastectomy, hair loss and other disease consequences as "threat to their body integrity", "a stigmatization" as well as an insult to their femininity. Breast removal and other body changes can bring a destabilization in patients' perception of their own bodies, negatively affecting (Piot-Ziegler et al. [12]) the establishment and the maintenance of a good social network.

In this scenario, patients' quality of life could be damaged, and scientific evidence has stressed that adopting a multidisciplinary team is the best way to re-establish it again. In this sense, professionals should adopt a biopsychosocial approach, caring for patients considering them as people acting in a context of constant changes and adaptation to the physical, relational and cultural environment [13]. In this perspective, the patient has to be considered as a system in which different components cooperate to shape an organizational entity with specific functions. Thus, physical conditions have to be taken into account together with the emotional and relational ones. At the same time, patients' needs cannot be separated from their caregivers' ones.

In a biopsychosocial point of view, the same experience of pain, for instance, can be perceived as the result of the interaction among physical, psychological and social factors. Biological factors produce the pain sensation, psychological factors contribute to the pain perception and to the cognitive and semantic consciousness, and finally social factors influence the individuals' reactions and behaviours in facing pain.

Collecting information on the different components of patient's experience is a way to improve both doctor-patient relationship and patients' clinical outcomes, increasing their adherence to treatments [14]. In fact, the link between psycho-emotional suffering and organic disease development has been amply revealed in scientific literature [15]. In the biopsychosocial model, communication is a powerful tool to investigate and deepen patient's needs. It is not just useful for collecting the patient's story but also for constructing a therapeutic path together with patients, adopting a shared decision-making process which takes into account their preferences, needs and habits.

In this domain, the subjective experience of breast cancer distress requires a specific psychological support in any different phases of the disease, from initial diagnosis to after the completion of cancer treatment.

73.2 Supporting the Diagnosis Phase: Improving Patient Empowerment

As we stressed in the first part of this chapter, the diagnosis of breast cancer is experienced most of the times as a biographic disruption by the patient [1]. Scientific evidence underlines that this phase is characterized by the highest prevalence of distress and PTSD symptoms [4]. In this sense, the psychological support in this delicate phase should aim to help the patient to manage the bad news and find resources to face the life fragmentation.

Although high state anxiety and depressive symptoms are important problems in women during and after the diagnostic process for breast disease, in many women, they can be considered as a momentary emotional condition characterized by natural subjective feelings of apprehension and tension. One of the most common errors that health professionals make is considering all the psychological natural reactions to the diagnosis as a sign of mental disorder. Sentences such as "that patient is depressed" are quite commonly used by the professional staff talking about a new breast cancer patient. From a psychological point of view, feelings of anxiety or mood swing can be considered as operational reactions to the diagnosis communication. As professionals, from a biopsychosocial point of view, it is necessary to take into account what the patient is communicating to us: she is feeling distress and she is reacting against the new condition of disease. Our role in supporting this phase is to help the patient to find the best individual resources considering her personal characteristics (personality traits, age, life goals, economic resources) and social and cultural support (significant relationships, presence of children, job position).

In this scenario of deep fragmentation and readjustment after the diagnosis, the patient is also involved in important decisions to make with her oncologist.

Box 73.1 Different experiences in decision-making on breast cancer surgery

The case of L.	The case of M.
L. is a beautiful 30 years old woman that came to the *** hospital for an oncological consultation after the diagnosis of cancer at her right breast. L. comes from a beautiful town in central Italy and is accompanied by her boyfriend. She affirms to be shocked because of her diagnosis: she's a medical student and she has always been very scrupulous with her health. In the last month after the bad new, she has visited several professionals searching for the best therapeutic option. Now she has two possibilities: the most advantageous from the oncologist point of view seems to be the mastectomy. The intervention is invasive but she will not need other therapies. The second option is a quadrantectomy: it will be less invasive and her mammary gland will be save, but she will need radiotherapy to complete the treatments. L. has a decisional dilemma: she's young and one of her main expectations from the future is to become mother. Furthermore, she has a very good relationship with her boyfriend and just before the diagnosis they were planning to get married. She has to decide between keep her breast going through heavy therapies or lose her breast undergoing a mastectomy.	M. is a 45 years old woman that came with her husband to the *** hospital after having received the diagnosis of mammary carcinoma at her right breast. After the bad new, M. decided to do the genetic test to investigate the presence of BRCA1 and 2 mutations. The test is negative. M. reveals to have been shaken for the diagnosis, but she is not new to this kind of disease. For several years she experienced this terrible disease while taking care of her best friend, who recently died for a breast cancer. She affirms to be not strong enough to face a new suffering. Although her oncologist has suggested her the opportunity to undergo a quadrantectomy considering her young age and her medical conditions, she refers to be absolutely sure that the mastectomy is the best option for her. She wants to reduce the risk of a second carcinoma and she asks for a mastectomy intervention. Furthermore, she tells that her breast has always been a problem for her: since puberty she felt pain and lack of self-confidence, especially in the sexual relationship with her husband. For this reason she also refused to breastfeed her two kids.

As we can see in the cases of L. and M. (see Box 73.1), every patient brings her own life story in medical decisions, and health professionals have to take it into account in defining and proposing the therapeutic path.

Although the two women apparently experienced a similar diagnosis, their personal and social characteristics have a great influence on their decision about the therapeutic path. L. is very young, and she is planning her life with the boyfriend. One of her main dreams is to have a baby. The fear for the physical consequences of therapies on her fertility is strong. On the other side, she would prefer to have a quadrantectomy saving her breast. On the contrary, M. appears very certain about her choice: she suffered for the recent loss of her best friend, and she wants to reduce as much as possible the risk of a second carcinoma opting for a mastectomy. Which is the most functional response that health staff can act to help the patient in this difficult choice?

During the decisional phase, the communication between the patient and the physician is a critical point: information given by all professionals involved in the care (surgeons, oncologists, nurses) have the aim to provide a clear description of the options and to facilitate the patient's accurate evaluation process which leads to realistic expectations on the final result [16].

In other words, professionals need to empower patients' role in the disease management.

Patient empowerment is defined as a social process in dealing with recognizing, promoting and enhancing peoples' abilities to meet their own needs, solve their own problems and mobilize necessary resources to take control of their own lives [17]. It refers to the need of actively involve patients in

treatment decision-making in order to promote decisions that are consistent with their values, preferences and daily life management possibilities. This shared decision-making process empowers the patient because it provides him/her with the chance of making his/her own well-discussed and well-informed choice concerning the treatment. In the specific case of breast cancer, the nature of malignant disease requires women to make difficult decisions regarding ensuing treatment, as we have seen in the L. and M. cases. Scientific evidence underlines that having relevant information not only helps cancer patients to understand the disease, but it also facilitates their decision-making and coping with the disease [18, 19].

Furthermore, patient empowerment is also a powerful instrument to face distress and life fragmentation: guided from the health staff, the patient will learn to manage information on the disease and to use them to make the best decision for their own life. This active role will provide the woman for new expectation for the future and new life goals that take into account the present condition of disease.

In this decisional context, the patient has to analyse benefits and risks of received information in short and long term, as well as the changes in her life style requested to implement the therapeutic path. The right choice seems to depend on both clinical and individual needs, as well as on patient's expectations and cognitive traits. Every woman has her own decisional style, defined as "the methodical inclination that the individual has when they face a decision making" [20]. Knowing the patient's decisional style can help professional in understanding how to conduct the encounter with the patient and the decision-making process. This will be a way to increase therapeutic alliance and the patient's adherence to the treatment.

73.3 Accompanying Patients in the Treatment Phase of the Disease: A Personalized Approach

For the majority of women facing a breast cancer, the treatment phase starts with breast surgery. As we have seen in the case of L., the two prevalent options are breast conservation surgery (with radiation therapy) and mastectomy with or without reconstruction [21]. Although both the interventions affect women's breast and body image, the psychological implication can be very different. Many women perceive mastectomy as a mutilation damaging both their body and their femininity. The psychological support, in this case, should aim to help the patient to accept the loss and the new body image. Furthermore, with the breast reconstruction, women experience a strong reduction of breast sensibility, with consequences on their intimacy and sexual relation with the partner. On the contrary, local tumour removal appears the best option in the case of early-stage breast cancer [21]. Beside the low invasiveness of conservative surgery in local tumors, several consequences are associated with the adiuvant radiation therapy, that is often needed after such a surgery: fatigue, skin changes, pain, psychological distress and interferences in daily functions [22].

Breast cancer patients are often involved in adjuvant systemic therapies causing several physical and neuropsychological symptoms [21] as pain, fatigue, nausea and vomiting, sexual problems, cognitive dysfunctions, sleep disorders, weight and appetite disorders. Scientific evidence has highlighted that reduced quality of life entails that a significant fraction of breast cancer patients is noncompliant with adjuvant therapies [23, 24].

Psychological support in this scenario strives for improving patients' decreased quality of life starting from the personal needs. In this sense, the treatment phase of disease needs a personalized approach [25, 26]: the main aim of health professionals is that of enabling patients to participate and guide their own healthcare, increasing their autonomy and self-determination. Studies assessing patients' wishes within a personalized medicine framework have underlined their need to have adequate information and permission to participate in decisions which affect them, as well as the request for receiving such information with empathy, dignity and respect, taking into account their preferences and their personal social characteristics [25]. Furthermore, studies demonstrated that when this kind of wishes is embraced, patients have better health outcomes, higher adherence to treatments and increased trust in health professionals [27]. According to the most recent approaches in medicine, therapies have to be tailored on the basis of both the biological and the molecular characteristics of the disease without ignoring the psychological and cognitive characteristics of the patients [28]. "The way in which each patient reacts to his/her illness, understands his/her clinical condition, forms an opinion about possible treatments, adheres to treatments, copes with treatment side effects, and interacts with the whole health care process adds new dimensions to human uniqueness in the same way that genetic information does" ([25], p. 685).

Other medical approaches, such as narrative medicine [29], point out the importance of considering the patients' individual life story in identifying the best therapeutic option for every specific patient [30].

In M.'s point of view, for instance, the psychological implications and the wish to reduce the risk of a secondary carcinoma are stronger than the physical and emotional impact of mastectomy. In supporting the decision-making process, oncologists have to consider M. personal characteristics: she is 45 and a mother of two children and she never felt comfortable with her breast. Although the clinical conditions would suggest the opportunity to opt for a breast con-

servation surgery, M. feels that mastectomy and reconstructive surgery are the best option for her.

Patients' psycho-cognitive traits also need to be considered by defining a personal profile of his/her specific needs and values, habits and behaviours, hopes and fears and beliefs [25].

Recently, the European Community has promoted research projects (www.p-medicine.eu) aiming to investigate the impact of personalized medicine on doctors' and patients' disease management. Questionnaires such as ALGA-C [28] have been validated in the field of breast cancer to obtain a patient's profile useful to help physicians achieve meaningful personalized care which supplements biological and genetic analysis and therapies.

73.4 After the Storm: Re-establishing the Life Balance

Substantial progress has been made in the early detection, diagnosis and treatment of cancer in the last two decades. More and more patients can now manage their disease as a chronic illness requiring long-term surveillance and, in some cases, maintenance treatment that stretches from prevention to the end of life.

Chronic cancer treatment places new demands on patients and families to manage their own care. On the other side, physicians need to manage long relationships with their patients, adjusting their care to the specific need of the patient in any phase of her life. In fact, patients undergo periodical treatments and tests, and the transition from treatments to survivorship is not exempt from emotional distress, feeling of anxiety and uncertainty [21].

Although studies highlight that quality of life improves for the majority of women [21], the need for being accompanied in this delicate transition is strong. This is the phase in which patients start to reintegrate themselves in their daily lives. In this sense, psychologists and health professionals have to encourage the retake of daily activities such as job and family activities, helping women to accept those changes that the disease inevitably brought in their lives. Once again, the therapeutic alliance has to focus on a personalized approach. If some cognitive and psychological patients' characteristics suggest to encourage a rapid separation from the "hospital world", other patients would need to be gradually accompanied in this process.

Scholars have found also that breast cancer survivors' memory and learning performance are significantly lower than the healthy control. Particularly, women undergoing endocrine therapy have weakness in initial encoding of information into working memory [31]. In the relationship with their patients, professionals have to inform about cognitive impairments due to hormonal therapies. In this sense, psycho-oncologists can address recommendations on cognitive rehabilitation strategies and help the patient to find compensatory strategies. In particular, it is important to limit distractions and multi-tasking at the time of learning, to suggest semantic or visualization strategies that emphasize deeper information processing levels, to reduce environmental cognitive load and to educate to self-monitoring for inattention and distraction [31].

In this transition to the survivorship, women could also need a support in the reconstruction of their routine with significant others: children, partners and parents. Caregivers' involvement in this transition is warmly recommended.

Despite the progress in diagnosis and treatment of breast cancer, many women face a disease progression and go through the transition from the active treatment to the palliative care. In this case, the psycho-oncological support has to take into account the individual need of every woman. The patients' emotional distress has to deeply consider in order to evaluate the boundary between an existential suffering due to the poor prognosis and a psychological disorders such as anxiety or depression [21]. Once again, a personalized approach will lead professionals to help the patient to focus on specific goals about quality of life, pain management and relationship with significant others, starting from the personal needs.

73.5 New Challenges in the Psychological Support of Breast Cancer

73.5.1 Managing Genetic Risk Information

Protocols and clinical indications in the field of breast cancer therapies are constantly developing. Similarly, psychological support in breast cancer has to accept the challenge and provide for the integration of new patients' needs in theoretical and intervention models.

Undoubtedly, one of the big advances in breast cancer diagnosis has been the identification of BRCA1 and BRCA2 mutation: researchers have found that approximately 10% of breast cancers are due to hereditary disposition. Breast cancer patients and healthy women have the opportunity to undergo genetic counselling to receive information on their cancer risk and psycho-decisional support to be guided in the evaluation of the available treatment options, their risks, costs, benefits and personal values and priorities.

Although identifying individual risk factors may allow the development of personalized interventions decreasing the probability of disease development, not all women are "information seekers", and some of them could prefer to not undergo genetic testing. Risk perception is extremely subjective and can depend on several factors as familiar story knowledge, patient activation, family communication issue, trust in medical sciences and physicians, personal cognitive

and thinking styles. Furthermore, studies identified copious factors predicting psychosocial distress in genetic testing process [21]. Among these, the experience of cancer in a family member seems to be a high-risk factor for emotional distress, as well as psychological traits as coping style and resilience and socio-demographic factors, such as having children.

In this domain, genetic testing protocols should involve psychological support across all the decisional phases. Psycho-decisional support should aim to investigate woman's decisional process focusing on individual and familiar issues.

We recommend to involve psychologists in genetic counselling in at least two phases of the decision-making process: when the woman is proposed to undergo genetic testing and when she receives test results.

73.5.2 Breast Cancer and Pregnancy

A second current big challenge in the field of breast cancer treatment and psychological support is the management of cancer diagnosed during pregnancy. The rate of breast cancer diagnosed during pregnancy, although rare, has increased in the last years also because of the continuous growth of the age of women pregnancy [32]. In this sense, the main goal of professionals and researchers in the field is to provide treatments as similar as possible to that offered to nonpregnant young patients with breast cancer.

In the delicate transition to motherhood, Henry et al. [33] found that physiological distress due to pregnancy is prone to become long-term distress in breast cancer patients because of the several worries and fears related with a cancer diagnosis.

When providing psychological support in breast cancer patients during pregnancy, many factors have to be considered. Professionals and patients face a big number of decisional dilemmas that have to be investigated starting from the individual needs of every woman. Among these, scholars and clinicians highlight the need of evaluating a hypothetic pregnancy interruption, the selection of the best surgery and the timing for breast reconstruction, the possibility of the sentinel lymph node biopsy as well as the decision about following therapies.

Although scientific evidence underlines that abortion does not improve survival of breast cancer patients [34], termination of pregnancy is often suggested, and women are asked to deal with the quandary of deciding between the pursuit of their own life and that of their children [33].

In defining treatment and surgery options, the gestational age is the most important factor to take into account [35]: in the first trimester, exposition to radiations and treatments has potential critical effects on the foetus that lead to not recommend them. Similarly, professionals suggest the delay of treatments in patients very close to term. In these cases, the biographic disruption due to the diagnosis of breast cancer has to consider both the implications on the women's life and the construction of the maternal role. Psycho-decisional support is strongly recommended to help women face decisional dilemmas about how to combine disease treatments and their children needs. For instance, in deciding between breast-conserving surgery and mastectomy, women have to consider that postsurgical radiation therapy is avoided [35] because of the high risk of malformations. Furthermore, breastfeeding is contraindicated in breast cancer patients undergoing chemotherapy, especially because of the cytotoxic agents detected in breast milk [36]. Given that breastfeeding is culturally and socially defined as the best healthy option for newborn nutrition, mothers might experience feelings of guilt and failure [33] increasing the level of distress. However, false beliefs on breastfeeding may be spread among breast cancer patients. Since any breast cancer patient's condition is different even in the possibility of breastfeeding, the patient's beliefs that breastfeeding after the treatment can be dangerous either for the newborn or for the possibility of cancer recurrence have to be considered and discussed with the patient, in order to avoid any possible false beliefs and consequent low-quality decision-making.

In supporting pregnant breast cancer patients, a particular attention has to be dedicated to confidence towards the health staff professionals: in doctor-patient relationship, many ethical frameworks can emerge. Professionals have to care for women and for their children, and opinions may differ about benefits and risks of decisions on medical treatments. Professionals may feel the double responsibility for women's and foetus's lives, facing high distress.

In this sense, psychological support to professionals in emotional management and support to medical decision-making are recommended too. The best option would be providing patients with a personalized approach through the implementation of a multidisciplinary team and the coordination of communication among professionals.

HIFU and Radio Frequency as Alternatives to Surgery

74

Franco Orsi and Giovanni Mauri

74.1 Introduction

Although the incidence of breast cancer is increasing in the last 10 years, the mortality rate was reduced by 20% due to the earlier tumor diagnosis (more and more frequently non-palpable intraepithelial neoplasia) and to improved therapies, tailored to each single patient [1–3].

Over the last four decades, the breast cancer surgical and nonsurgical treatments have undergone continuous and deep changes thanks to the improvements in diagnostic imaging developments and the diffusion of wider screening programs that have allowed the detection of subclinical small tumors [4].

Regarding the local treatments, the breast-conserving surgery has been progressively validated as a safe and effective alternative to radical mastectomy, for those patients diagnosed with an early-stage breast cancer [5–8]. The first world trial on this new concept began in Italy at the Milan Cancer Institute in 1973. It reported the same long-term survival rate with acceptable rates of local relapse between breast-conserving surgery (quadrantectomy and complete axillary dissection followed by radiation therapy) and radical mastectomy, but with a much better cosmetic result in the first group of patients [5]. Few years later, another large trial in the USA obtained the same result [8].

In the recent years, there has been a further trend to progressive reduction in invasiveness of local treatments, aiming to achieve the same result as standard options, but with less morbidity and a better quality of life that opened up new horizons toward minimally invasive techniques in several different fields of oncology, such as percutaneous treatment of liver and kidney tumors [9–12]. Recently, following experience in other oncologic disciplines where they demonstrated high efficacy in achieving local control in several types of malignancies, some studies focused on application of minimally invasive image-guided ablations in breast cancer care [13–46].

Among the percutaneous minimally invasive thermal ablation techniques, the radio frequency ablation (RFA), the cryoablation, the laser ablation therapy (LA or LITT), and the microwave ablation (MWA) were investigated in early breast cancer local treatment and reported as comparably feasible and safe, but to be still considered at the investigative stage. The rationale behind these thermal ablation techniques is the absolute sensitivity of biological tissue to the heat. Every cell is supposed to die, due to protein denaturation and the subsequently coagulative necrosis, if exposed to a temperature higher than 50 °C for 4–6 min.

In this scenario, the advent of more and more precise and sophisticated imaging tools has led to a resurgence of interest in an old "noninvasive" thermo-ablative technique, based on the use of ultrasound energy. The high-intensity focused ultrasound (HIFU) is a highly precise medical procedure, which employs focused ultrasound energy to burn and destroy the tumor tissue deeply located within the body, selectively, and without harming overlying and adjacent structures within the path of the beam [47, 48].

The idea of developing an ultrasound-focused therapy based on controlled local heating phenomena was introduced by Lynn et al. in the 1940s, but the technique was not developed at that time because of inadequate imaging guidance as targeting methods. The development of the new diagnostic imaging tools, such as ultrasound, magnetic resonance, and computed tomography, has led to a resurgence of interest in HIFU therapy [48, 49].

Unlike RFA/MWA or cryoablation, which are also used to percutaneously ablate tumors, HIFU is completely noninvasive and can be used to reach tumors that are deep within the body. The presence of an adequate acoustic window for allowing for the transmission of ultrasound energy is crucial for the feasibility of this technique. Preliminary reports underlined a reduced toxicity with HIFU ablation compared with other ablation techniques because of the noninvasive nature of the procedure.

First devices widely used in clinical practice were transrectal probes, which have been used predominantly to treat prostate cancer. Extracorporeal devices are significantly larger and can be used to treat a variety of problems, most commonly intra-abdominal solid tumors. As a result, these extracorporeal devices use transducers with a longer focal length and use both US and MRI for targeting the organ.

74.2 Basic Principle of HIFU

Higher energy and intensity are used in therapeutic purpose than in diagnostic US, though HIFU principles are the same as conventional US. The main mechanisms of HIFU ablation involve mechanical and thermal effects at the level of the "focal point," where US energy is focused and concentrated.

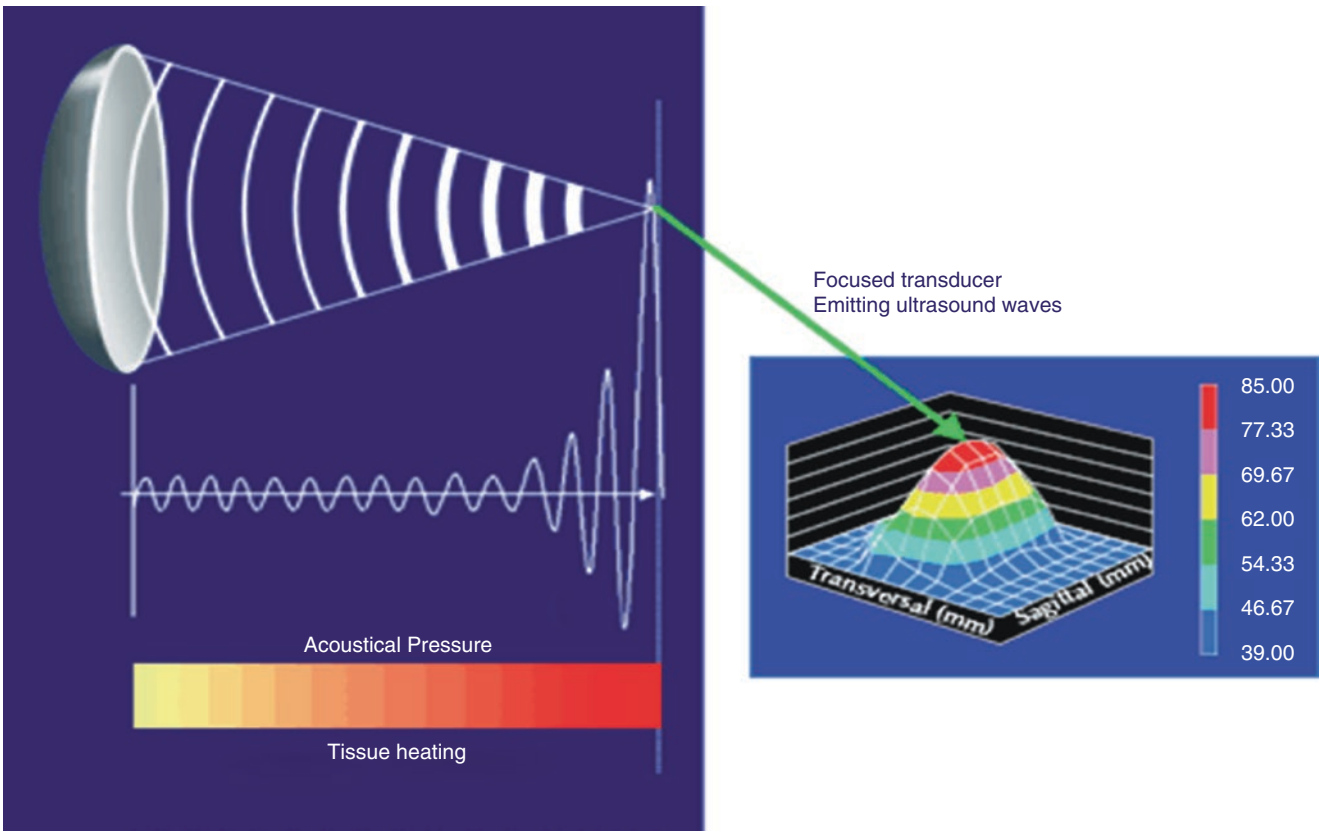
Localized heat generation due to absorption of the acoustic energy is the main biological effect in tissues where it rapidly raises temperatures from 55 to 100 °C, causing coagulation necrosis within a few seconds. The precise and well-delimited US focusing minimizes the potential thermal damage to the tissue located along the acoustic pathway, because the energy is much lower outside the focal region. Mechanical phenomena, in addition to thermal effects, are associated only at high energies and include micro-streaming, radiation force, and cavitation.

Cavitation is the most important mechanical phenomenon; it can be defined as the creation or motion of gas bubbles within an acoustic field due to alternating compression and expansion of tissue as ultrasound waves propagate through it. Thermal effects, acoustic cavitation, and vessel damage can occur simultaneously within the targeted tissue in HIFU ablation. Therefore, the coagulation necrosis induced by HIFU can be considered as the result of biological effects from a combination of heat, cavitation, and vascular destruction on tissue. Combination between imaging and technologies for local therapy has made ablative procedures more reliable and practical, allowing for safe and feasible application of HIFU treatments in clinical practice.

Clinical HIFU procedures are generally combined with magnetic resonance imaging (magnetic resonance -guided focused ultrasound = MRgFUS) or ultrasound imaging (ultrasound-guided high-intensity focused ultrasound = USgHIFU) as image guidance and treatment monitoring [47–49].

Guidance and monitoring of acoustic therapy is a crucial issue to ensure that the desired region is treated and for minimizing the possible damage to the adjacent structures.

Both MRI and ultrasound guiding methods have their advantages and disadvantages. Real-time imaging, such as US, ensures that HIFU beam targeting is maintained within the correct area throughout the procedure. MRI has the



advantage of providing temperature data within seconds after HIFU exposure (sonication). The MRgFUS procedure in clinical setting was established for the treatment of symptomatic benign uterine tumor and palliative treatment for patients with painful bone metastases.

However, MRI guidance is expensive, labor-intensive, and of lower spatial resolution in some cases, although it is superior to sonography in obese patients. Sonographic guidance provides the benefit of using the same form of energy that is used for therapy. The significance of it is that the acoustic window can be verified according to the US findings. In addition, the use of contrast-enhanced ultrasound (CEUS) can be also used for evaluating efficacy of HIFU treatment immediately after treatment.

74.3 HIFU in Breast Cancer

In the present era of conservative medicine, few studies on limited number of patients investigated the application of different minimally invasive techniques in the treatment of breast cancer [50–59]. With all the classical methods of percutaneous thermal ablation, including RFA, cryoablation, MWA, and LA, no banal complications as skin burn ulceration and necrosis, often at the puncture site; pneumothorax; moderate pain; and muscle burn were recorded.

The main reason of the very small diffusion of these methods is probably the percutaneous approach and the reported side effect if compared to the well-established surgical technique.

Today, among all the minimally invasive techniques, high-intensity focused ultrasound ablation is the only really noninvasive option available that doesn't cause any direct skin damage due to the needle insertion and doesn't use ionizing energies.

In 2001, Huber et al. described the first MRgFUS treatment in a breast cancer patient [50]. Subsequently, other authors reported their experience on MRgFUS ablation of malignant breast tumors prior to surgical resection, with the common statement that MRgFUS ablation is technically feasible in breast cancer. Complete tumor necrosis, however, was achieved in only 20–50% of patients [51–54].

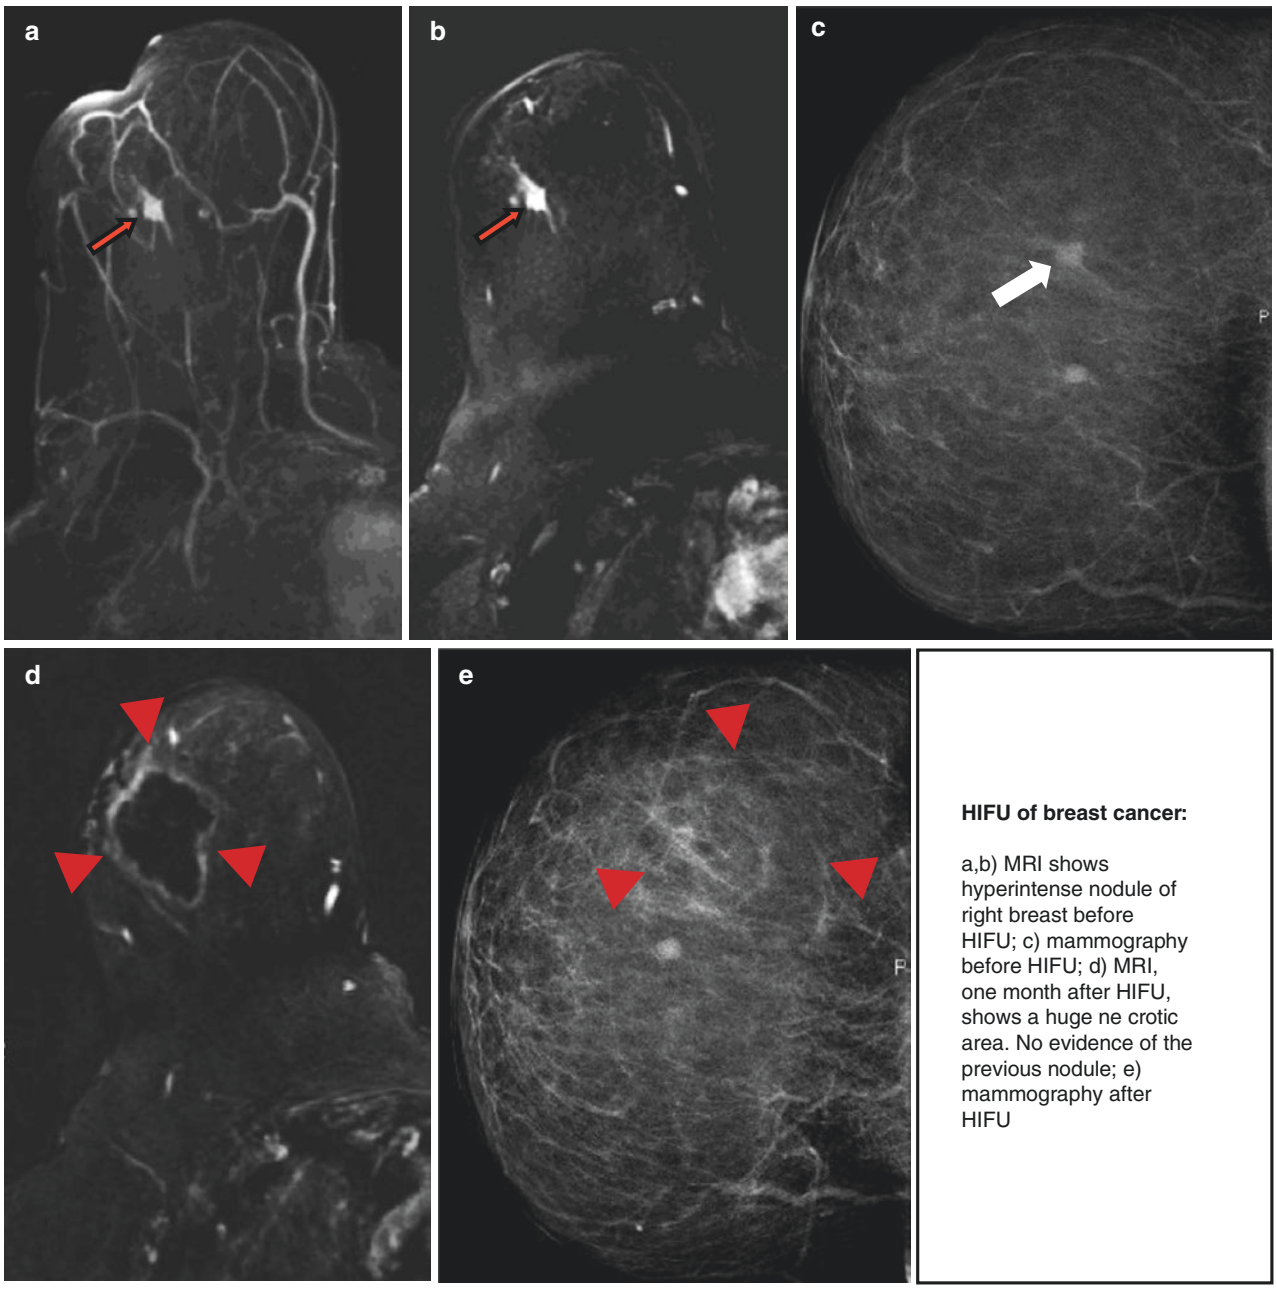
Wu et al. showed complete necrosis of tumor cells by HIFU technique and concluded that HIFU system could be safe and effective in localized breast cancer treatment, but more clinical trials are needed for defining the future role of this promising technique [55]. In Li's review on breast cancer treatments using HIFU, guided by US or MRI, between 2002 and 2010, 173 patients with tumor extent from 0.5 to 6.0 cm were reported. Complete ablation rate was 71% (123/173) by MRI-guided HIFU or US-guided HIFU therapy [58]. The complete necrosis rates were 59% (71/121) by MRI-guided HIFU and 96% (50/52) by US-guided HIFU therapy.

There are several advantages of HIFU therapy for breast cancer treatment, including preserving the structure and function of breast, no bleeding, no scarring, and no radiation. Li A and Wu PH [58] reported three major limitations related to HIFU ablation: (1) it is difficult to confirm whether ablation margin is free, (2) recurrence concern exists in multifocal breast cancer, and (3) necrotic masses remaining in the breast after HIFU therapy could cause additional psychological burden to the patient.

A recent systematic review of HIFU ablation for breast cancer treatment showed a lack of reports for consistent histopathology, addressing for large, prospective clinical trials evaluating results according to lesion histopathology and imaging follow-up for margin necrosis assessment [59]. Because of the need of these crucial histopathological feedbacks after HIFU, between December 2007 and April 2010, an open prospective, single-center nonrandomized phase 2 study on USgHIFU for breast cancer was conducted at the European Institute of Oncology. Healthy adult woman affected by unifocal early breast cancer visible at US imaging was considered eligible for this "ablate and resect" study. Eighteen patients underwent USgHIFU ablation for 18 previously core-biopsied tumors up to 15 mm, before undergoing surgery for histopathological assessment. The median value of tissue necrosis percentage obtained, evaluated by HE staining, was 95%. In seven patients, a complete necrosis (100%) was showed, and in two patients it was more than 95%. However the TTC evaluation for biological status showed a complete necrosis in 16 patients. In three cases with complete absence of tumor, the lesion was vanished by cells' cavitation and vaporization. In one patient, the lesion appeared perfectly intact with no necrosis, because it was completely missed during HIFU treatment.

In our preliminary experience, based on this "pilot study," among the other local treatments for breast cancer, HIFU has the advantages to be completely noninvasive and feasible under sedation and local anesthesia, in a day hospital setting, allowing for considerable cost reduction compared to traditional surgery. The risks of surgery-related complications (e.g., infection, seroma, and bleeding) are also eliminated.

In conclusion, USgHIFU treatment was shown to be reliable and feasible in unifocal early breast cancer. We can be very confident in this method that, with necessary improved technology, will take the lead among the alternative treatments to surgery, but several larger and really well-conducted



HIFU of breast cancer:

a,b) MRI shows hyperintense nodule of right breast before HIFU; c) mammography before HIFU; d) MRI, one month after HIFU, shows a huge ne crotic area. No evidence of the previous nodule; e) mammography after HIFU

clinical trials are needed before considering this noninvasive approach as an effective cancer treatment in breast disease.

74.4 Radio Frequency Ablation in Breast Cancer

Radio frequency (RF) ablation is the first technique that was used to perform image-guided thermal tumor ablation. Traditionally used in the liver, RF is applied through an electrode (i.e., the needle) under imaging guidance to induce focal high-temperature cytotoxic heating in target tumors. The patient is part of a closed-loop circuit made by the needle, the power generator, and a ground pad. This allows for having an alternated electric field within the tissue of the patient. As biological tissues are poor electricity conductors, ionic friction takes place and leads to heat generation (i.e., the Joule effect). The discrepancy between surface of the needle and of the ground pad allows for concentrating most heating power around the needle itself. Thus, up to 5 cm of tissues around the needle tip can be focally heated up to 100 °C. High temperature implies tissue dehydration

and water vaporization, thus leading to coagulative necrosis. Different technical solutions (e.g., needle shape and length, cooling systems, etc.) allowed for improving the performance of RF in various body districts. One drawback of RF system is that margins of ablation volume can be poorly predicted. The first experience with RF ablation of breast cancer is dated 1999, and five patients were treated with complete ablation in four of them [13].

The evidence regarding these techniques is quite sparse, especially if we consider not only the technical success but also the efficacy and the rate of complications. Moreover, published studies frequently enrolled small groups of patients not allowing for drawing reliable conclusions.

From a recent systematic review and meta-analysis on 576 patients treated with RF ablation for breast cancer, technical success of the technique has been found to range between 87% and 100%, with a largely variable technical efficacy, ranging between 29% and 100%. The large variability of technical effectiveness in comparison with the elevated rate of technical success might be ascribed to various factors, including the small number of cases treated in each series (reflecting an initial experience with the technique), the wide difference in treated tumor sizes, and the different histological subtypes.

In the analyzed papers, major complications were reported to occur in a range between 0% and 8% and minor complications in the range between 4% and 62%, being the most frequent complications represented by skin burns grade 2 or 3, tissue necrosis, and pneumothorax.

In conclusion, RF ablation of breast cancer has been reported as a feasible technique, with low rate of serious complications. However, results in terms of efficacy are still quite inhomogeneous, and several factors, which might affect the result of the procedure, have not been investigated yet. Thus, even if image-guided percutaneous ablations of breast cancers, and in particular RF, seem to offer some advantages over surgery and promising results, the available clinical experiences are still too limited to propose their application in the clinical practice. Further studies are needed to better clarify the best technology for performing percutaneous image-guided ablations of breast cancer and the correct indication for a wider clinical application.

Hyperthermia with Radiotherapy and with Systemic Therapies

75

J. van der Zee and G.C. van Rhoon

75.1 Introduction

Hyperthermia (HT) is a treatment during which the temperature of tissues is increased a few degrees above the physiological level, to a range of 39–45 °C. The modern era of this treatment modality started in 1975, when the first international hyperthermia meeting was held in Washington DC. The clinical experience presented at that meeting was limited to the application of fever therapy, whole-body HT and perfusion of limbs or the bladder. From experimental studies it had become clear that HT would be useful mainly in combination with radiotherapy (RT) or chemotherapy. The first available techniques for clinical application of hyperthermia with ultrasound or electromagnetic radiation had been developed. After this meeting, many institutes started clinical research on hyperthermia. Most clinical research groups started with treating patients who were progressive after all kinds of other therapies. Nowadays, a number of randomized trials have demonstrated that HT, in addition to radiotherapy (RT) and/or chemotherapy, considerably improves the clinical outcome in patients with a large variety of tumours. Among the first treated patients were patients with breast cancer recurring after previous RT, in whom HT was combined with relatively low doses of reirradiation (reRT). Presently, recurrent breast cancer after previous RT is one of the indications where HT is considered part of standard treatment.

75.2 Rationale for Hyperthermia in Cancer Treatment

Hyperthermia at a temperature of 39–45 °C has various effects. One effect is direct cell kill, for which the main molecular event is protein damage [1]. Cell death may result directly or from triggering apoptotic pathways [2]. The effect depends on the height of temperature and the duration of treatment, which two factors determine HT dose. Environmental factors such as hypoxia and low pH, which under normal conditions are present only in tumour tissue, due to insufficient perfusion, make cells more sensitive to an increased temperature. When both a tumour and its surrounding normal tissues are heated to a similar high temperature of up to 43 °C, part of the tumour cells will be killed without damage in the normal tissues. In patients with breast cancer, it was demonstrated that the HT dose needed for cell necrosis and vessel damage is higher in normal tissue than in tumour tissue [3]. The effects of HT specifically in regions of hypoxia and low pH make the treatment complementary to both RT, for which cells in a hypoxic environment are less sensitive, and chemotherapy, since the drug concentration will be lower in a region with insufficient perfusion.

Besides inducing direct cell kill, HT sensitizes cells to both RT and a number of cytotoxic drugs. One important mechanism for this sensitizing effect is inhibition of DNA repair [4, 5]. The magnitude of this sensitizing effect of hyperthermia is called thermal enhancement ratio (TER): the ratio between the RT and chemotherapy dose needed for a certain effect, divided by the RT or chemotherapy dose required for the same effect when combined with HT. Hyperthermia may further increase the effects of RT and chemotherapy by an increase in blood flow [6]. An increased blood flow may result in an increased oxygenation, which makes radiotherapy more effective. When combined with chemotherapy, an increased blood flow will increase the drug delivery to the heated tissues.

75.2.1 Radiosensitization

Heat is probably the most potent radiosensitizer known [7]. The sensitizing effect of HT depends on height of temperature and duration of treatment and decreases with longer time intervals between the two treatment modalities. For example, with

e-mail: j.vanderzee@erasmusmc.nl

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_75

HT and RT applied simultaneously, the TER was 5 for 90 min heating at 43 °C in a mouse mammary carcinoma. When HT was applied 4 h after RT, the TER was 2 for the same HT dose. In clinical comparative studies, iso-effect TERs of 1.5–1.6 have been found [8]. Experimental studies have shown that the radiosensitizing effects disappear faster in normal tissues than in tumour tissues, so that the therapeutic ratio is maximum when hyperthermia follows radiotherapy after 2–4 h [9]. For the radiosensitizing effect of HT, nuclear protein damage is probably the key event [1]. The heat-induced nuclear protein aggregation leads to inhibition of repair of radiation-induced DNA damage, resulting in more lethal DNA lesions.

75.2.2 Chemosensitization

The effects of several drugs are enhanced by HT [10]. The TER depends, also for chemosensitization, on the height of temperature and the duration of treatment. For various drugs, TERs of 1.05–3.6 were found at 41.5 °C and of 1.6–2.7 at 43.5 °C. The mechanisms for sensitization are an increased rate of alkylation, an increased drug uptake and inhibition of repair of drug-induced sublethal damage. Some drugs are only enhanced above a threshold temperature, e.g. bleomycin, doxorubicin and actinomycin are sensitized only at temperatures above 42 °C, while platinum drugs and alkylating agents show a gradual increase of effect with increasing temperatures. The optimal sequence is simultaneous application for most drugs, provided that the organ with dose-limiting toxicity is not included in the heated volume. For gemcitabine, synergism was only observed when it was applied 24 h before or after HT.

An interesting approach is to combine HT with thermosensitive liposomes. Hyperthermia may increase the local blood flow and further increases the gaps between vascular endothelial cells. As a result, more liposomes will enter the interstitial space and release their contents within the heated tissue. Experimental studies have shown that more drugs enter the tumour by this approach and also that the therapeutic effect is increased [11].

75.2.3 Immune Modulation

Hyperthermia modulates innate and adaptive immune responses. When a tumour cell is heated, protein aggregation and denaturation induces a stress response in the cell, resulting in an increase in the transcription of inducible heat shock protein 70 (HSP70) and an increase in exposure of HSP70 on the cell surface. HSP-expressing cells are more susceptible to lysis by natural killer effector cells. Furthermore, hyperthermia results in enhanced levels of tumour antigens inside the cell. If the treatment results in cell death, HSPs acting as danger signals and HSP/antigen complexes are released. In addition, HSPs and tumour antigen-containing exosomes can be discharged from apoptotic and necrotic tumour cells. Such exosomes as well as the Hsp/antigen complexes activate and attract dendritic cells. These take up tumour antigen, present it with costimulation to CD8 + T cells and thereby induce cellular antitumour immunity by priming cytotoxic T lymphocytes which then attack and may kill the tumour cells [12]. Tumour growth in a rat model was significantly inhibited following a pre-implantation heat treatment, while splenic lymphocytes displayed specific cytotoxicity against the implanted cells [13]. The remarkable clinical outcome in the patient presented in Fig. 75.1 and the reported overall survival of 66–75% after 3 years and 60% after 5 years in patients treated with reirradiation and hyperthermia after resection of recurrent tumour (see below) may be the result of such an immune stimulation.

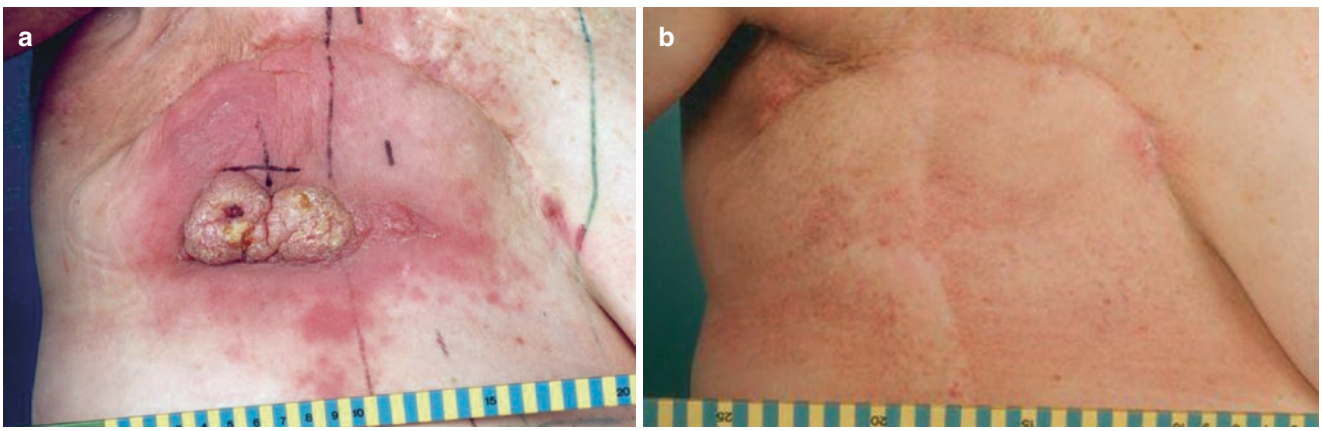

Fig. 75.1 This patient was primarily treated with lumpectomy and radiotherapy. Within 2 years, mastectomy followed after tumour recurrence. Six months later, she had a large and fast-growing tumour on the chest wall (**a**), which was treated with reirradiation (eight fractions of 4 Gy twice weekly) and hyperthermia, resulting in a complete response (**b**). Up to the last follow-up, 16 years after reirradiation and hyperthermia, there was no evidence of disease

75.3 Techniques for the Application of Hyperthermia

Hyperthermia can be applied to the whole body, regionally or locally. Breast cancer is mainly treated with local HT. Local HT can be applied by external or interstitial methods. Energy is delivered to the tissue with ultrasound or electromagnetic radiation. The volume that can be heated depends on the physical characteristics of the energy source and on the type of applicator. The energy distribution in the tissues is strongly dependent on tissue characteristics and thereby inhomogeneous. The resulting temperature is not directly related to the local energy absorption, but also depends on thermal characteristics of the tissue, the blood flow and the temperature of the surrounding [14]. For interstitial HT, small applicators are inserted into the tissue, usually within catheters that are used for brachytherapy as well. A disadvantage of interstitial HT is that the temperature decrease in the tissue around the applicator is very steep. Most clinical experience in breast cancer patients is with external HT by (non-ionizing) electromagnetic radiation. The depth to which tissues can be heated adequately decreases with increasing frequencies and can be influenced by a perfused water bolus on the skin surface [15]. Hyperthermia treatment planning is available, which helps to select the optimum heating technique for specific patients [16]. For the treatment of recurrent breast cancer, which usually requires heating of a large area, multi-applicator systems have been developed (like the one presented in Fig. 75.2). Temperatures should be preferably measured both interstitially and on the surface, so that the power output of the applicators and the temperature of the water bolus can be adjusted for the achievement of an optimized temperature distribution.

75.4 Clinical Results

75.4.1 Clinical Results in General

In most clinical studies, HT is applied once or twice weekly during one hour. Fourteen early studies with HT as single modality have shown clinical complete response (CR) rates of 0–40%. Overall, HT alone to total 433 lesions resulted in 14% clinical CR [17]. These lesions usually were small and superficially located and could be heated well. The CRs after HT alone generally were short-lasting; it is therefore not recommended to use HT as single modality. Several studies have compared the effect of RT to that of RT plus HT in patients with multiple lesions. In some of these studies, the treatment was randomly selected; in other studies the larger lesions were treated with the combination. In all these studies, the CR rate was higher after combined treatment than after RT alone. A summation of the data of all these studies, with total 713 lesions, shows CR rates of 31% and 67% after RT alone and RT plus HT, respectively [17]. A number of randomized trials have given evidence of considerable improvement of clinical outcome from addition of HT to RT, chemotherapy or both. Benefit has been shown in a large variety of tumour types, including breast cancer, and for various outcomes, including local tumour control (LC) and overall survival [17].

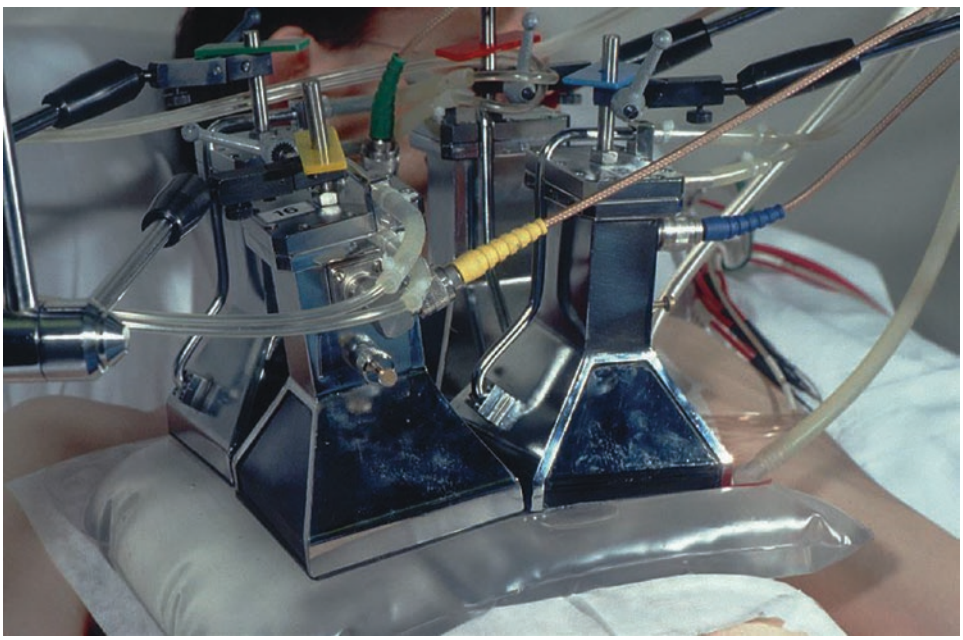

Fig. 75.2 Applicator set-up for treatment of the thoracic wall (Rotterdam). This custom-built system uses 433 MHz electromagnetic radiation for heating. Up to six applicators can be used simultaneously, to treat an area of 20 × 30 cm^2 to a depth of up to 4 cm

From clinical results of HT combined with RT for locally advanced or recurrent breast cancer, a TER of 1.5 was derived [8]. One study combining five separate randomized trials comparing RT to RT + HT included patients with primary breast cancer, recurrent breast cancer and recurrent breast cancer after previous radiation [18]. The difference in CR rate between the radiotherapy alone (41%) and the combined treatment arm (59%) was significant. After 3 years of follow-up, the local control rate in the RT-alone arm was 24% and in the combined treatment arm 46% ($p = 0.007$). In this study the strongest effects of HT were seen for patients treated with reirradiation: the CR rate increased from 31% after reRT alone to 57% after combined treatment.

75.4.2 Toxicity

Hyperthermia may damage normal tissues when the tolerance limits are exceeded. Most tissues tolerate treatment of 1 h at 43 °C; only nervous and gastrointestinal tissues appear more sensitive [19–21]. Tissues with disturbed blood flow will heat easier and, when oxygen supply is decreased, will be damaged at lower temperatures. During treatment, it is therefore important to avoid pressure on normal tissues. It is not always possible to avoid high temperatures in normal tissues, due to the heterogeneity of temperature distribution and the limited thermometry. Patients are instructed to mention unpleasant feelings which may result from a hot spot, but this is not always possible, e.g. after surgery in the past resulting in disturbed sensitivity. Toxicity of superficial HT is most often a skin burn, in 9–28% of patients with recurrent breast cancer [22–28], which heals with conservative treatment. In the randomized studies comparing between RT and RT plus HT, no significant differences in acute or late radiation toxicity were found [17]. In the studies combining hyperthermia with chemotherapy, toxicity was not higher than was expected from chemotherapy alone.

75.4.3 Hyperthermia in Primary Breast Cancer

Hyperthermia has been applied to primary breast cancer by several groups. Only two studies were comparative. Savchenko et al. [29] published in 1987 results of a randomized study in 507 patients with advanced breast cancer, preoperatively treated with RT, with or without HT. The patients treated with the combination tended to have a better survival, 87% and 73% after 3 and 5 years, while it was 77% and 67% for patients treated with RT alone. In the study by Vernon et al. [18], results in primary breast cancer (total 30 patients) were not significantly different between the two treatment arms.

Jones et al. [26] treated 18 patients with advanced breast cancer preoperatively with three cycles of taxol, RT to a total dose of 50 Gy and HT twice weekly. The clinical response rate was 83% including six (33%) complete responses, which was considered high. Of the 13 patients who underwent mastectomy, 3 patients showed a pathological CR. Vujaskovic et al. [27] treated 47 patients with preoperative liposomal doxorubicin, paclitaxel and hyperthermia. This treatment was well tolerated. Eight patients had breast conservative treatment thereafter; 39 underwent modified radical mastectomy. There were 4 pathological complete responses (9%) and 22 partial responses (51%). They found more pathological responses with higher HT doses, which is important since a pathological response is related to a favourable overall outcome. Hofman et al. [28] treated 40 patients with advanced tumours, mainly T3 and T4, with RT (50 Gy) and HT. Clinically a complete response was achieved in 39%. They concluded that for better results, the RT dose should be increased and the quality of the HT treatment improved.

In two studies, interstitial HT was applied in combination with brachytherapy. Chichel et al. [30] treated 57 patients with brachytherapy after lumpectomy. In 32 patients they applied interstitial HT as well. After median 40 months of follow-up, the LC rate was 100% for both treatment groups. Hartmann et al. [31] combined preoperative chemotherapy (several types) with RT and HT in 158 patients with stage IIA–IV breast cancer. Radiotherapy consisted of an interstitial RT boost of 10 Gy followed by interstitial HT at 43.5–44.5 °C for one hour. Thereafter, external beam RT was given to a total dose of 50 Gy. Breast conservative surgery was possible in 52% of the patients. After a median follow-up period of 20 months, a local recurrence was observed in only 1 patient (0.6%). These results were considered promising, since more than half of the patients had a tumour diameter of more than 5 cm.

75.4.4 Hyperthermia and Radiotherapy in Recurrent Breast Cancer

Published results of primary RT combined with HT are scarce. The largest series is reported by Refaat et al. [32]. Eighty-five patients were treated with 50–60 Gy. The CR rate was 61% and after median 13 months LC rate was 55%. Amichetti et al. [33] report 100% CR in eight patients treated with 60 Gy and HT and a 3-year LC rate of 88%. Scott et al. [34] compared the CR rate following RT alone to that following RT plus HT in 17 patients with multiple lesions. The total radiation dose was 60–66 Gy for all lesions. Complete response was achieved in 47% of the lesions treated with RT alone and in 94% of the lesions treated with the combination.

A similar comparative trial is reported by Li et al. [35]. Ten patients with primary breast cancer and 30 patients with recurrent breast cancer were treated on total 64 lesions. The average total RT dose was 47 Gy. For the larger lesions (average 38.7 cm^2), RT was combined with HT; RT alone was applied to smaller lesions (average size 12.1 cm^2). Complete response rates were 36% after RT alone and 64% after combined treatment.

75.4.5 Hyperthermia and Reirradiation in Recurrent Breast Cancer

Patients with an irresectable recurrent tumour after previous radiotherapy to the same area have limited treatment options. Reirradiation (reRT) is the only local treatment option, but the dose that can be given without a high risk of unacceptable toxicity is lower than considered adequate [36, 37]. Furthermore, tumours growing in irradiated tissues are less sensitive to RT and systemic therapy [38]. An uncontrolled recurrent breast cancer will cause problems such as pain, bleeding, ulceration with bad smell and the psychological burden of seeing a growing tumour, while the patient still may have considerable time to live. Many of the centres starting with applying local HT used it for treating patients with this condition, in combination with low doses of reirradiation. An early publication by Tait et al. [39] describes a study in patients with multiple lesions. Lesions were treated with various doses of RT, which in some lesions was combined with HT. From the differences in growth delay, the TER was calculated. For patients with breast cancer, the TER varied from 1.1 to 3.4, with a median of 2.2.

The study by Vernon et al. [18] clearly demonstrated a benefit from adding HT to reRT, with the CR rate increasing from 31% following reRT alone to 57% following reRT and HT. Van der Zee et al. published in 2010 [40] an overview of all studies on reRT and HT in patients with previously irradiated breast cancer, published between 1981 and 2008. The CR rate varied from 28% to 58% (overall 32% in 170 patients) after reRT, while it was 20% to 95% (overall 61% in 974 patients) after combined treatment. Since then, several more studies were published, which are summarized, together with studies in which reRT alone was applied, in Table 75.1. Two studies using RT alone at mean doses of 47 and 48 Gy report CR rates of 36% and 39%, respectively, which is lower than the CR rates of 52–70% reported for lower doses of RT combined with HT. Harms et al. treated 30 patients with RT using a brachytherapy mould, with two fractions of 20 Gy. They report a CR rate of 80% and 3-year LC of 75%.

Table 75.1 Results after reirradiation, with or without hyperthermia, for irresectable breast cancer recurrences

Reference	RT dose	CR after RT (total *n*)	CR after RT + HT (total *n*)	3-year LC	5-year LC
With HT					
[40] Review of 24 studies	Predominantly 30–40 Gy	28–58% (170) 32%	20–95% (974) 61%		
[41]	Mean 40 Gy		(241) 52%		
[25]	32 Gy		(248) 70%	40%	39%
[42]	Mean 22.5 Gy		(72) 69%		
[24]	32–36 Gy		(414) 58%	25%	
Without HT					
[43]	Mean 47 Gy	(22) 36%

RT radiotherapy, *HT* hyperthermia, *CR* complete response, *LC* local tumour control

75.4.6 Hyperthermia and Reirradiation in Recurrent Breast Cancer, After Resection

Patients with resectable recurrent breast cancer have a high risk of recurrence when the resection margin is tumour positive (R1 resection) and, in case of close margins, a large or multicentric tumour or multiple recurrences on the same location in the past. With radiotherapy doses that are considered appropriate for elective treatment (45–50 Gy) or for treatment of microscopic disease (50–60 Gy) [36, 37], the risk of unacceptable toxicity is too high. Four publications report on local control rates after postoperative reRT and HT of breast cancer recurrences. Kapp et al. [46] evaluated local control in 262 fields treated electively in 89 patients, of which 54% had been treated with RT before. The mean RT dose was 42 Gy. LC rate at 3 years was 74%. Two studies evaluated LC after reRT with eight fractions of 4 Gy, twice weekly, combined with once weekly HT, after resection of recurrent disease. Oldenborg et al. [22] treated 78 patients of whom 39% after resection with tumour negative margins (R0 resection) and 61% after R1 resection. LC rates after 3 and 5 years were 78% and 65%, respectively. In this study, 3-year overall survival after reirradiation was 66%. Linthorst et al. [25] treated 198 patients of whom 54% after R0 and 46% after R1 resection. LC rates were 83% and 78% after 3 and 5 years, respectively. Three-year and 5-year overall survival

Table 75.2 Results after (re)irradiation of recurrent breast cancer, with or without hyperthermia, after tumour resection

Reference	RT dose	2-year LC	3-year LC	5 -year LC
Reirradiation with HT				
[41] 195 fields	Mean 44 Gy	74%		
[23] 198 pts	32 Gy		83%	78%
[22] 78 pts	32 Gy		78%	65%
[47] 14 pts	Median 60		86%	
Reirradiation without HT				
[44] 28 pts	2 × 20 Gy		71%	
[47] 2 pts	Median 60		50%	
Primary radiotherapy, without HT				
[48] No adjuvant tamoxifen	50 Gy		77%	71%
Adjuvant tamoxifen			90%	87%
[49]	50–60 Gy		60%	
[50]	60 Gy			48%

RT radiotherapy, *HT* hyperthermia, *LC* local tumour control

after reirradiation were 75% and 60%, respectively. In spite of the relatively low reRT doses, the LC rates after reRT plus HT are comparable to the results after higher RT doses which have been applied, without HT, postoperatively for primary or recurrent breast cancer (summarized in Table 75.2).

75.4.7 Hyperthermia and Chemotherapy in Recurrent Breast Cancer

Zoul et al. [51] combined paclitaxel with local hyperthermia in a pilot study on seven patients. Patients had an inoperable local recurrence after mastectomy, irradiation and systemic therapy. Paclitaxel infusion was followed by 45 min of hyperthermia, for 6–18 cycles. All patients responded: complete response in four and partial response in three. There were no toxicities higher than grade 2. Three of the complete responders were still locally controlled after 12, 13 and 16 months, which seems a rather good effect.

75.4.8 Combination of Hyperthermia with Radiotherapy and Chemotherapy in Recurrent Breast Cancer

Feyerabend et al. [52] combined RT with epirubicin and ifosfamide, in which drugs were given once weekly, during HT. In patients who were reirradiated (reRT dose 36–60 Gy), a CR was achieved in 4 of 18 patients (22%). In seven patients not previously irradiated (RT dose 50–70 Gy), the CR rate was 86%. Remarkably, tumour progression was observed within 10 months after treatment in eight of the ten complete responders. Zagar et al. [53] treated 27 pts of whom 23 had received radiotherapy in the past with (re)RT to a total dose of median 45 Gy with HT and chemotherapy (capecitabine in 21, vinorelbine or paclitaxel in 6). In 16 of 20 evaluable patients, a CR was achieved (CR rate between 59% and 85%). Kouloulias et al. [54] treated 15 patients with a recurrence after previous surgery and RT with six courses of liposomal doxorubicin combined with HT, of which the first course was given during reirradation with 30.6 Gy. They achieved a complete response in three patients (20%). So far, these results have shown feasibility, but do not indicate a benefit from adding chemotherapy to (re)RT and HT.

Conclusions

The results achieved with hyperthermia added to radiotherapy and/or chemotherapy for primary breast cancer suggest that hyperthermia has the potential of further improving the clinical outcome by adding it to preoperative treatments.

The results of the studies comparing the effect of radiotherapy plus hyperthermia with that of radiotherapy alone in patients with recurrent breast cancer indicate that hyperthermia increases the effect of radiotherapy. Whether the improvement by hyperthermia in addition to full dose radiotherapy is worthwhile still has to be established by a randomized trial.

A beneficial effect of hyperthermia in addition to reirradiation has been established for patients with irresectable breast cancer recurrences. The only study in which radiotherapy alone resulted in a higher complete response rate applied two fractions of 20 Gy with a brachytherapy mould, which is a feasible approach in only a subgroup of patients.

The local tumour control rates after combined reirradiation at relatively low doses and hyperthermia, after resection of breast cancer recurrences, are similar to the local control rates reported for higher doses of radiotherapy after resection of not previously irradiated recurrent tumours. This strongly suggests a beneficial effect of hyperthermia in this patient group as well, although this can only be confirmed by a randomized trial.

The one small study combining hyperthermia with paclitaxel shows that this treatment is feasible and seems effective. The studies performed so far with the combination of hyperthermia with radiotherapy and chemotherapy do not suggest an advantage of the addition of cytotoxic drugs.

In view of the benefits shown for subgroups of patients and the potential benefits in other subgroups of patients, hyperthermia should be available for breast cancer patients, to be used either as part of standard treatment or as an additional modality in clinical studies.

Electrochemotherapy of Breast Cancer

76

Luca G. Campana, Louise Wichmann Matthiessen, Marko Snoj, and Gregor Sersa

76.1 Electrochemotherapy: Basic Concepts

Electrochemotherapy is being recognized an effective local ablative therapy that combines administration of a cytotoxic drug with tumor electroporation. At present, established drugs used during electrochemotherapy treatment are bleomycin and cisplatin [1, 2]. Electroporation is a phenomenon induced on cell membrane, which occurs when cells are exposed to appropriate external electric fields. Exposure of cells to high-amplitude electric pulses induces destabilization of the cell membrane (i.e., opening of aqueous pores), which enables diffusion of water-soluble drugs into the cytosol. When specific electrical parameters are selected, the aqueous pores on the cell membrane are transient, and electroporation results in an effective drug delivery system [3].

Bleomycin and cisplatin have high cytotoxicity, but low transmembrane permeability, unless combined with electroporation. In these circumstances, bleomycin cytotoxicity is increased several hundredfold and cisplatin several tenfold according to several observations in animal tumor models. Extensive preclinical data on experimental tumors confirmed the effectiveness of electrochemotherapy on a variety of solid tumors [4].

Several mechanisms of action have been identified in electrochemotherapy. The predominant mechanism is represented by the effective delivery of drug molecules into tumor cells, which is the main effect of electrochemotherapy [1, 5]. The indirect effects of electrochemotherapy are mediated by its vascular-disrupting action. Vascular-disrupting action is caused by a cytotoxic effect of bleomycin or cisplatin on endothelial cells [6]. Noteworthy, recent experimental data indicate that the vascular-disrupting effect of electrochemotherapy occurs selectively on tumor vessels [7, 8]. Specifically, normal vessels in the treated area are spared, while the cytotoxic effect is limited to the tumor vasculature [9]. According to the intriguing results of experiments in animal models, the second indirect mechanism of action observed after electrochemotherapy is the elicitation of a local immune response, which is likely the consequence of tumor necrosis and immunologic cell death [10]. In these studies, complete tumor eradication could be obtained only in immunocompetent mice [11]. It is hope of researchers that electrochemotherapy-induced local immune response may drive a systemic antitumor effect and ultimately lead to complete tumor eradication. With the recent availability of new, highly effective immunomodulatory agents, local tumor response to electrochemotherapy could be switched into a systemic immune response [12–14].

76.2 Electrochemotherapy Procedure

Efficacy of electrochemotherapy relies on two components that needs to be fulfilled. The first is that chemotherapeutic drug must be present in the target tumor tissue in sufficient concentration; the second is the adequate coverage of tumor with electric fields to induce electroporation of tumor cells. Therefore, the procedure consists of drug administration followed by local application of electric pulses. These voltages are generated by an electric pulse generator and are delivered

by means of different kinds of electrodes that are selected by the clinician according to the specific clinical situations (e.g., tumor size, anatomical location, etc.). Treatment details have been standardized in 2006 thanks to the joint experience of four leading centers performing the procedure and are now available as the European Standard Operating Procedures of Electrochemotherapy (ESOPE) [15, 16].

76.2.1 Drugs and Their Administration

Bleomycin and cisplatin represent the two chemotherapeutic agents used for treatment with electrochemotherapy. Bleomycin is nowadays the drug of primary choice, since it can be administered either intravenously or intratumorally (Fig. 76.1a). According to the ESOPE, instead, cisplatin can be only injected intratumorally [16]. Intravenous bleomycin (at a dosage of 15 units/m^2) is administered in bolus, and the application of electric pulses can be performed starting after 8 min from drug infusion, in order to achieve adequate drug distribution in tumor tissue. The therapeutic window for the application of the electric pulses has been set to 20 min. Nevertheless, recent pharmacological data on elderly (>65 years) patients suggest that it can be effectively extended 40 min or even longer (unpublished data). Intravenous bleomycin is generally used when dealing with patients presenting with multiple metastases, when tumors are larger than 3 cm, and when target tissue has hard consistency, making it difficult to be directly infiltrated. In general, it is a common experience that electrochemotherapy can be safely performed also in elderly patients [17]; however, when repeatedly using intravenous bleomycin, care should be taken not to exceed its recommended maximal cumulative dose (maximum total lifetime dose should not exceed 400 units). On the other hand, intratumoral drug injection, either bleomycin or cisplatin, is indicated for the treatment of patients with a single or few, small-size tumor nodules. In this case, the application of electric pulses to the tumors can be started shortly after drug injection [16].

(**a**) Preparation of cytotoxic chemotherapy: drugs can be administered as either intravenous bolus (large syringe) or direct intratumoral injection (small syringe); (**b**) the electric pulse generator in the operating room; (**c**) an *hexagonal array* electrode; (**d**) electrode application on a patient with chest wall recurrence after mastectomy

76.2.2 Electric Pulse Generators and Electrodes

Nowadays, electrochemotherapy is being used throughout Europe in more than 150 centers with the newly developed Cliniporator™ pulse generator that is CE certified for use on patients (Fig. 76.1b). This electric pulse generator has several advantages that make it a leading product on the market in this area. It generates square-wave electric pulses with variable amplitude and possesses two options for the frequency of the delivered electric pulses (1 or 5000 Hz). The device is computer controller by the operator. In addition, it provides storage of the patient's characteristics as well as of the electrical parameters used for the treatment including traces of voltages actually applied as well as electric current flowing through target tissues during the procedure. Tumors can be effectively electroporated by a train of square-wave electric pulses, usually of the amplitude over distance ratio of 1000–1300 V/cm. During the procedure, each pulse delivery consists of a train of eight electric pulses at 5000 Hz repetition frequency [16]. Delivery of electric pulses can be performed by means of electrodes with different size and geometry. These pulse applicators can be divided into non-invasive, i.e., plate electrodes, or invasive, i.e., needle electrodes [1, 16, 18]. The plate electrodes are intended for superficial tumors and are used by placing tumor tissue in-between their blades, if tumor size is up to 8 mm, or placing consecutively the device more times on the target area, until the whole tumor and safety margins are covered with electric pulses. The needle electrodes are provided with different configurations, according to the specific clinical requirements. Two main electrode types are generally used during breast cancer treatment, the *linear array* electrode and the *hexagonal array* electrode. The linear array electrode is composed of two, 4 mm spaced, rows of 2 cm long needles and is aimed to treat small-sized nodules or tumors confined in a limited area. On the other hand, the hexagonal array needle electrode is composed of seven needles arranged in a hexagonal fashion and can be provided with 2 or 3 cm long needles, according to tumor size and depth (Fig. 76.1c). It is intended at treating bigger and deeper tumors. A single application of the hexagonal electrode covers indicatively an area of 2 cm^2, but during the procedure it can be placed several times on the target area and allows for extensive coverage of tumor-infiltrated skin on the chest wall (Fig. 76.1d).

76.2.3 Anesthesia

Overall, treatment with electrochemotherapy is well tolerated by patients. Nevertheless, the application of the electrodes, especially the needle devices, and subsequent pulse delivery may be two painful procedures, depending also on tumor size and extension. The pain induced by electric pulses is dependent on their amplitude, which in turn is dependent on the distance between the needle electrodes. Therefore, linear array electrodes generally induce less painful pulses for patients. In these cases, only local anesthesia can be used. However, when dealing with patients with multiple tumor nodules or bulky tumors (indicatively larger than 3 cm) or tumors located in delicate or sensitive anatomical areas, general sedation and, in selected cases, general anesthesia represent a reasonable choice. However, also in the rare patients in whom general anesthesia is preferred, the period of assisted ventilation is limited. Generally, posttreatment pain is easily managed with intravenous analgesics during the first hours following the procedure and then by means of oral analgesics. Of course, the intensity of pain treatment depends on the extent of treatment field, its anatomical location, and local conditions of skin and soft tissues, as well as on the electrode type used during the procedure, concomitant sites of disease (e.g., bone metastases), and ongoing pain drugs.

76.3 Indications, Results, and Side Effects

76.3.1 Indications

Electrochemotherapy is currently being used for treatment of cutaneous and subcutaneous metastases from different tumor histotypes. Based on the accumulated experience, accepted indications to electrochemotherapy are the following: (a) curative treatment for patients with multiple skin cancers not amenable with surgery or other local therapies; (b) locoregional treatment of patients with unresectable metastases that are refractory to conventional oncological therapies; (c) exclusive treatment in elderly or frail patients who are deemed not suitable for systemic antineoplastic treatments, radiotherapy, or surgical resection; and (d) palliation of symptomatic (e.g., bleeding) superficial metastases. The first clinical trial was published in 1993 [19], and, since then, several studies have been published, predominantly on malignant melanoma, basal cell carcinoma, head and neck squamous cell carcinoma, and breast cancer. Reported objective response rates range between 72% and 100% for tumors smaller than 3 cm, while significantly decreasing in larger lesions [20–25]. In metastatic patients with skin tumor involvement, the main purpose of a locoregional treatment is not objective response, but to give symptomatic relief in terms of reduced exudate, odor, and bleeding and, ultimately, to preserve patient quality of life. Thanks to its prominent vascular-disrupting action, electrochemotherapy [8, 26] allows to rapidly and effectively manage local bleeding in

patients with ulcerated cutaneous metastases, thus reducing the need of repetitive dressings [27–29]. Furthermore, according to several experiences, electrochemotherapy has proven a reliable palliative tool in the management of painful skin metastases [15, 30, 31] and should therefore be considered a locoregional treatment option that can ensure effective local tumor control and improvement of patient quality of life [23, 32]. Noteworthy, electrochemotherapy has shown activity also in previously irradiated areas and in patients who were refractory to several systemic therapies [15, 32]. Furthermore, it may provide a reasonable alternative in patients in whom surgical resection cannot be attempted or would not be radical. Finally, as opposed to radiation, electrochemotherapy can be safely repeated in order to consolidate tumor response (e.g., to treat patients with partial response after the first cycle) or to treat newly occurred metastases outside the treatment field [22, 23, 32].

76.3.2 Results

According to a large meta-analysis including 44 studies (although mainly performed before the standardization of the procedure in 2006) and 1894 tumors, electrochemotherapy has significantly higher antitumor activity (by more than 50%) than bleomycin or cisplatin alone [33]. Treatment effectiveness was significantly higher for intratumoral than for intravenous administration of bleomycin, while bleomycin and cisplatin administered intratumorally proved to be equally effective when combined with electric pulses. Regardless of drug and route of administration, reported overall and complete response rate were 82.8% and 62.6%, respectively. In a recently published meta-analysis, efficacy of electrochemotherapy in treatment of patients with skin metastases was estimated to be comparable to other skin directed therapies such as radiotherapy, photodynamic therapy, intralesional therapy with antineoplastic agents, and topical therapy [34].

76.3.3 Side Effects

Side effects to electrochemotherapy are generally limited and mild, so that treatment is well tolerated also by elderly and frail patients [35]. Nevertheless, insertion of electrodes and delivery of electric pulses may cause different grades of pain. Moreover, electric pulses may induce an involuntary contraction of underlying muscles, and this may cause an unpleasant sensation for patient, particularly if the procedure is being performed under local anesthesia [15, 36]. Consequently, electrochemotherapy can be administered under either local or general sedation/general anesthesia, according to disease extension, anatomical location, and patient preference. Following the procedure, transient pain and mild inflammatory reaction in the treated field are generally observed. In the following weeks, tissue necrosis and ulceration may occur in a minority of patients. Skin hyperpigmentation can be seen as a well-known side effect of bleomycin, particularly after repetitive treatments [37]. Systemic side effects such as nausea and fever, which are generally transient and mild, are caused by the drugs used during anesthesia and by bleomycin. As a note of caution, electrochemotherapy with intravenous bleomycin should not be used when the cumulative dose exceeds 400 units, due to the risk of pulmonary toxicity (i.e., lung fibrosis) [38]. Posttreatment pain is another crucial issue when considering electrochemotherapy in patients with cutaneous metastases from breast cancer. The management of posttreatment pain may be particularly challenging when dealing with large (>3 cm in diameter) or widespread tumors on the chest wall [24]. Nonetheless, in most patients, posttreatment pain seems to decrease after 45 days according to a retrospective multicenter study conducted on 121 patients with different tumor types [31]. In this study, the authors were able to identify the following parameters as the most reliable predictive factors for posttreatment pain following electrochemotherapy: diagnosis of breast cancer, large tumor size, presence of pain before treatment, and previous radiotherapy. The severity of patient-reported posttreatment pain increased with the increasing number of electrochemotherapy cycles in a phase II study including previously irradiated mastectomy patients [32]. In summary, although electrochemotherapy is a local treatment, which is generally well tolerated by patients, it should be taken into careful consideration that it is not free from possible, sometimes troublesome, side effects. Therefore, it should be clear to the treating physicians that, in patients with rapidly progressive disease, control of cutaneous metastases cannot always be obtained, and if an improvement in symptoms is not reliably expected, treatment should be postponed or avoided. This means that, although expected side effects are few and generally mild in most cases, they should be always carefully weighed against foreseen, realistic benefits. It is advisable that clinicians take into account these elements before recommending treatment with electrochemotherapy and discuss this treatment option in the frame of multidisciplinary meetings (Table 76.1).

Table 76.1 Advantages and limitations of electrochemotherapy

Advantages	Disadvantages
Possibility to be performed under short general sedation (20–30 min)	Treatment-induced pain (depending on disease extension)
Suitable also for frail and elderly patients	Electrode application is operator-dependent
The procedure is easy to perform	Skin hyperpigmentation
Treatment has minor side effects	Possible tissue necrosis
High response rate and limited effect on healthy tissues	Lack of electrodes suitable for targeting tumors with different size, morphology, and location
Short hospital stay required	Possible skin ulceration
Rapid management of symptomatic metastases (painful, bleeding, oozing)	Lung fibrosis (bleomycin-induced, after repetitive treatments)
Preservation of patient function and quality of life	
Favorable cost/benefit ratio	
Treatment	
Reproducibility durable local tumor control

76.4 Clinical Experiences in Breast Cancer

Several early clinical studies on electrochemotherapy treatment of skin metastases included also breast cancer patients [20, 21, 23, 35, 36, 39]. The results of these preliminary and isolated experiences were summarized in a review, which pointed out that the activity of electrochemotherapy on cutaneous metastases from breast cancer is comparable to that reported in other tumor histotypes [40]. In particular, overall objective response rate in breast cancer patients was 89% (59% complete), and in patients with other tumor histotypes, it was 78% (52% complete). Since 2012, five studies (four from Italy and one from Denmark) with electrochemotherapy in patients with cutaneous recurrences from breast cancer have been published. Two of them were single-center phase II studies [24, 32], while the others were retrospective reports (Table 76.2) [17, 41, 42].

76.4.1 Prospective Phase II Study on Bulky Recurrences

A phase II study from Copenhagen University Hospital, Herlev, was focused on electrochemotherapy treatment of bulky (i.e., larger than 3 cm) cutaneous recurrences from breast cancer in patients who exhausted standard oncologic treatments [24]. Seventeen patients were included between 2008 and 2010. Enrolled patients had a total of 25 metastases whose median diameter was 9 cm (range 3–25). All patients were extensively pretreated: all of them received previous chemotherapy (median number of chemotherapy cycles was 4, range 1–7), 8 hormone receptor-positive patients received endocrine therapy, 5 patients received HER2-targeted therapy, and 16 patients were irradiated on the chest wall. Electrochemotherapy was performed under general anesthesia and, in most cases, using intravenous bleomycin. Five

patients were lost to follow-up due to systemic disease progression, thus leaving 12 patients evaluable after at least 8 weeks. A median of one electrochemotherapy session (range 1–4) was administered, and median duration of the procedure was 23 min (range 10–36). By using clinical examination, the authors observed one complete tumor regression and one partial response. Nonetheless, posttreatment CT scan showed that 4 out of 12 patients achieved over 50% tumor shrinkage. In five of 12 patients, a reduction of exudate from treated metastases was reported. Treatment was well tolerated with local posttreatment pain being the main side effect. The study concluded that electrochemotherapy is an active treatment in a heavily pretreated patient population and ensured appreciable tumor reduction and symptomatic relief.

76.4.2 Prospective Phase II Study on Previously Irradiated Chest Wall Recurrence

A phase II Italian study from the Veneto Institute of Oncology and University of Padova enrolled 35 patients with chest wall recurrence after mastectomy from 2006 to 2011 [32]. Enrolled patients were unsuitable for radical surgery and unresponsive to at least two lines of systemic treatment. Of note, all enrolled patients were previously irradiated for chest wall recurrence, and 85% of them received radiotherapy also at the time of primary breast cancer. The majority of them had hormone receptor-positive tumors (68.6%) and visceral involvement (68.6%). Overall, the authors administered 62 electrochemotherapy cycles (a median of two cycles per patient, range 1–3), and median duration of the procedure was 25 min (range 15–35). Average hospital stay was 1 day (range, 1–3). The procedure was well tolerated, and there were no serious treatment-related adverse events. Early toxicity, which was graded G1–G2 according to the Common Toxicity Criteria v4.0, included transient fever and pain in the treated area, which was easily manageable in most cases, although it increased after the following electrochemotherapy cycles. Late side effects included pain and dermatological toxicity as well. One month after electrochemotherapy, patients reported a "moderate" level of pain in 6%, 13%, and 17% of these after the first, second, and third electrochemotherapy session, respectively. As to dermatological toxicity, G3 skin ulceration was reported by five (14%) and two (6%) patients after 1 and 2 months after electrochemotherapy, respectively. Of interest, three (8.5%) patients reported a G1 transient alopecia, likely induced by systemic bleomycin. A total of 516 metastases were treated (median 15 per patient, range, 1–50), and tumor response was assessed on 196 target lesions. Two months after the first electrochemotherapy, an objective response was observed in 32 of 35 patients (91.4%), and 19 patients achieved complete response. Among the complete responders at first electrochemotherapy, ten patients remained local disease-free at a median follow-up of 32 months. The estimated 3-year local progression-free survival was 81%. However, 23 (65.7%) of 35 patients developed new lesions outside the treatment field. The percentage of patients who developed new lesions was significantly lower in complete responders compared with non-complete responders at first electrochemotherapy (47.4% vs. 87.5%, $P = 0.029$). At the end of the study, 12 out of 35 patients achieved both local tumor control (i.e., complete or partial response on electroporated metastases) and freedom from new lesions on the chest wall. These patients represented the subgroup who achieved an effective chest wall control after treatment with electrochemotherapy.

76.4.3 Retrospective Study on Elderly Patients

In a small retrospective study from the Veneto Institute of Oncology of Padova, 52 breast cancer patients who underwent electrochemotherapy were retrospectively analyzed with particular interest for the clinical outcome of elderly patients [17]. Enrolled subjects were divided in two subgroups according to their age (<70 years or ≥70 years). Overall complete response rate was 40%, but, interestingly, it was significantly higher in the elderly compared to the younger patients (57% vs. 26%, $P = .023$) and in patients with better performance status (PS = 0–1, 53% vs. PS = 2, 21%, $P = .048$). Two-year local progression-free survival among elderly patients was 67%. Interestingly, older women seemed less likely to progress outside the electrochemotherapy field (2-year new lesion-free survival, 39 vs. 30%, $P = .075$), but discontinued treatment more frequently due to impaired performance status ($P = .002$). Finally, treatment-related toxicity was not negligible in this cohort. In fact, local pain was graded ≥3, according to a 10-point visual analog scale, by 16/28 (57.1%) and 8/28 (28.6%) elderly patients at 4 and 8 weeks after electrochemotherapy, respectively; moreover, debridement due to extensive tumor tissue necrosis or skin ulceration was required in 5/28 (18%) of older women.

76.4.4 Retrospective Multicenter Study on Predictive Factors

More recently, 125 breast cancer patients who underwent electrochemotherapy were analyzed in the frame of an Italian multi-institutional retrospective study [42]. Objective response rate was 90.2%, with 58.4% of patients achieving complete response. In multivariate analysis, small tumor size ($P < 0.001$), estrogen receptor positivity ($P = 0.016$), low

Ki-67 index ($P = 0.024$), and absence of visceral metastases ($P = 0.001$) were associated with complete response achievement and could represent useful parameters for improving patient selection in future studies.

76.5 Established Indications in Breast Cancer

Cutaneous metastases occur from breast cancer mainly on the chest wall, but they can be observed, although less frequently, also on other anatomical locations (e.g., contralateral breast, upper arm, shoulder, neck, scalp, abdominal wall) (Fig. 76.2). In some patients, they represent the exclusive site of an isolated locoregional recurrence, while in other patients they occur outside the chest wall. They can be associated with lymph node and/or visceral metastases. In theory, both patients with locoregional recurrence (skin-only recurrence) and patients with metastatic disease associated with skin tumor involvement represent suitable candidates for treatment with electrochemotherapy. Nevertheless, due to the lack of solid clinical evidence supporting its application, at present, electrochemotherapy is not included in the clinical practice guidelines for the treatment of locally recurrent or metastatic breast cancer [43, 44]. Consequently, electrochemotherapy is currently used for the treatment of superficially metastatic breast cancer when (a) cutaneous metastases are not amenable with surgery, (b) there is no space for radiotherapy, and (c) the patient has failed conventional systemic treatments. It is therefore evident that, up to now and in current clinical practice, electrochemotherapy is applied mainly with palliative intent (Fig. 76.3).

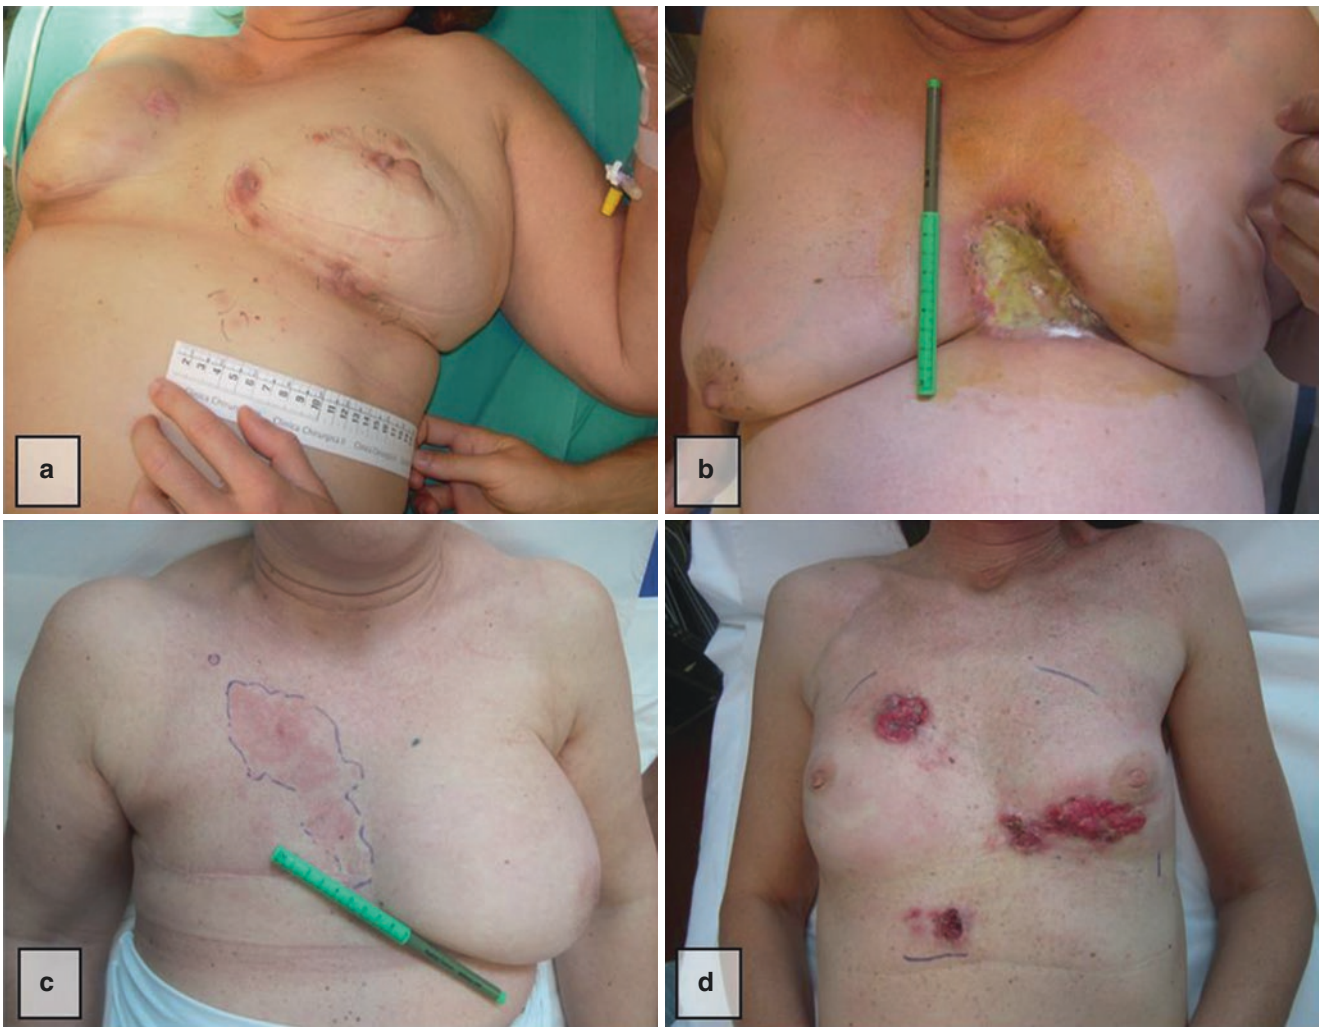

Fig. 76.2 Skin metastases from breast cancer. Different clinical presentations of superficially recurrent breast cancer: (**a**) tumor nodules on the skin of the contralateral breast; (**b**) ulcerated recurrence in the sternal region; (**c**) chest wall recurrence after mastectomy; (**d**) skin tumor involvement of both breasts and abdominal wall

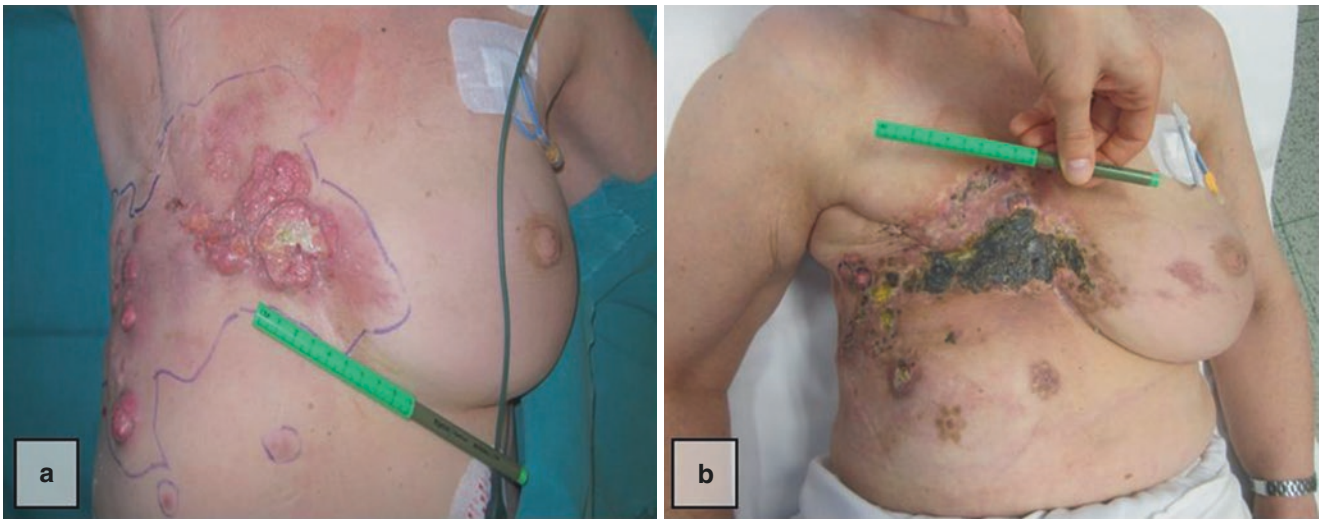

Fig. 76.3 Response to treatment in a breast cancer patient with cutaneous metastases on the chest wall. Preoperative tumor assessment (**a**). Postoperative tumor response (**b**)

76.5.1 Locoregional Recurrence After Mastectomy

Locoregional recurrence after mastectomy (Fig. 76.2c) for invasive breast cancer may be a harbinger of distant metastases and, as such, is generally considered an ominous event. Its occurrence vary widely in the literature, ranging from 5% to more than 40% [45–47]. Also in recent studies and despite widespread use of adjuvant therapies, the occurrence of locoregional recurrence after mastectomy is reported in up to 9% of patients [48]. For patients presenting with locoregional recurrence without evidence of distant metastases, aggressive multimodality therapy is warranted because many of these patients can be rendered disease-free. Therefore, locoregional recurrence after mastectomy, in the form of superficial (i.e., confined to the skin and subcutaneous tissue) locoregional recurrence, represents a suitable target for electrochemotherapy in breast cancer patients. However, in the clinical practice, cutaneous metastases can be observed in very different scenarios. For example, they can occur around the mastectomy scar or, alternatively, on the skin of the contralateral breast. Finally, they can also develop in patients with prosthetic implants; the latter event makes electrochemotherapy particularly challenging due to the possibility of damaging the underlying prosthetic implant with needle electrodes or the possibility of provoking tissue necrosis and skin loss above it [17].

76.5.2 Skin Metastases in Other Anatomical Locations

Breast cancer dissemination can follow either a lymphatic or hematogenous tumor spread. Accordingly, there may be different patterns of superficial tumor dissemination. As a result, lymphatic infiltration can produce large tumor-infiltrated skin areas not only on the chest wall but also on the neck, upper limb, abdomen, etc. Alternatively, discrete tumor nodules may be observed in different anatomical locations as the result of hematogenous dissemination (Fig. 76.2a, b, d). In both cases, cutaneous metastases are the hallmark of widespread tumor dissemination; nevertheless, also in these patients, tumor control remains a fundamental goal because of its potential effect on survival and, most of all, because of its tremendous impact on quality of life. Therefore, electrochemotherapy should be considered if cutaneous metastases are symptomatic (e.g., painful, bleeding, oozing, etc.) and there is the plausible chance to effectively manage them with treatment. In general, when dealing with patients in advanced stages of disease, the value of a locoregional treatment (electrochemotherapy, radiation, etc.) should be thoughtfully balanced against best supportive care, taking into account patient general conditions, life expectancy, disease behavior, superficial disease extension, and location as well as superficial disease-associated symptoms, patient preference, and possible treatment side effects (Fig. 76.4).

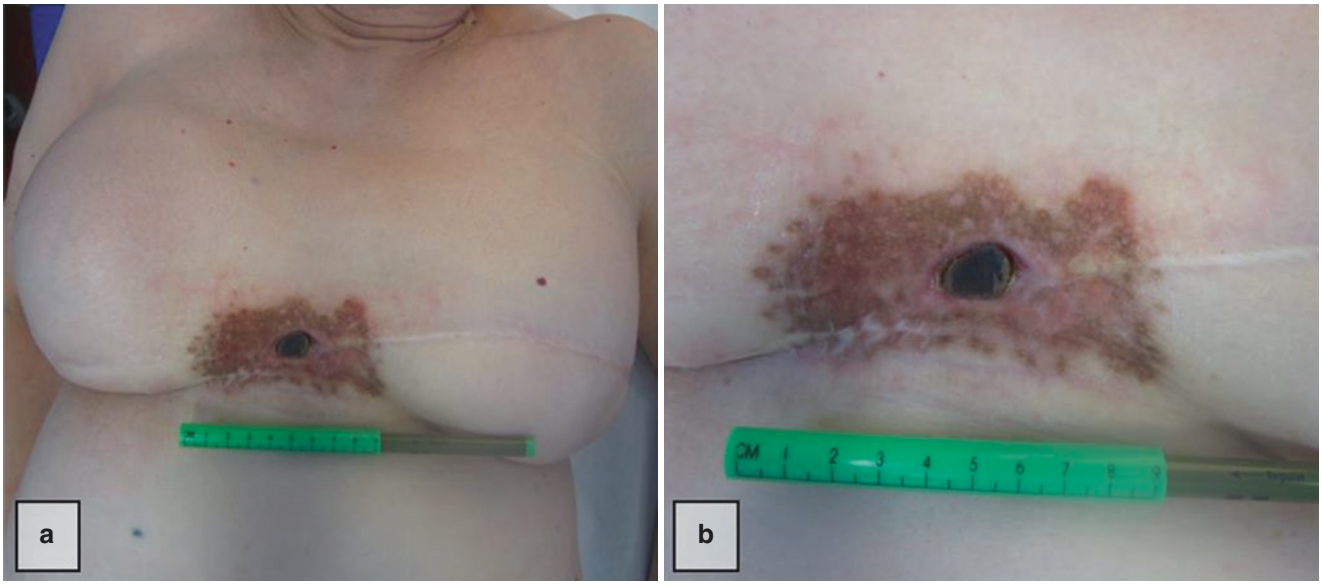

Fig. 76.4 Treatment toxicity. (**a**) An example of coexisting dermatological toxicities following electrochemotherapy. This patient developed both necrosis of tumor tissue, which was easily removed, thus leaving a small tissue ulceration and skin hyperpigmentation in the treatment field (**b**)

76.6 Future Directions

In electrochemotherapy of breast cancer, at least three main research directions deserve investigation in future studies. These are (a) the individualization of new treatment indications (i.e., earlier stages of disease), (b) the combination of electrochemotherapy with systemic treatments, and (c) the development of technological advancements in electrochemotherapy instrumentation aimed at improving treatment delivery and extend treatment indications.

76.6.1 New Clinical Indications

76.6.1.1 Primary Tumors

At present, electrochemotherapy has no indication in the treatment of primary breast cancer. In patients with inoperable, locally advanced disease, electrochemotherapy may be considered as a palliative or neoadjuvant treatment in very selected cases. A single case report has been published so far, where the authors successfully used electrochemotherapy as a neoadjuvant treatment, in order to cytoreduce a large, inoperable locally advanced primary tumor [49].

76.6.1.2 Adjuvant Setting

The sustained antitumor activity of electrochemotherapy makes this therapy a potential valuable option also in the adjuvant setting. In particular, its application may allow targeting minimal residual disease after surgical resection. In particular, when radical resection with clear margins cannot be accomplished, intraoperative electrochemotherapy could be applied to sterilize tumor bed and surgical margins, thus reducing the incidence local recurrence. Although promising in theory, this strategy has not been formally explored, and only a single case report has been published so far, where electrochemotherapy was intraoperatively applied on the tumor bed after tumor resection, in a patient who was unsuitable for adjuvant radiotherapy in order to treat the area at risk of recurrence [49].

76.6.2 Combination with Systemic Treatments

It has been demonstrated that electrochemotherapy is a safe and highly active antitumor treatment; nevertheless, its potential value in breast cancer patients still needs to be explored. Unfortunately, up to now, electrochemotherapy has been mainly used when conventional treatment options

were exhausted and, likely, patients' general conditions were in some way compromised. As a matter of fact, the advanced disease stage and previous extensive treatments likely rendered patient immune system less fit to develop effective antitumor immunity. This hypothesis is corroborated by the absence of any abscopal effect in advanced melanoma patients who were nevertheless successfully treated for superficial metastases by electrochemotherapy [50]. On the other hand, it has been reported that objective response after electrochemotherapy decreases with the increasing size of treated tumors [25]. This indicates that patients with less advanced disease have a higher chance of response to treatment and experience better local control. These observations prompt for considering electrochemotherapy in earlier stages of disease, when tumor size is smaller, and in combination with systemic treatments. Interestingly, electrochemotherapy has been shown to induce extensive tumor necrosis (Fig. 76.3) and to expose tumor antigens [10, 13]. The rational combination with immunomodulating agents may allow capitalizing local immune response and induce a systemic immune response, which could represent an effective strategy to tackle oligometastatic disease. Moreover, since tumor heterogeneity is a common finding in advanced breast cancer patients and mixed response to systemic therapies are commonly observed, the availability of a new, effective, locoregional treatment for superficial metastases may represent a useful tool to combine with or alternate to ongoing systemic therapy, as already suggested in melanoma patients ([51]).

76.6.3 Technological Advancement of ECT Instrumentation (Grid Electrodes, Long Needle Electrodes)

With the adoption of electrochemotherapy by a continuously increasing number of European centers, also the technology has made significant advancements, thus opening the possibility to treat more challenging patients, such as those with widespread tumor dissemination or those with deep-seated metastases.

76.6.3.1 Treatment of Deep-Seated and Visceral Metastases

In recent years, electrochemotherapy equipment has been implemented for the treatment of deep-seated tumors. In particular, thanks to design and development of long (20 cm) needle electrodes, it is now possible targeting a variety of large and deep tumors, including also metastases on soft tissue, bone, and liver [52, 53]. There are several ongoing trials investigating electrochemotherapy, administered by means of dedicated devices, in the treatment of liver and bone metastases [54, 55]. According to the preliminary results of these studies, electrochemotherapy has the potential to spare healthy tissue and holds an exciting potential for the treatment of tumors that lay close to vital structures (i.e., major blood vessels in the liver) where surgery resection is much challenging or not possible [56–58].

76.6.3.2 Treatment of Widespread Superficial Tumors

A subset of patients with locoregional recurrence from breast cancer presents widespread lymphangitic tumor spread on their chest wall. In these patients, tumor recurrence may have ill-defined borders, but the amount of tumor-infiltrated skin is invariably large enough to prevent effective treatment delivery with standard pulse applicators (Fig. 76.3). In order to tackle these challenging situations, some prototypes of a new grid electrode have been recently developed [59]. These new flexible devices adapt to the chest wall and are intended to manage large skin surfaces. This technical advancement may allow homogenizing treatment delivery to the skin and reducing the duration of the procedure, in order to reduce the time of anesthesia, but, most of all, exploit the interval of maximum tumor exposure to drugs.

Conclusions

The treatment armamentarium for superficially metastatic breast cancer has been enriched by the introduction of electroporation technologies in the clinic. Electrochemotherapy represents a promising locoregional treatment modality, which allows effective local drug delivery and concentration within tumors. As a result, clinicians have now the opportunity to apply a rapid, well-tolerated, and effective therapy, which ensures a highly personalized treatment, tailored to the extent of tumor spread. The introduction of a new, effective, and low toxic locoregional treatment, coupled with the advent of new systemic drugs, provides exciting research opportunities to develop novel effective treatment strategies in the challenging setting of locally advanced and metastatic breast cancer. The close collaboration among experts in different fields (medical oncology, surgical oncology, radiotherapy, biomedical engineering) will help to clarify the most appropriate timing and indications for electrochemotherapy and will drive the integration of this therapy in the treatment of breast cancer.

Acknowledgments The Slovenian Research Agency has supported this research by grant P3-0003. Research was conducted in the scope of the EBAM European Associated Laboratory (LEA) and resulted from the networking efforts of the COST Action TD1104 (www.electroporation.net).

Circulating miRNA in Early Diagnosis

77

Fabrizio Bianchi

77.1 Background

Breast cancer is the most common female cancer worldwide and the second leading cause of cancer death among women. In 2015, there were an estimated 231,840 new cases and 40,290 deaths in the USA alone [1]. However, mortality can be drastically reduced if this disease is diagnosed at an early stage, before it spreads to other organs. Indeed, the 5-year survival rate for breast cancer patients with such localized disease is ~99% compared to ~25% in patients with metastasis to distant organs (such as to bones, brain, or lungs) [1]. For this reason, there has been a strong drive to promote breast cancer screening programs that allow early-stage diagnosis. This is particularly important in postmenopausal women and in women with multiple cases of familial breast cancer, for whom the risk of developing breast cancer is up to 80% if they are carriers of mutation in BRCA1 or BRCA2 or both [2]. However, there are several drawbacks with this approach: (1) mammography screening is recommended for women over 40 years old; (2) ~20% of tumors will be missed by mammography; (3) cumulative false-positive rates are high leading to overtreatment; and (4) overdiagnosis of tumors that would not have become clinically relevant is common. In addition, the efficacy of mammography screening in reducing mortality is currently debated due to a recently published randomized trial involving ~90,000 women [3–5]. The study showed that breast cancer mortality was not reduced in the mammography-screening arm and that 22% of screen-detected invasive breast cancers were overdiagnosed [3].

The development of cancer biomarkers to be used in addition, or as an alternative, to mammography may change this scenario by increasing the sensitivity (i.e., the ability to detect breast cancer) and specificity (i.e., the ability to exclude the presence of a tumor lesion) of a screening test. Such a test, possibly minimally invasive and relatively cheap, should reduce the size of the target population to be screened and would undoubtedly be advantageous in terms of minimizing harms/maximizing benefits of screening, reducing costs, increasing screening uptake rates, and reducing medicalization of participants.

A blood test for early-stage breast cancer would be ideal as a first-line screening procedure to preselect high-risk individuals who require further diagnostic investigation by mammography or MRI. The relative low-invasive procedure used for collecting material and the possibility to obtain multiple samples from the same patient make liquid biopsy screening (i.e., blood, urine, saliva, etc.) an attractive field for cancer biomarker discovery. Recently, with the discovery of circulating free-microRNA (cf-miRNA), the assortment of molecules analyzable in the blood samples has been expanded. MicroRNAs (miRNAs) are short noncoding RNA molecules functioning as endogenous triggers of the mRNA interference pathway and are involved in the regulation of many cellular processes, including differentiation, proliferation, and apoptosis [6, 7]. MicroRNAs were shown to be remarkably stable in body fluids [6, 8, 9].

There is growing interest in miRNAs, both as potential cancer determinants and biomarkers [10]. Generally, miRNA profiling might be advantageous over mRNA profiling, since the miRNome complexity is approximately tenfold lower than that of the transcriptome (~1900 miRNAs vs. ~20,000 coding genes). This means that a much lower number of samples are needed in the analysis in order to reach a sufficient statistical power. This is relevant particularly in those studies involving human pathological samples, in which genetic heterogeneity among individuals and tumor samples represents a relevant confounding factor. Importantly, the expression of miRNAs is often deregulated in human tumors, both in a tissue- and cancer-specific manner [11].

77.2 Small Noncoding RNA: The MicroRNA

In 1993, Victor Ambros et al. discovered that the lin-4 (abnormal cell LINeage) gene was involved in the larval development of the nematode *Caenorhabditis elegans* (*C. elegans*), one of the most used model organisms in development biology and genetic research [12]. Lin-4 is a repressor of another gene called lin-14. Lin-14 codes for a protein required for the division of a group of cells during postembryonic development. As opposed to lin-14 gene, lin-4 gene does not encode for a protein but for two small noncoding RNAs [13] measuring 61 nucleotides (nt) and 22 nt, respectively. The longer small noncoding RNA (61 nt) folds into a stem-loop structure that is the precursor of the shorter noncoding RNA (22 nt). This shorter noncoding RNA binds to the 3′ untranslated region (3′-UTR) of the lin-14 messenger RNA (mRNA) through antisense complementarity forming an RNA duplex [13, 14]. This RNA duplex is a signal for the intracellular degradation and translational repression of lin-14 mRNA. Through this molecular mechanism, lin-4 reduces LIN-14 protein level and mediates repression of its biological function [13, 14]. Importantly, lin-4 RNA has been the first identified member of an abundant class of small, regulatory, noncoding RNAs called microRNAs [15–17]. miRNAs have been identified in a wide range of organisms, ranging from simple multicellular, such as poriferans (sponges) and cnidarians (starlet sea anemone), to *Homo sapiens.* Animal miRNAs are supposed to have evolved separately from plant miRNAs due to differences in sequences, structure, and biogenesis mechanisms [18, 19].

77.3 MicroRNA Biogenesis and Function

The mature and active form of a miRNA contains about 22 nucleotides (nt), and it is the result of a complex multistep RNA-processing mechanism which starts in the nucleus and continues in the cytoplasm. MicroRNAs are embedded in an ~33 bp double-stranded stem characteristic of hairpin structures contained in the "precursor microRNA" called pre-miRNA, which can be of several kilobases of length (Fig. 77.1). The transcription of most pre-miRNAs is mediated by RNA polymerase II (Pol II) [20, 21], although a small group of miRNAs that are associated with Alu repeats (i.e., a short stretch of repeated DNA elements) can be transcribed by Pol III [22]. While still in the nucleus, pre-miRNAs are cut at 11 bp from the base of the hairpin stem by Drosha, an RNase III-type endoribonuclease (Fig. 77.1). The result is a shorter RNA with a stem-loop structure of ~70 nt, i.e., the precursor miRNA (pre-miRNA) (Fig. 77.1). Drosha alone is not able to process pre-miRNA, but it works in complex with the dsRNA-binding protein DGCR8 (the DiGeorge syndrome critical region 8, also known as Pasha). DGCR8 works as a "molecular ruler" to guide Drosha cutting. Indeed, mouse embryonic stem (ES) cells deficient in the Dgcr8 gene fail to produce miRNAs and manifest defects in proliferation and differentiation [23].

Subsequently, pre-miRNA is exported to the cytoplasm through the Exportin5-Ran-GTP complex [24] (Fig. 77.1). In the cytoplasm, pre-miRNA is further processed by another enzyme (an endoribonuclease) called Dicer [25, 26]. Dicer belongs to the RNase III protein family and is characterized by a DEXD/H ATPase domain, a DUF283 (a dsRNA-binding) domain, a PAZ domain, an unannotated region ("ruler domain"), and a tandem RNase III domain (RNase IIIa and RNase IIIb) that is the catalytic core [27]. Dicer cleaves the pre-miRNA at a site close to the terminal loop (22 nt away for the dsRNA stem). Following Dicer cleavage, the resulting ~22 nt RNA duplex with protruding 3′ overhangs at both ends (Fig. 77.1) is loaded onto an Argonaute protein (AGO) [28], where one strand, complementary to the target mRNA (guide strand), is selected and subsequently generates the mature miRNA. The mature miRNA-AGO becomes then part, with also the scaffold protein GW182, of the "effector RNA-induced silencing complex" known as miRISC complex (Fig. 77.1) [25, 26]. The "guide strand" directs target mRNA recognition by Watson-Crick base pairing, whereas the other strand of the original duplex (i.e., the passenger strand) is discarded. Argonaute proteins are characterized by the presence of four domains: the PAZ domain (present also in Dicer enzymes), the PIWI domain that is unique to the Argonaute superfamily, and the N and Mid domains. Studies using small interfering RNA (siRNA) duplexes that are similar to miRNA [29] indicate that the relative thermodynamic stability of the two ends of the duplex determines which strand is to be selected [30, 31]. Because strand selection is often not a stringent process, some hairpins produce miRNAs from both strands at comparable frequencies.

77.4 MicroRNA Target Prediction

A significant difference is observed between plants and animals. In the former, targets can be efficiently detected simply by searching for extensive complementarity between the miRNA and 3′ UTR sequences, as shown in [32]. In plants, regulation of transcripts mainly occurs by means of slicing rather than translational repression. In animals, the situation is far more complicated. Extensive complementarity between miRNA and the 3′ UTR sequence exists but is rare [33, 34], and the largest part of validated targets interact with their corresponding miRNA by imperfect match. The initial research effort to reliably identify miRNA targets in animals was heavily based on computational

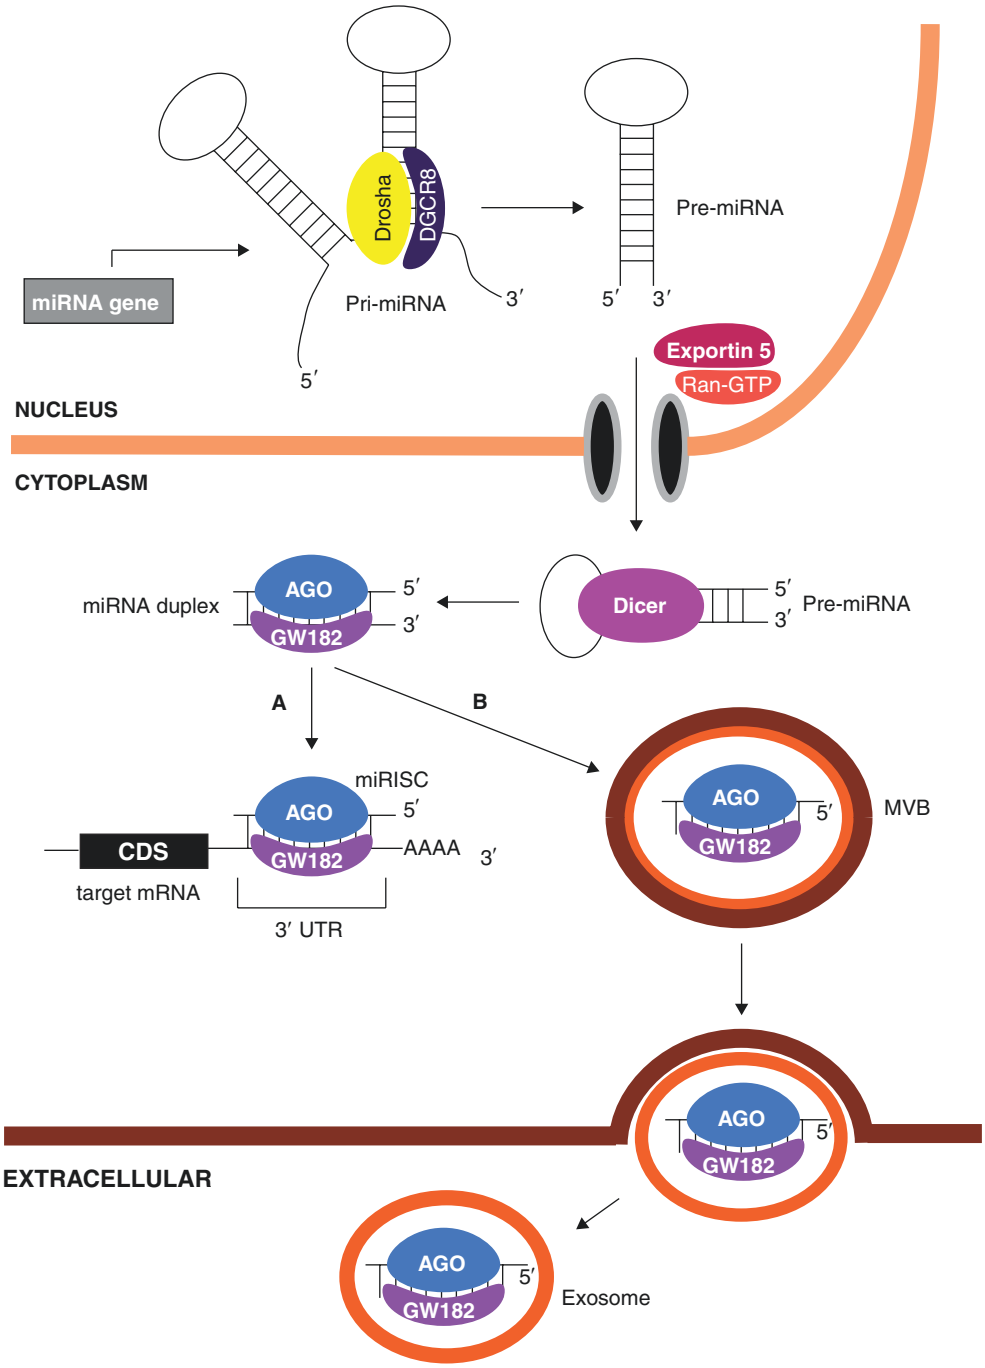

Fig. 77.1 The biogenesis and function of miRNAs. (*A*) Intracellular miRNA mediated silencing of target mRNA. (*B*) Extracellular-vesicle exporting of mature miRNA

tools; thus, a number of different methods were developed. The list of targets produced by these methods, however, showed little overlap which suggests a bias in these results due to intrinsic methodological differences [35]. One of the main problems that occur during miRNA target prediction is the large fraction of 3′ UTR fragments having identical alignment score to the miRNA of interest [36]. Therefore, the inclusion of preferential evolutionary conservation to distinguish a true target from the multitude of equally matching 3′ UTR fragments is considered as mandatory.

Overall, three major aspects should be considered when looking for evolutionary conserved miRNA targets:

1. The seed region, i.e., the 5′ region of the miRNA centered on nucleotides 2–7 [37–41]
2. The conservation of the seed region across different species [38, 42, 43]
3. The observation that highly conserved miRNAs have many conserved targets [38, 42, 43]

In addition, some prediction algorithms (e.g., TargetScan [44]) reward the presence of an adenosine in the "target mRNA" opposite to the first nucleotide (7mer-A1) of the miRNA seed region in order to increase the fraction of true positives findings. This relies on the increasing evidence that a non-Watson-Crick pairing at the first nucleotide of the miRNA is somewhat favored as confirmed both by site-conservation analyses and by array and proteomics data [40, 45]. Another feature considered in some prediction algorithms, although less frequent, is the presence of an additional perfect match in the eighth position (7mer-m8) [35].

77.5 Extracellular MicroRNAs: Mechanisms of Release and Functions

In 2008, pioneer studies demonstrated that microRNAs were detectable in cell-free blood plasma and serum [8, 46, 47]. Other research studies showed subsequently that miRNAs were present in virtually all other body fluids [48–51]. Together these important discoveries posed several questions regarding the way miRNAs remain stable in the body fluids, how they are released from cells, and if they could exert any biological function. Of note, microRNAs were found in the extracellular space within microvesicle/exosome [52, 53], apoptotic bodies (AB) [54], HDL structures [55], or complexed with AGO protein [56, 57], which would confer to miRNA an increased resistance to degradation via RNAse action in the blood [8]. The upload of miRNAs within these structures appears to be guided by either specific or random processes. For example, the AGO-GW182-bound miRNAs were shown to reside in multivesicular bodies (MVB) that give rise to exosomes, which indeed contain high-level of the GW182 protein [58] (Fig. 77.1). This may suggest a random process for miRNA selection within newly formed exosomes, while the observed preferential selection of particular miRNAs can be explained by different decay kinetics [59]. Nevertheless, there are now mounting evidences that positive selection mechanisms do also exist to package specific miRNA species in MVBs [60]. The ceramide-dependent secretory pathway which is controlled by nSMase enzyme (e.g., the ceramide biosynthesis neutral sphingomyelinase) was recently shown to be involved in exosomes and miRNA release [49]. nSMase2 hydrolyzes sphingomyelin to produce ceramide that is essential for budding of intracellular vesicle into the MVBs [61]. Inhibition of nSMase2 specifically reduces miRNA level in secreted exosomes but not the intracellular level of miRNAs [62]. However, how exactly miRNAs are selected and loaded to exosomes/microvesicles, and how the trafficking is regulated in physiological and pathological conditions, is presently unknown. In addition, what is the biological function of these extracellular miRNAs is still an unanswered question. In cancer cells, the extracellular release of miRNAs can be a strategy to reduce intracellular level of miRNAs with antitumor activity [63]. On the other end, the release of miRNAs can function as a paracrine signal to reprogram tumor microenvironment and favor cancer progression. Recently, new evidences favoring this second hypothesis were obtained. Exosomal/MVB/AB miRNAs were shown to be delivered to neighboring cells where, following uptake, they exerted transcriptional modulation of target mRNAs [49, 52, 64–67]. Fascinatingly, an alternative mechanism of action for cancer-derived extracellular miRNAs was also proposed: two independent research groups discovered that AGO2-complexed miR-21 and miR-29a act as signaling molecules via binding to intracellular Toll-like receptors (murine TLR-7 and human TLR-8), which are a family of receptors characteristic of immune cells involved in innate immune system [68]. The activation of immune cells expressing TLRs was shown to be responsible of secretion of inflammatory cytokines that may induce cancer cells spread [68].

77.6 MicroRNAs as Circulating Biomarkers for Early Cancer Detection

Importantly, fluctuations of miRNAs in serum and plasma samples were shown to be associated with many malignant and nonmalignant diseases [8, 69, 70]. Contrary to circulating tumor DNA (ct-DNA), where there are evidences that only a fraction of early-stage tumors may release sufficient quantities of circulating DNA to be detected in the blood [71], circulating free-miRNAs (cf-miRNA) appear to be excellent candidates for blood-borne tumor markers for the early diagnosis of different tumors [72, 73]. Notably, fluctuations in cf-miRNAs have been associated with malignant and nonmalignant diseases [8, 70, 74], which make them excellent candidates for tumor markers for the diagnosis, prognosis, and therapy response prediction.

In line with this hypothesis, our lab and others have recently shown that omics-based analyses of serum/plasma samples are powerful tools for the identification of reliable cancer biomarkers [75, 76]. We successfully derived a cf-miRNA signature capable to early diagnose lung cancer in asymptomatic individuals enrolled in the COSMOS (Continuing Observation of Smoking Subjects) lung cancer early detection trial (ClinicalTrials.gov Identifier: NCT01248806 [77]). From the cf-miRNA analysis, we derived a serum 34-miRNAs signature (Table 77.1) diagnostic for asymptomatic, early-stage, lung cancer (AUC = 0.89, $p < 0.0001$) [75]. The 34-miRNA signature paved the way for the identification of an innovative diagnostic test, the miR-Test (Table 77.1), which once validated in an additional independent cohort of 1115 high-risk individuals confirmed an AUC of 0.85, accuracy of 74.9%, sensitivity of 77.8%,

[a]miR-Test composition: miR-92a-3p, miR-30b-5p, miR-191-5p, miR-484, miR-328-3p, miR-30c-5p, miR-374a-5p, let-7d-5p, miR-331-3p, miR-29a-3p, miR-148a-3p, miR-223-3p, miR-140-5p

[b]Predicted performance when applied to independent samples

and specificity of 74.8% [78]. Similar studies were performed in breast cancer patients though none of the proposed cf-miRNA signatures have been validated in actual breast cancer screening studies (Table 77.1) [79–84].

Overall, detection of extracellular microRNAs in body fluids is emerging as a promising approach for developing innovative, minimally invasive, cost-effective, diagnostic tests to be used as first-line screening procedures. Several cf-miRNA signatures were recently found and proposed for cancer early diagnosis [76, 78, 85–88], prognosis [89–92], and response to therapy [93–98] and applied in cancer screening studies [78, 87].

Almost half of the published cf-miRNA signatures were discovered analyzing serum samples, while the others were derived from plasma samples (Table 77.1). Serum and plasma cf-miRNAs can be different in terms of quantities and species, and this is ascribed to differences in the chemical composition and in the technical preparation of these two biological specimens [99, 100]. This should be taken into account when searching for overlapping cf-miRNA in different studies or when cf-miRNA biomarkers are validated using external independent cohorts.

77.7 Future Perspective

Liquid biopsies research field is making fast progresses due to the rather simple way to collect biological material and the variety of the analyzable circulating molecules. For these reasons, it is tempting to speculate that liquid biopsies molecular analysis will become the gold standard for developing noninvasive tests for personalized medicine. Population-based liquid biopsies screenings may increase the chance for cancer early diagnosis. In addition, the collection of multiple liquid biopsies from the same patient will allow better evaluation of the therapeutic effect and could anticipate cancer recurrence. Nevertheless, there are still some methodological limitations that need to be resolved before the large-scale application of these molecular tests. For example, the extraction and analysis of circulating nucleic acids require expensive and complex equipment that is currently available only in few cancer centers worldwide. Furthermore, the sensitivity and specificity of these molecular tests should be improved to augment the detection rate and avoid false positives and negative results, which are detrimental for cancer early detection screening programs. Lastly, the possibility to perform molecular tests directly in the blood without nucleic acid extraction by using point-of-care testing (POCT) [101, 102] will definitely facilitate application in a population scale of such molecular tests.

Relevance of Stem Cells

78

Salvatore Pece, Maria Grazia Malabarba, Pier Paolo Di Fiore, and Daniela Tosoni

78.1 Introduction

The incorporation of multidisciplinary care schemes and the introduction of improved chemotherapeutics and molecularly targeted therapies in both the adjuvant and the metastatic setting have significantly ameliorated the clinical management and the survival of breast cancer patients. However, despite these advances, a significant proportion of patients continue to experience therapy failure and disease progression, due to the occurrence of primary or acquired resistance to currently available therapies [1, 2]. Over the last few years, it has become increasingly clear that intra-tumor heterogeneity represents the major underlying cause of disease progression and recurrence following therapy failure in several types of tumors, including breast cancer [3–6]. The tenet of intra-tumor heterogeneity is that the tumor cells that compose the bulk tumor mass, despite their clonal origin, may display a high degree of genetic and phenotypic diversity, which is believed to be at the basis of the emergence of clones of tumor cells that are able to resist to therapies and, eventually, to promote disease recurrence and metastasis [7–9]. This poses a tremendous challenge for the clinical management of breast cancer, in particular with regard to the characterization of biomarkers that can aid prognostic and therapeutic decision-making, and to the development of more effective breast cancer therapies. Here we review the relevance of the cancer stem model to breast cancer and argue that integrating knowledge based on the cancer stem cell paradigm with a better understanding of the molecular alterations underlying breast tumorigenesis holds the key for the development of more refined therapies to combat breast cancer.

78.2 Cellular and Molecular Bases of Breast Tumor Heterogeneity: The Cancer Stem Cell and the Clonal Evolution Model

The clinical and pathological heterogeneity of human breast cancer has long been recognized [10]. In recent years, molecular profiling studies have tackled the question of inter-tumor heterogeneity in breast cancer, with the recognition of major molecular subtypes (luminal A, luminal B, basal-like, HER2) with different characteristics and clinical behavior [11, 12]. The integration of this new molecular taxonomy with the traditional histopathological parameters (e.g., histological type, grade, estrogen/progesterone receptor, and HER2 status) has revealed critical for informing patient management in the clinical practice. However, converging evidence from a variety of cytogenetic, comparative genomic hybridization and, more recently, parallel sequencing studies support the notion that breast tumors, likewise other solid tumors, rather than being composed of cells with identical functional and phenotypic

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_78

traits, can display varying degrees of intra-tumor heterogeneity, characterized by the coexistence of subpopulations of cells that may profoundly differ in their genomic landscape and behavioral traits [13–18]. These differences exist both in the context of the primary tumor and between the primary tumor and its metastasis [19, 20]. The two models that have been put forward to explain the genesis of intra-tumor heterogeneity are the clonal evolution and the cancer stem cell model [4–6, 21]. There are a number of common features between these two models, and it is becoming increasingly clear that, at least in tumors with high genomic instability, they are not mutually exclusive [3, 4, 20].

Both models hold that tumors originate from single cells that have acquired unchecked proliferative potential and, occasionally the ability to metastasize, through multiple molecular alterations that have enabled tumor cells to break normal tissue constraints. The clonal evolution model, however, posits that tumorigenesis is driven by the clone that has acquired the highest degree of fitness through the accumulation of a series of random genetic and epigenetic alterations, occurred in a spatial and temporal fashion according to a Darwinian evolutionary process [22–24]. In this model, tumor heterogeneity is accounted for by the presence of multiple clones harboring specific genetic and epigenetic aberrations, where one of these clones outcompetes all the others and drives tumorigenesis. In this scenario, also the emergence of therapy-resistant clones, by definition responsible for tumor recurrence and metastasis, becomes the consequence of stochastic molecular alterations that confer a positive selective advantage to specific tumor cells in response to environmental selective pressures, first and foremost anticancer therapies [25, 26]. The therapeutic implication of the clonal evolution model is that eradication of cancer can be achieved only when the entire subpopulation of cells derived from the selected tumor clones are killed by therapies, considering that they all display equivalent degree of fitness and behavioral characteristics.

By contrast, the cancer stem cell model presupposes that tumors are caricatures of normal tissues, and, therefore, the phenotypic and behavioral differences among the tumor cells are the consequence of the hierarchical organization of the tissue generated in the course of a morphogenetic program, albeit aberrant. This model has been validated in several types of solid and hematological malignancies and posits that at the apex of the tumor tissue hierarchy there exist a minority of cells endowed with unlimited self-renewal ability and tumorigenic potential: the cancer stem cells [21, 27–29]. In this model, the bulk tumor population is made of a progeny of tumor cells with only a limited proliferative potential and deprived of any residual tumorigenic ability. The therapeutic implication of this model is that a cure can be achieved when targeted therapies specifically eradicate the cancer stem cells [7, 22, 30]. This concept is of paramount importance in light of increasing evidence that in different types of cancers, including breast cancer, cancer stem cells are inherently resistant to therapies that kill the bulk tumor population, and therefore, able to promote tumor progression and recurrence after a transient response [7, 9, 31, 32].

The clonal evolution and the cancer stem cell models are not necessarily mutually exclusive. Indeed, if it is true that the nature of intra-tumor heterogeneity in the cancer stem cell model is largely phenotypic, recent studies suggest that cancer stem cells may also contribute to the genetic diversity of tumors, due to the presence of cancer stem cell clones that are genetically heterogeneous [13–18]. This can be explained by the high rate of mutations that, in tumors with high genetic instability, may drive clonal evolution of the original cancer stem cell, thus originating a hierarchy of cancer stem cells with varying genetic landscapes. Another possibility is that genetically different clones of cancer stem cells derive from the *de novo* appearance of stemness traits in more differentiated progenitors that have undergone phenotypic plasticity and reprogramming, a phenomenon that, in preclinical studies, has been largely attributed to the activation of epithelial-to-mesenchymal transition (EMT) programs [33, 34]. In keeping with this idea, poorly differentiated breast cancers, which are intrinsically enriched in cancer stem cells [35], frequently display increased mesenchymal-like features [36], and the occurrence of mesenchymal phenotypes has been associated with resistance to hormonal and chemotherapeutic treatments [30, 37–39]. Whichever the underlying cause, the emergence of genetically different cancer stem cell clones would be unavoidably associated with the coexistence of multiple genetically distinct lineages of tumor cells, a scenario that is typical of polygenomic breast cancers [14, 18].

The idea that integrating the cancer stem cell and the clonal evolution models may provide a more comprehensive understanding of tumorigenesis, with profound clinical implications, is of the utmost relevance to breast cancer. On the one hand, the degree of molecular resemblance to stemness traits may constitute a measure of the molecular, biological, and clinical heterogeneity of breast cancers, as indicated by the notion that the biological aggressiveness of breast cancers can be predicted by their intrinsic content in cancer stem cells [35]; on the other hand, recent parallel sequencing studies have demonstrated that breast tumors may display varying degrees of intra-tumor genetic heterogeneity [14, 15, 17], which can even affect well-established driver somatic mutations, such as those involving TP53 and PIK3CA [18]. As to this latter observation, while it has not yet formally proven that this is the consequence of the coexistence of multiple genetically distinct cancer stem cells, it has been demonstrated that either a spatial heterogeneity, with different lineages present across different geographical

areas of the primary tumors, or a temporal heterogeneity, with genetically distinct clones between the primary tumor and its metastasis, is both a possible occurrence in breast cancer [14–16, 40].

78.3 Stem Cells in the Normal Mammary Gland and in Breast Cancer

In normal tissues, stem cells endowed with unique self-renewal and multi-lineage capacity fuel the process of tissue morphogenesis in which stem cells retain their immature state and give origin to progenitors that progressively lose their proliferative ability to undergo terminal differentiation [21]. The concept that tumorigenesis can be regarded as to normal morphogenesis gone awry, with the corollary that tumors are hierarchically organized similarly to normal tissues, suggests that normal and cancer stem cells may share several similarities [6, 27–29, 41, 42]. Indeed, a number of common phenotypic and functional properties have been described between normal and tumor stem cells, such as the ability to self-renew and differentiate into multiple lineages, thus recapitulating the phenotypic heterogeneity of the original tissue, the telomerase and the antiapoptotic activity, the increased membrane transporter activity, and the ability to resist to genotoxic stresses [4, 41, 43]. Moreover, evidence in support of the existence of cancer stem cells in several types of solid cancers, including breast cancer, has been provided through the use of the same *in vitro* surrogate assays, such as sphere formation in anchorage-independent conditions, differentiation and clonogenicity assays, and *in vivo* transplantation techniques (limiting dilution xenografting in orthotopic or heterotopic sites) adopted to study the biology of normal stem cells [4, 44, 45]. Further supporting the idea of the similarities between normal and cancer stem cells, the prospective isolation of rare subfractions of tumorigenic cells from the bulk tumor mass has often been based on the use of cell surface markers derived from the characterization of the normal stem cells in the tissue of origin [29, 35]. The idea of the congruence between normal and cancer stem cells is relevant to breast cancer, where the use of the molecular profile of human normal mammary stem cells has revealed a useful tool to interrogate the molecular, phenotypical, and clinical heterogeneity of breast tumors, with the observation that their intrinsic biological aggressiveness is a function of their content in cells displaying stemness traits [35].

This notwithstanding, it has to be clearly stated that the cancer stem cell concept does not necessarily address the original cellular target of malignant transformation. The mammary gland constitutes a paradigmatic model in support of this concept. In fact, while it is true that—as shown in preclinical models of breast tumorigenesis—breast cancer stem cells may derive from alterations of the homeostasis of normal mammary stem cells [34, 46], it has also been shown that cells with tumorigenic ability may originate from immature progenitors and terminally differentiated cells reprogrammed to a stem cell-like state through phenotypic and molecular plasticity consequent to the activation of an EMT program [34, 47]. This notion is in keeping with the well-established role of EMT in the transdifferentiation of normal mammary epithelial cells to a more mesenchymal state [33] and with evidence implicating EMT in therapy resistance and cancer progression [39, 48, 49]. Therefore, the concept of cancer stem cell is rather an operational definition that, irrespective of the cell of origin, indicates—in the context of the hierarchical organization of breast tumors—the true underlying cause of the tumorigenic process and, most likely, the ultimate responsible for tumor progression and metastasis after therapy failure.

The relevance of the cancer stem cell paradigm to breast cancer is also underscored by accumulating evidence that cancer stem cells are inherently resistant to conventional chemo- and radiotherapies, thus being able to drive tumor progression and recurrence even when standard of care treatments have yielded an initial response in terms of debulking of the primary tumor. While data are emerging in support of this view [7, 30, 37–39], the mechanisms underlying the therapeutic resistance of breast cancer stem cells remain elusive. A number of properties likely contribute to the emergence of therapy-resistant breast cancer stem cell clones, such as the high capacity for DNA repair, the relative dormancy/slow cell cycle kinetics, and the expression of multiple drug resistance membrane transporters (e.g., ABC transporters) and of anti-apoptosis determinants. These mechanisms have been, therefore, proposed as potential therapeutic targets to eliminate breast cancer stem cells and to achieve a definitive cure [9].

78.4 Molecular Mechanisms Underlying the Origin of Breast Cancer Stem Cells

The mammary gland represents a paradigmatic example of how the coordinated execution of normal tissue morphogenesis represents *per se* an effective tumor suppressor barrier. Over the past decade, evidence has accumulated that hijacking the developmental pathways that control the self-renewal of normal stem cells and tissue morphogenesis (Notch, Hedgehog, and Wnt) can be involved in breast tumorigenesis [50–55]. Therefore, much interest has grown concerning the possibility that targeting these pathways, in combination with conventional anticancer treatments, could improve the clinical management of breast cancer [41, 56–59].

The intimate relationship between deregulation of the mechanisms that tightly regulate normal mammary morphogenesis and onset of breast tumorigenesis is epitomized by the

Numb-p53 tumor suppressor circuitry. Dysfunction of this functional axis results in the emergence of cancer stem cells at multiple levels of the mammary tissue hierarchy [34]. At the level of the mammary stem cell compartment, proficiency of the Numb-p53 circuitry is required for the correct execution of asymmetric cell divisions by normal mammary stem cells [34, 46]. Asymmetric cell division is the process through which, at mitosis, a normal mammary stem cell self-renews and withdraws into quiescence while originating a progenitor that actively proliferates in the transit-amplifying compartment and is fated for terminal differentiation [60]. The ability to generate two daughter cells with opposite proliferative and differentiative fates through asymmetric cell divisions is vital to prevent the uncontrolled expansion of the stem cell compartment. The regulatory function exerted by Numb, by the liaison of p53, over this process safeguards against the emergence of cancer stem cells with unlimited proliferative and high tumorigenic potential [34]. The Numb-p53 circuitry, however, also counteracts the appearance of cancer stem cells at the bottom of the mammary gland hierarchy, in the compartment of differentiating progenitors and terminally differentiated cells. At this level, Numb-p53 dysfunction disrupts proper progenitor maturation and induces, through EMT activation, reprogramming and dedifferentiation of progenitors to a stem-like state, a process that is also accompanied by acquisition of tumorigenic potential [34]. Remarkably, restoration of the proficiency of the Numb-p53 circuitry efficiently curbs tumorigenesis, an effect that depends on the selective targeting of breast cancer stem cells, in the absence of a significant impact on the bulk tumor population [34]. These findings represent an important proof of concept that the elucidation of the molecular mechanisms responsible for the appearance of cancer stem cells may have an important impact on the development of new specific anticancer stem cell therapeutics that, integrated with conventional chemo- and radiotherapies, may significantly aid the clinical management of breast cancer.

78.5 Use of the Cancer Stem Cell Concept to Drive the Discovery of Targeted Therapies: The Paradox of Response and Survival in Cancer Therapeutics

The concept that cancer stem cells may represent the Achilles heel of tumors has also profound implications for the rationale designing of new anticancer drugs. Presently, evaluation of the efficacy of new cancer therapeutics in clinical trials is largely based on the objective clinical response, i.e., the assessment of changes in the bulk tumor mass according to RECIST (Response Evaluation Criteria in Solid Tumors) criteria, achieved by direct measurement or diagnostic imaging [61]. The principle at the basis of this approach is that objective evidence of clinical response, which can be assessed over weeks to months, constitutes a surrogate for biological activity and clinical benefit. By contrast, disease-free survival, which would be the ideal clinical endpoint to establish the efficacy of a cure, would require long-term follow-up. There is, however, increasing concern that assessment of the short-term effects of a drug in phase 2 trials using RECIST criteria might underestimate the effects of compounds with a selective anticancer stem cell action [9]. Indeed, the short-term reduction in the tumor mass largely reflects the impact of a given drug on the bulk tumor population. By contrast, a drug with a selective level of action against cancer stem cells may display only a modest, if any, effect in short-term treatments, while it could show a clinical benefit in terms of long-term survival. The idea that current drug development designs are more suited for the selection of therapeutics directed against the bulk tumor population, rather than against cancer stem cells, might also explain why, in a variety of hematological and solid malignancies, including breast cancer, the initial clinical response does not necessarily translates into increased patient survival [62]. While using disease-free survival as a primary clinical endpoint to assess the efficacy of a new drug against cancer stem cells is impractical, the task of translating new drugs to the clinical practice should integrate new preclinical and clinical methodologies that include the cancer stem cell concept. One possibility is, for instance, the routine implementation of neoadjuvant clinical trials (where a complete pathological response is a reliable surrogate for reduced recurrence rate) in which the objective response is integrated with cancer stem cell-based biological endpoints (biomarkers or functional proxies *in vitro* and/or *in vivo*) assessed on biopsy specimens obtained before and after therapy.

78.6 Concluding Remarks

The cancer stem cell paradigm is destined to profoundly revolutionize our way to diagnose, prognose, and cure breast cancer. While surgery and adjuvant therapies remain the standards of care for the treatment of breast cancer, the integration of our increasing understanding of the genetic and epigenetic bases of breast tumor heterogeneity with a more complete understanding of the cancer stem cell biology is likely to provide in the forthcoming future new therapeutic strategies to combat breast cancer and to overcome therapy resistance and tumor progression that often detrimentally affect breast cancer patient survival.

Subgroup Analyses and Information from Clinical Trials on Breast Cancer

79

Wai-Ki Yip

79.1 Introduction

At the 14th St. Gallen International Breast Cancer Conference in 2015, a panel of breast cancer experts reviewed and endorsed evidence-based local and regional treatments for early breast cancer [1], drawing on the research presented at the conference and identifying therapeutic targets based on disease heterogeneity.

As evidenced in the St. Gallen Conference, medical research is now more focused on providing personalized care for patients, which requires investigating how patient characteristics, including novel biomarkers, modify the effect of current treatment modalities. This phenomenon is known as heterogeneity of treatment effects. A better understanding of the interaction between treatment and patient-specific prognostic factors will enable practitioners to expand the availability of tailored therapies, with the goal of improving patient outcomes. But, how do we collect and analyze heterogeneity information?

79.1.1 An Example of Traditional Subgroup Analysis in Clinical Trials: The HERA Trial

The HERA (Herceptin Adjuvant) trial is an international, multicenter, randomized, open-label, phase 3 trial comparing treatment with trastuzumab for 1 and 2 years with observation following standard neoadjuvant, adjuvant chemotherapy, or both in patients with HER2-positive early breast cancer. Trastuzumab's benefit was first reported in 2005 [2] and was further documented in two follow-up analyses [3, 4] demonstrating that treatment with adjuvant trastuzumab for 1 year following chemotherapy provided significant clinical benefits (disease-free survival, overall survival) for patients with HER2-positive breast cancer. The HERA trial used a randomization procedure with stratification according to region of the world, age, nodal status, type of chemotherapy, and hormone receptor status together with intention to use endocrine therapy. Figure 79.1 shows the forest plot of an exploratory disease-free survival subgroup analysis comparing 1 year of trastuzumab versus observation, at 2 years "median" follow-up.

The forest plot [5, 6] is a popular graphical way to present the result of an exploratory subgroup analysis from a randomized clinical trial (RCT). Note that the overall result from the trial is positive (with hazard ratio [HR] = 0.64) and the main objective is not to test the null hypothesis within each subgroup but rather to assess heterogeneity around the overall effect which is indicated by the *solid vertical line* in Fig. 79.1. This (marginal) subgroup analysis was prespecified in the protocol and Cox proportional hazards models including interaction terms for treatment and each indicator of the individual subgroup factor were computed. Thus, visually, the forest plot summarizes the heterogeneity of treatment effects in all the subgroups for all prespecified factors in a single plot. The solid vertical line represents the overall hazard ratio (HR) comparing trastuzumab versus observation. The dotted vertical line is at HR = 1 which represents the null hypothesis of no effect. From the forest plot, the HRs for the different subgroups of the nodal status (positive, negative) were very similar (homogeneous). However, the trastuzumab effect for patients enrolled from Central and South America appears to be less than for patients from other regions of the world. How does one interpret such results from the subgroup analysis? Are the results trustworthy? Should regulators and/or clinicians recommend different treatments for, say, different regions of the world based on these results? Note that similar questions may be asked about very large tumors (>5 cm) or older patients (>60 years old). Additional subgroup analyses using some of the proposed methods here may help to answer some of these questions.

As the confidence intervals of all the subgroups in the forest plot include the solid vertical line, none of the

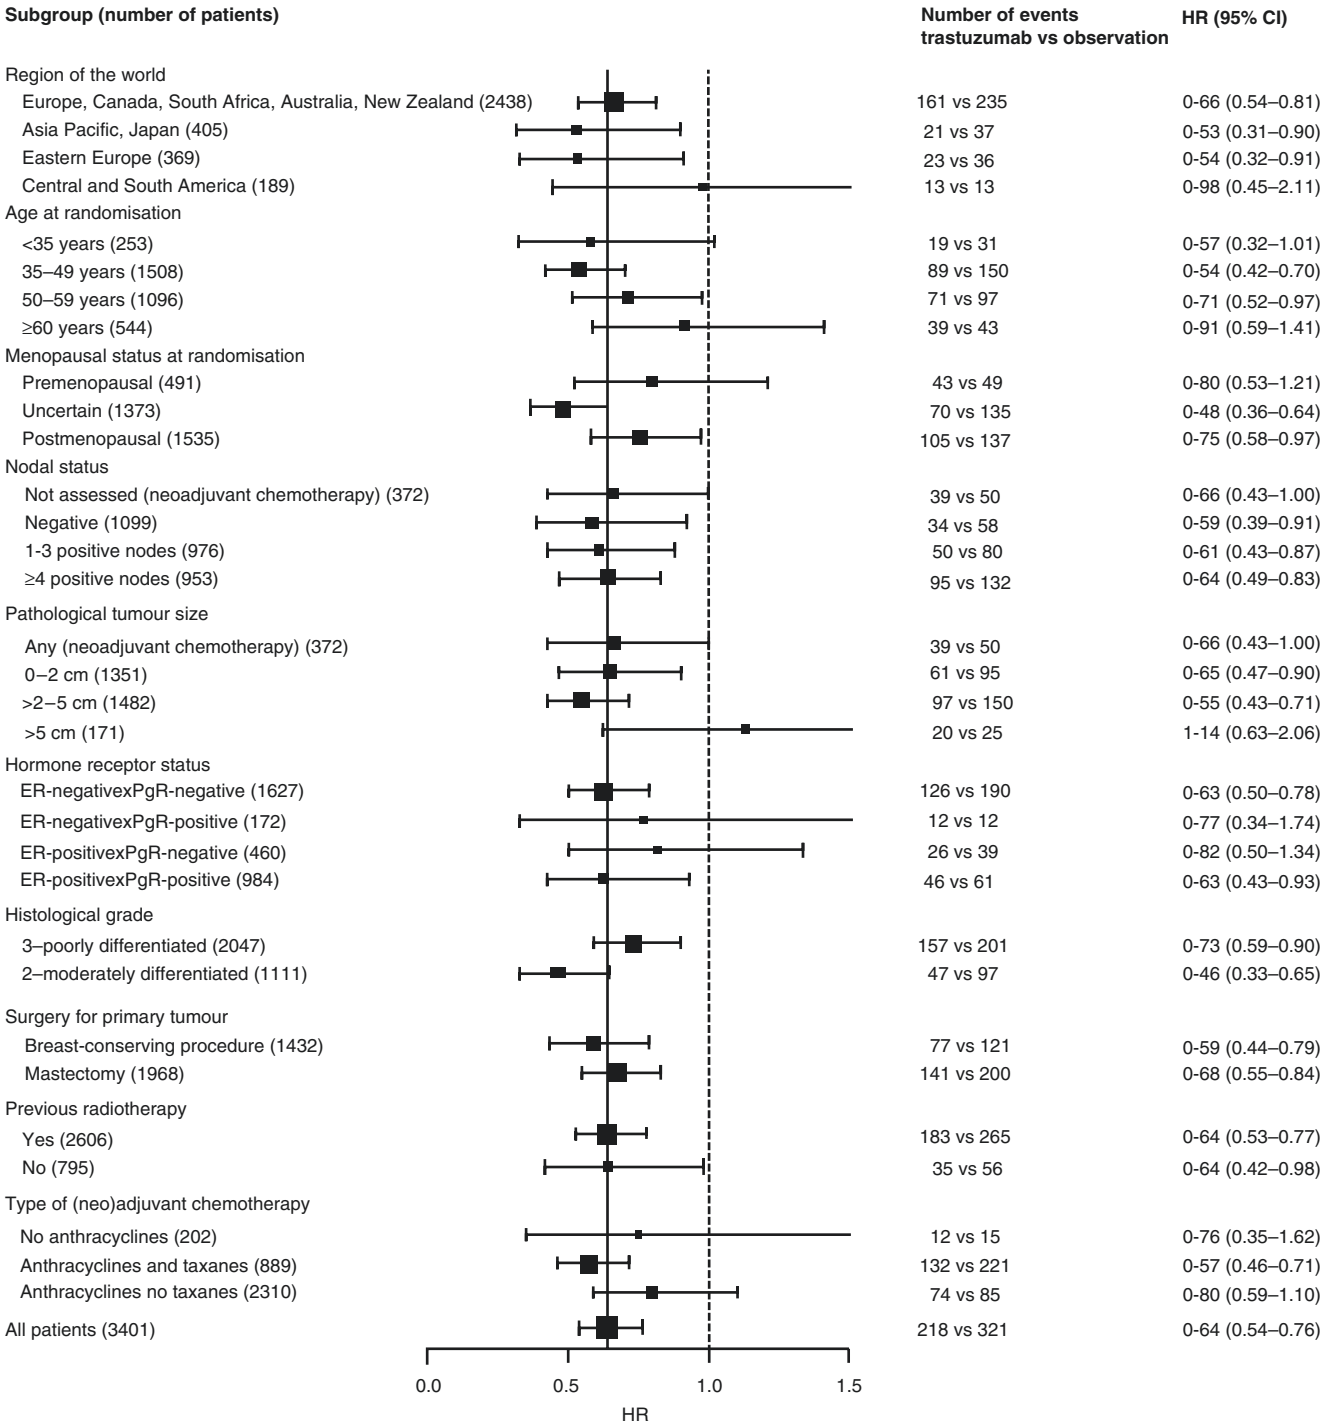

Fig. 79.1 Forest plot of subgroup analysis for 1 year of trastuzumab versus observation with disease-free survival as outcome [3]. Reprinted from The Lancet, Vol. 369 Smith I., et al., 2-year follow-up of trastuzumab after adjuvant chemotherapy in HER2-positive breast cancer: a randomized controlled trial. pp. 29–36. © (2007), with permission from Elsevier

heterogeneities shown were statistical significant. However, some of them warrant further investigation. In the later section entitled Tools for subgroup analysis, we describe a number of statistical methods that one could use to analyze and explore these treatment effect heterogeneities.

79.2 Subgroup Analysis and Breast Cancer

Results from RCTs provide the foundation of evidence-based medicine by comparing the treatment effects of competing therapies. Assessment of effectiveness is generally

based on the entire cohort of patients enrolled in the study. As shown in the HERA analysis, the magnitude of the treatment effect may not be the same across different patient subpopulations. Thus, the traditional one-size-fits-all treatment recommendation may not be optimal for an individual patient. Evaluating the interaction between treatment group and patient characteristics may provide the information necessary for clinicians to customize treatment to individuals and maximize the treatment benefits. For example, if the overall trial results fail to show significant treatment effects between new and conventional treatments, the new therapy may still be better in certain patients in particular subgroups.

A common approach is the one illustrated above, i.e., to evaluate the treatment effects for specific end points for subgroups of the patient population defined by baseline characteristics. An "interaction" statistical test of the null hypothesis that the treatment effects are the same in these subgroups can then be performed. Heterogeneity is classified as quantitative when the new treatment is superior across subgroups but the magnitude of the benefit differs and is classified as qualitative when the treatment is superior in one subgroup but has no effect or is inferior in another subgroup. Clinically, the qualitative interactions are more interesting. This approach to the study of treatment effect heterogeneity is known as "subgroup analysis" [7].

Breast cancer is a very diverse and complex disease. We have yet to understand fully the causes and the underlying biological mechanisms involved in the disease. There are a number of prognostic factors that could affect the disease outcome. By analyzing subgroups of patients with different prognostic factors, we may be able to identify specific subgroups which may respond well to different treatments. Hence, research results from subgroup analyses could allow clinicians to customize treatments for breast cancer patients for better outcomes.

79.3 Breast Cancer Heterogeneity

Subgroup analysis should be carefully planned and justified. Although the determination of pathophysiological heterogeneity is needed, Rothwell [8] has suggested four additional indications for subgroup analysis. They are discussed below with examples from breast cancer studies. Note that these indications are not mutually exclusive as some of these indications can always be traced to some underlying physiological conditions. The investigation of the following types of heterogeneity in breast cancer may provide necessary clinical information for treating an individual:

1. *Heterogeneity related to risk*—Clinically important heterogeneity of treatment effect is common when groups of patients have different absolute risks with or without treatment or with two or more evaluated treatments. The need for reliable data regarding risks and benefits in subgroups and individuals is greatest for potentially toxic interventions, such as cytotoxic therapy, which provide overall benefit but can harm a proportion of patients. Thus, the probable balance of risk and benefit in individual patients needs to be assessed. Subgroup analysis and risk models can be the correct tools to use. For example, because the risk of recurrence is higher for patients with more positive lymph nodes, the absolute benefit of trastuzumab is greatest in HERA for the 4+ nodes subgroup despite similar relative risk reductions across nodal subgroups (Fig. 79.1).
2. *Pathophysiological heterogeneity*—Subgroup analyses are most informative when they are based on prospectively defined, biologically based assumptions. Differences between groups of patients in underlying pathology, biology, or genetics can each lead to clinically important heterogeneity of treatment effects. Better understanding of the underlying molecular mechanisms of the disease will lead to better treatment. Clinicians often have to treat patients with ill-defined clinical tumors, which probably have many underlying pathologies, rather than one disease. At the 13th St. Gallen conference [9], there were efforts to characterize tumor subtypes and to classify breast cancer as luminal A, luminal B, Erb-B2 overexpressing, and basal like. Different therapies were recommended for patients according to these subtypes. Subgroup analyses can also be useful when there are predictable differences in the biological response to the underlying disease. Genotype is an important determinant of both the response to treatment and the susceptibility to adverse reactions for a wide range of drugs. The mutations of BRCA-1 and BRCA-2 genes may affect the prognosis. Additional biomarkers such as Ki-67, status of ER, nodes positive/negative, and HER2 help to identify optimal treatment regimes. In the PACS01 trial, it was suggested that Ki67 is a biomarker candidate for predicting docetaxel efficacy in ER-positive breast cancer [10]; in the BIG 1-98 study, it is suggested that patients with higher Ki-67 values who were assigned to receive tamoxifen had poorer prognosis compared with letrozole [11]. Using information from gene expression profiles such as the 21-gene RS [12, 13], the 70-gene signature [14], or PAM-50 [15] to name a few, provides prognostic and perhaps predictive information regarding the utility of cytotoxic therapy. Although the molecular gene scores provide useful prognostic information, they can be too expensive to be applied in developing countries.
3. *Heterogeneity related to practical application*—The main potential of subgroup analysis is in answering practical questions about how treatments should be used most

effectively, such as at what stage of the disease is treatment most effective, how long a particular therapy should be applied to achieve optimal results, or how the risks and benefits are related to comorbidity. The effect of treatment is often critically dependent on its duration. The optimal duration of adjuvant tamoxifen was addressed by the ATLAS study, which suggested a significant benefit for extending such treatment to 10 years rather than 5 years after the diagnosis of estrogen receptor-positive breast cancer [16]. A joint analysis of two randomized trials (International Breast Cancer Study Group [IBCSG] VI and German Breast Cancer Study Group) concluded that three initial cycles of adjuvant cyclophosphamide, methotrexate, and fluorouracil (CMF) chemotherapy were as effective or ineffective as six cycles for older premenopausal women (≥40 years old) with ER-positive tumors [17]. For node-positive breast cancer, a number of analyses suggest the efficacy of adjuvant docetaxel in several breast cancer subtypes [18–20]. Less invasive and less expensive treatment may be more appropriate for early-stage breast cancer. For example, two large studies support the safety and efficacy of shorter courses of whole breast radiation therapy (40 Gy in 15 or 42.5 Gy in 16 fractions) which offer advantages of convenience and cost compared with the previous standard of 50 Gy in 25 fractions [9].

4. *Underuse of treatment in specific groups*—Treatments that are effective in trials are often underused in specific groups of patients in routine practice. For example, selective estrogen receptor modulators (SERMS) such as tamoxifen were not used in younger patients for many years. In general, older patients and minorities have been underrepresented in clinical trials and more attention is needed so that these groups can be included in trials to determine the effectiveness of treatments for them. Proof of the generalizability of benefit is another major function of subgroup analyses.

79.4 Methodological Issues Concerning Subgroup Analysis

Performing subgroup analysis is a challenging task as documented by many researchers [7, 8, 21]. In fact, many examples of subgroup analyses that suggested clinically important heterogeneity of treatment effects have subsequently been shown to be false. For example, a published report in the New England Journal of Medicine claimed that tamoxifen citrate was ineffective for women aged <50 years with breast cancer [8]. This result was refuted in subsequent research [22]. As statisticians have pointed out, many such analyses have been overinterpreted and led to further research that was misguided or led to suboptimal patient care [8].

Subgroup analysis is inherently problematic. The first problem is due to multiplicity of testing, as it is a common practice to perform multiple subgroup analyses. Thus, the probability of a false-positive finding (type 1 error) increases as the number of subgroup analyses increases. If one performed just 14 independent analyses, there would be a 50% chance of getting a p-value ≤ 0.05 in at least one of them, even if there were no treatment effect at all. While subgroup analyses on the same data are not independent, the principle remains valid that the probability of at least one false-positive signal across all analyses will tend to be inflated. Thus some researchers recommend not presenting the p-values for within-subgroup comparisons but rather to give an estimate of the magnitude of the treatment differences and a corresponding (marginal) confidence interval. In the HERA trial, ten prognostic factors were examined. The effective type I error (probability of declaring significance when there is no real heterogeneity) can be computed under independence as being $(1-(0.95)^9) = 0.40$ if the α level for each separate test is set at 0.05.

In addition, any subgroup analysis, by definition, is not powered to detect the magnitude of effect anticipated for the trial, as the size of the subgroup is smaller than the entire cohort. So even if the overall result is significant, the test conducted for the subgroup may not have enough power to detect a significant result.

The biggest problem with subgroup analyses are their post hoc nature (also known as data dredging or fishing [23]). Post hoc analyses refer to those in which the hypotheses being tested are not specified prior to examination of the data. They are likely to be driven by trends seen in the data. Often, it is unclear how many post hoc subgroup analyses were performed. Thus, the type I error rate can be substantially higher than the nominal rate of 0.05. Since most publications contain only significant results, a significant report from one of these post hoc analyses would therefore potentially lead to misguided recommendations. Ideally, subgroup analyses should be prespecified and documented in the study protocol or at least prior to the examination of any of the data. If p-values are presented, the results need to correct for multiple testing. All the subgroups being analyzed in the HERA trial were prespecified in the protocol; however, after a simple Bonferroni correction, none of the individual subgroup results would be significant.

Although subgroup analyses have certainly led to mistaken clinical recommendations and possible harm to patients, it is imperative to glean the correct information from subgroup analyses because not doing so may also be harmful [8]. To counter some of these problems, the investigators should plan subgroup analyses in trial design by identifying prognostic factors that could potentially interact with treatment as secondary end points and designating their analyses as "exploratory." They must refrain from conducting

"data dredging" as it will most likely result in a false-positive outcome, misguiding future research. Subgroup analyses must also follow stringent reporting guidelines.

Ultimately, if certain prognostic factors are identified as interacting with treatment effects in exploratory analyses, a properly designed and adequately powered trial should be conducted to detect them reliably or pooled meta-analyses of several trials should be undertaken to confirm the result.

79.5 Practical Issues Concerning Subgroup Analysis

Besides some of the inherent methodological issues, there are practical issues when one performs a subgroup analysis.

79.5.1 Definition of a Subgroup

The problem starts with how to define a subgroup. A subgroup is based on one or more patient baseline characteristics that may be categorical or continuous.

(a). Categorical—Some subgroups can be well defined. For example, patients can be identified as male or female. However, it is not easy to define some of the seemingly well-known subgroups. For example, in breast cancer, women whose disease has positive estrogen receptors (ER+) respond well to endocrine therapy, while those with ER disease do not [24]. Similarly, women with human epidermal growth factor receptor 2 disease (HER2+) respond well to anti-HER2 therapy such as trastuzumab [2–4]. But, it is not easy to determine a universally accepted cut point for ER+ versus ER− [25] and also for HER2+ versus HER2− [26, 27].

(b). Continuous—Sometimes the boundaries of subgroups are not clear, especially if the characteristics are measured on a continuous scale. For example, age groups can be categorized in many ways. Sometimes, a cut point is created for convenience or size of populations instead of for definition of meaningful clinical subgroups. However, the specific categorization may affect whether or not a treatment effect is suggested. An example from the IBCSG Trial IX [28] illustrates this situation. This study is the largest randomized clinical trial comparing three courses of CMF chemotherapy followed by up to 5 years of tamoxifen versus tamoxifen alone for 5 years for postmenopausal women with node-negative disease. To evaluate treatment effect heterogeneity, we performed subgroup analyses of young versus old. The older cohort appeared to possibly benefit from CMF when patient age was dichotomized into two groups with <65 versus ≥65 years, but the younger cohort appeared to benefit when age was dichotomized using <60 versus ≥60 (see Fig. 79.2). Thus, the selection of cut points may influence the result of the subgroup analysis.

(c). Combination of characteristics—Subgroups can also be defined using combinations of characteristics. For example, the four widely measured immunohistochemical (IHC) biomarkers (estrogen receptor, progesterone receptor, Ki-67, and HER2) can be combined into a single continuous score known as the IHC4 score [29]. The development of such a score is usually based on a regression model from a particular study cohort, which is then validated using independent studies. The resulting score can then be used to define subgroups. Thus, it simplifies the problem of defining cut points for multiple characteristics to just one. However, the clinical interpretation of the subgroups defined based on the score could be diffi-

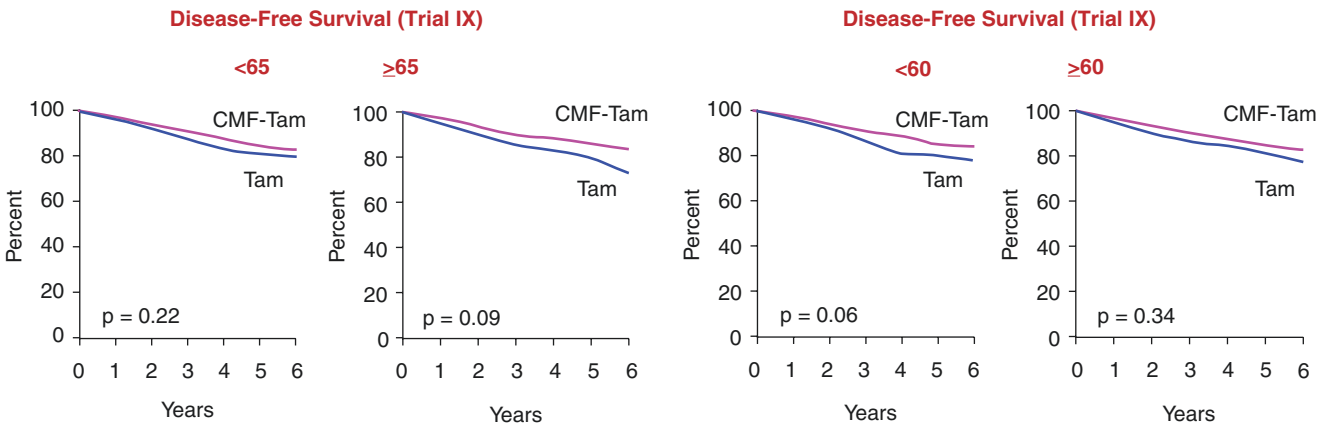

Fig. 79.2 The Kaplan-Meier plots on the *left* did not indicate any strong significance of the two age subgroups when the cutoff is at age 65 but may suggest the presence of an effect for the older group. The Kaplan-Meier plots on the *right* showed borderline-significant difference for the younger age subgroup when the cutoff is at age 60 (Courtesy Prof. R. Gelber)

cult. On the other hand, the definition of subgroups by stratifying with respect to a combination of characteristics is likely to produce a large number of subgroups with too few patients in them to perform useful analyses.

79.5.2 Guarantee-Time Bias (GTB)

Guarantee-time bias (also known as immortal time bias) occurs whenever an analysis that is timed from enrollment or random assignment, such as disease-free or overall survival, is performed to compare subgroups defined by a classifying event that occurs sometime beyond baseline during follow-up [30]. It is not trivial to recognize the potential for GTB, and even experienced investigators and journal editors can overlook the problem when a subgroup analysis is performed. For example, the NSABP B-30 trial, a randomized clinical trial, compared the effectiveness of concurrent versus sequential regimens of anthracyclines and taxanes. An unexpected finding reported that "chemotherapy-induced" amenorrhea appeared to be associated with increased survival among both ER-positive and ER-negative subgroups. Ovarian suppression has value in the treatment of breast cancer, but the effect was logically thought to be restricted to women with ER-positive disease [31]. The subgroup analysis, however, was biased because 24 months of follow-up was required to classify women in the amenorrhea subgroup, and those who relapsed or died before reaching 24 months (predominantly in the ER-negative group) were more likely to be classified as no amenorrhea. A subsequent corrected analysis of NSABP B-30 found no effect of amenorrhea for the ER-negative cohort and concluded that "women in whom amenorrhea developed as a consequence of adjuvant therapy had significantly better overall survival and disease-free survival than did women without amenorrhea, particularly when the tumor was ER-positive" [32]. Using data from the IBCSG 13-93 trial, the problem can be illustrated in the comparison of disease-free survival (DFS) according to amenorrhea status using naïve and 18-month landmark analyses. The naïve analyses, which suffer from GTB, showed highly significant reductions in hazards of DFS events independent of ER status, while the 18-month landmark analyses, which account for GTB, showed significant reductions only in women with ER-positive disease but not in women with ER-negative disease [30] (see Fig. 79.3).

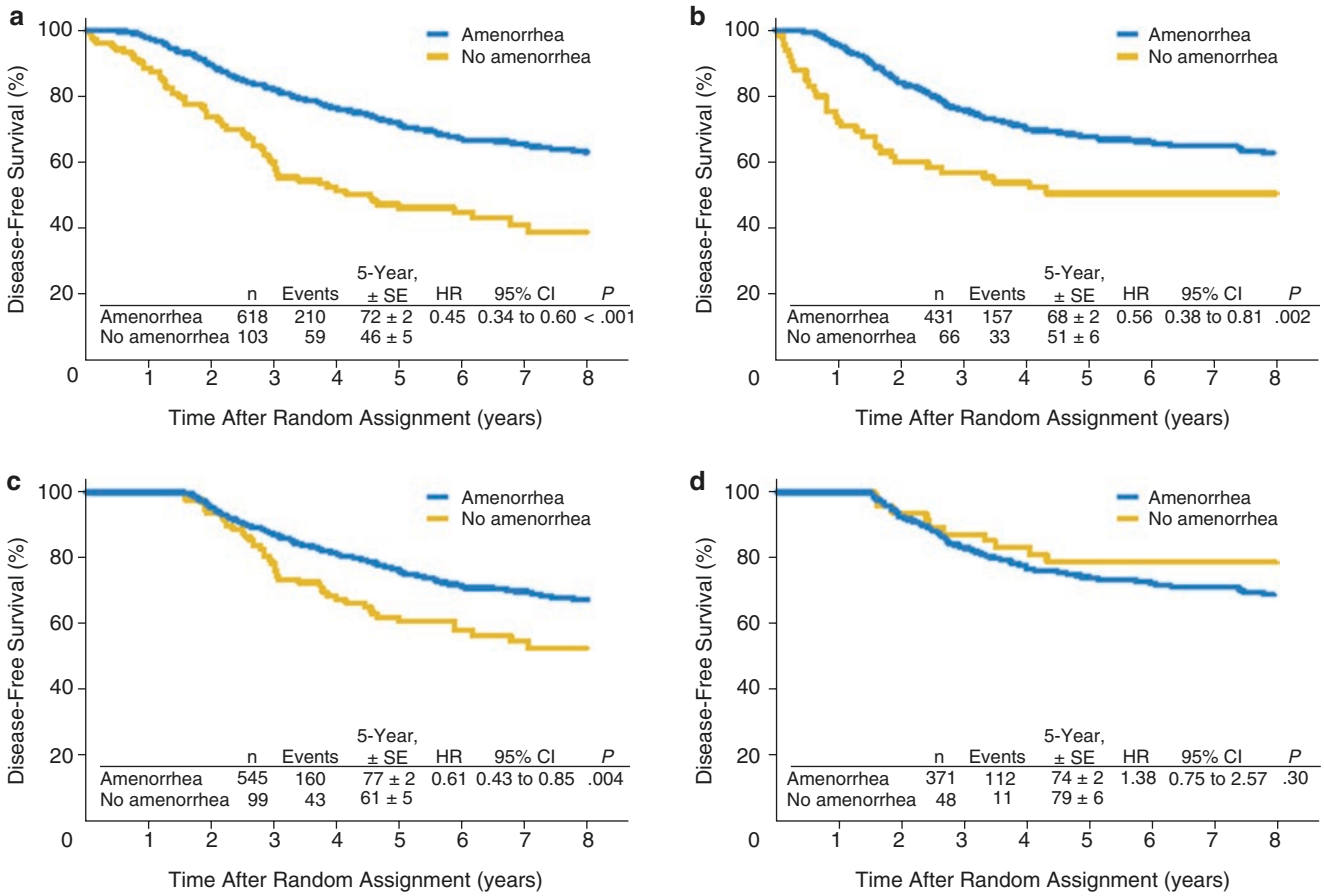

Fig. 79.3 Comparisons of DFS in IBCSG 13-93 according to amenorrhea status using naïve and 18-month landmark analysis. (**a**) Evaluates women with ER-positive disease and (**b**) with ER-negative disease using naïve analyses. (**c** and **d**) Evaluates the same subgroups using 18-month landmark analysis. The significant reductions in DFS of women with ER-negative disease disappear [25]. Reprinted with permission. © (2013) American Society of Clinical Oncology. All rights reserved

As described by Giobbie-Hurder et al. [30], three analytic techniques can be used to adjust for guarantee-time bias: conditional landmark analysis, extended Cox model with time-varying covariates, and inverse probability weighting.

79.5.3 Confirmation, Confirmation!

Many of the problematic issues can be resolved through confirmation. Once an effect in a subgroup is detected, confirmation can be obtained by looking at comparable subgroups in other clinical trials to see if a similar effect exists in the confirmatory datasets as was observed in the initial subgroup analysis dataset. Stronger evidence is obtained if several trials produce consistent results. For example, an evaluation of 2233 premenopausal patients who received chemotherapy alone without hormonal therapy in several IBCSG trials conducted prior to 1993 showed that those who were <35 years old with ER-positive disease had a particularly poor prognosis (*orange circles* in Fig. 79.4). This observation was contrary to expectations at the time as it was assumed that ER-positive disease was lower risk than ER negative. The unexpected IBCSG subgroup analysis required confirmation, which was obtained when NSABP, ECOG, and SWOG repeated the analysis on the premenopausal women who had received chemotherapy alone without endocrine therapy in their adjuvant trials [33, 34]. The estimates of the hazard ratios for the four subgroups (ER−, <35; ER+, <35; ER−, 35+; ER+, 35+ [reference group]) are plotted and show very similar outcomes (see Fig. 79.4).

Another example of the value of confirmation relates to the controversial role of bisphosphonates in early breast cancer. The AZURE [35] trial is a randomized clinical trial evaluating whether treatment with zoledronic acid, in addition to standard adjuvant therapy, improves disease outcomes in early-stage breast cancer. The protocol-defined secondary end points included analyses of effects in specific patient subsets and demonstrated that baseline menopausal status was the only factor that significantly influenced the effect of zoledronic acid on DFS. Results from the ABCSG-12 trial and the three related studies of Z-FAST, ZO-FAST, and E-ZO-FAST trials also support the proposition that zoledronic acid may be most effective for improving DFS in the adjuvant breast cancer setting for postmenopausal women or for those women with endocrine therapy-induced menopause [36]. Recently, a systematic review and meta-analyses of 13 trials came to a similar conclusion [37].

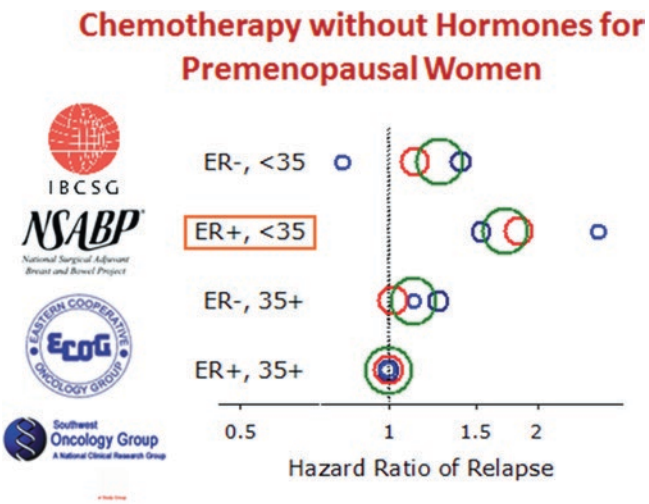

Fig. 79.4 The hazard ratios of relapse of four subgroups from four different clinical trials are plotted together. The results from IBCSG are represented by an *orange circle*, NSABP by a *black circle*, ECOG by a *blue circle,* and the Southwest Oncology Group by a *green circle* (Courtesy of Prof. Stefan Aebi)

79.5.4 Detection and Interpretation of Treatment Effect Heterogeneity Depends on the Scale Selected for Assessing Heterogeneity (Relative Differences or Absolute Differences)

Evaluation of treatment effect heterogeneity should be done in both absolute (e.g., absolute difference between two survival curves at a particular time point) and relative terms (e.g., hazard ratio). Absolute effects are useful for clinical purposes when individual treatment decisions are made between two competing therapies, which require assessment of benefit and risk for the patient. Relative effects are most important for comparing treatment effectiveness relative to a control group in the general patient population. An interaction detected between a covariate and treatment effect measured on the absolute scale may not be detected if the treatment effect is measured on the relative scale. For example, in the BIG 1-98, we evaluated whether Ki-67 labeling index was associated with treatment effect heterogeneity when comparing tamoxifen versus letrozole using the STEPP method described in the next section (see Fig. 79.5). If the treatment effect is measured in the absolute scale of the difference in 4-year DFS, we see a significant difference when Ki-67 is high, because both the predictive and the prognostic features of the marker influence the absolute difference (Fig. 79.5a, b). However, if the treatment effect is measured in the relative scale (hazard ratio), the relative effect is not significant (Fig. 79.5c) [11]. Thus, the significance of a test of heterogeneity in treatment effect may depend on the scale in which the effect is measured. Figure 79.5 will be explained in more details later on in the Sect. 79.5.5.2.

79.6 Tools for Subgroup Analysis

Given all of these issues, new methodologies and software have been developed to assist statisticians in performing subgroup analyses. These methodologies do not solve all of the issues, but they provide a set of tools that allow exploration. The following are some that are currently used.

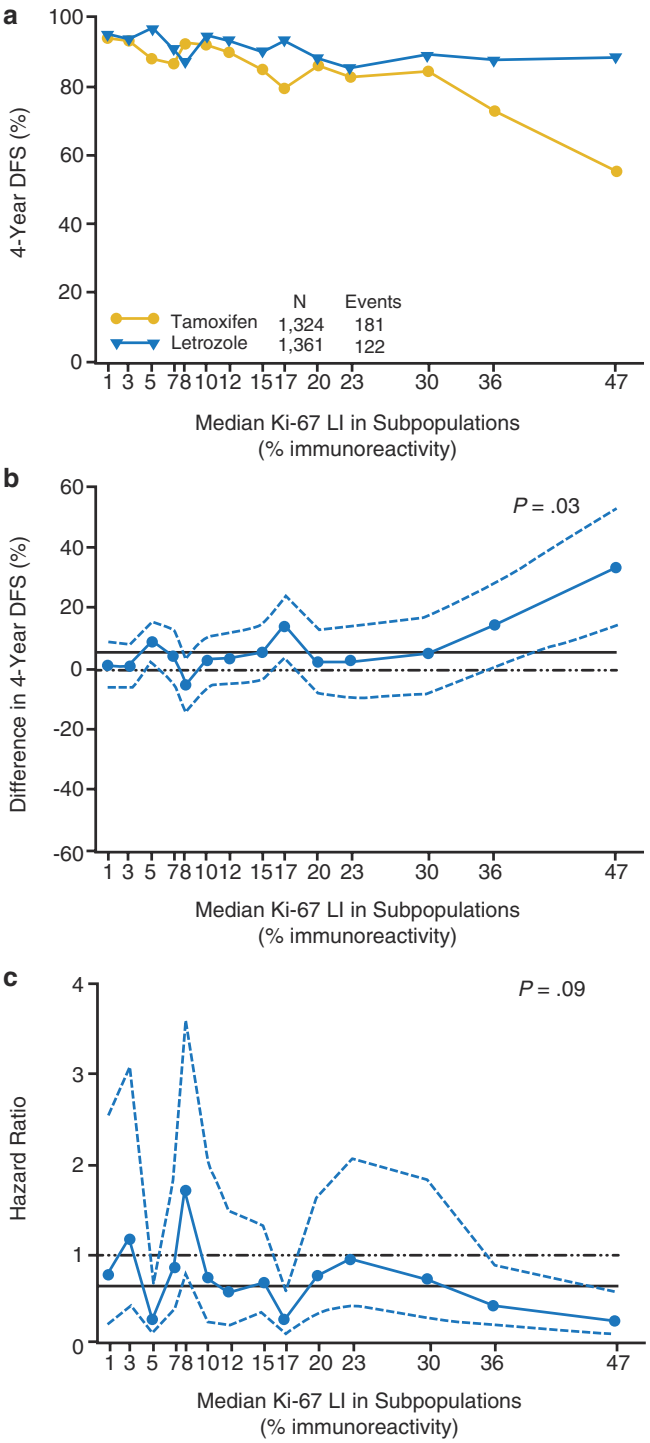

Fig. 79.5 Evaluation of treatment effect heterogeneity using biomarker Ki-67 (BIG 1-98) considering (**a**) 4-year DFS, (**b**) difference in 4-year DFS and (**c**) hazard ratio: using biomarker KI-67 in the BIG (Breast International Group) 1-98 RCT comparing letrozole with tamoxifen as adjuvant therapy for postmenopausal women with hormone receptor-positive breast cancer. STEPP analyses showed patients with higher Ki-67 values who were assigned to receive tamoxifen had the poorest prognosis and may benefit most from letrozole. [11, 38] Reprinted with permission.

79.6.1 Regression Model with an Interaction Term

The simplest approach is to use "standard" methodologies. As illustrated in the HERA trial subgroup analysis, one can use Cox proportional hazards model with interaction terms for the treatment effect by subgroups formed by each covariate. Thus, testing for any subgroup treatment effect is the same as testing for the null hypothesis that the coefficient for the interaction term in the Cox model is equal to zero. If the null hypothesis is rejected, one can conclude that there is evidence to support the hypothesis that the treatment effects in some subgroups may be different. It is important to remember to do multiple test corrections if more than one subgroup analysis is performed. The simplest is the Bonferroni correction which adjusts the significance level by the number of subgroup analyses done. Other advanced statistical methods such as false discovery rate (FDR) [39] can also be used. The subgroup analysis results are usually presented as a forest plot as shown in Fig. 79.1, with the solid vertical line drawn at the overall treatment effect [5], the fulcrum for interpreting treatment effect heterogeneity, as described earlier.

79.6.2 STEPP Analysis [11, 40–44]

STEPP stands for Subpopulation Treatment Effect Pattern Plot. It is a nonparametric tool to analyze survival data (Kaplan-Meier at a specific time point, cumulative incidence, or Cox proportional hazard models). In addition to survival data, it can be used to analyze continuous, binary, and count data that are modeled with generalized linear models. The key feature of STEPP is that one can create overlapping windows of subgroup populations based on a continuous covariate of interest. There are two methods used to define the overlapping subpopulation: sliding window and tail oriented.

A sliding window approach is the process of creating subgroups based on the continuous value of the covariate of interest, moving the windows from the lowest values of the covariate on the left and the highest values of the covariate on the right. The construction of the windows relies on two quantities: r1, minimum number of patients included in both adjacent overlapping subpopulations, and r2, minimum number of patients in each subpopulation. Assuming no ties, the first window consists of r2 patients with the lowest values of the covariate. Then, the next window consists of r2 patients but with a maximum of r2–r1 of the patients with the lowest values of the covariate replaced by r2–r1 of the patients with the next highest values. So, the first and the second windows will have r1 patients in common. Subsequent windows are created similarly from left to right by replacing r2–r1 patients

until the population runs out. The sliding window approach is useful for detecting treatment effect patterns along the continuum of covariate values. An example of how the subpopulations are constructed for a population of 749 patients along their ages ranging from 29 through 78 years is shown in Table 79.1. The minimum size of patients in each subpopulation is 100 (r2), and 70 (r1) patients are included in both adjacent overlapping subpopulations. Fifteen overlapping windows of subpopulations are created as a result. Note that due to ties, the sample size for each subpopulation is ≥100, and the sample size for the last subpopulation is less than 100.

One can also create a nested set of tail-oriented windows where nested subsets of windows are created starting with the entire population and creating subpopulations with progressively higher or lower median values for the covariate of interest. With this approach, the overall study population is used to obtain the treatment comparison result in the center of the STEPP plot. Subsequent windows to the left of center are constructed by successively removing patients with the highest covariate values, thus forming subpopulations with lower and lower median covariate values. Similarly, by successively removing patients with the lowest covariate values, windows to the right of center include patients with progressively higher values of the covariate. This method is intended to illustrate monotonic treatment effect patterns as the covariate value either decreases (to the left) or increases (to the right), and effects can be appreciated compared to the overall population result illustrated in the middle of the plot. The treatment effect is computed based on each subpopulation of each treatment group. Figure 79.6 illustrates the two subpopulation patterns.

Table 79.1 Subpopulation summary information of the 15 subpopulations constructed using a sliding window approach according to the age of patients

Subpopulation	Median Age (yrs)	Minimum (yrs)	Maximum (yrs)	Sample Size
1	43	29	47	112
2	46	42	49	100
3	49	46	50	100
4	50	48	51	101
5	51	50	52	106
6	52	51	54	121
7	54	53	56	107
8	57	55	59	128
9	60	58	61	108
10	61	60	63	106
11	64	62	66	107
12	66	64	68	102
13	68	66	71	105
14	70	68	74	103
15	73	70	78	92

The minimum number of patients per subpopulation (r2) is set to 100, and the largest number of patients in common among consecutive subpopulation (r1) is set to 70

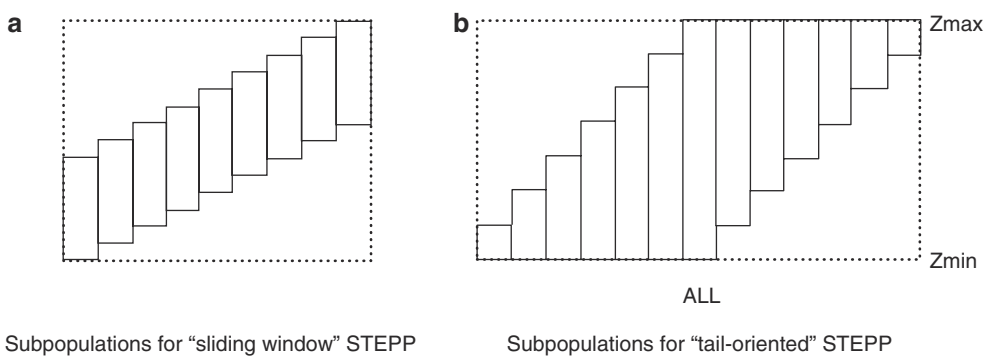

Fig. 79.6 Illustration of the two subpopulation patterns. Zmax and Zmin are the maximum and minimum values of the covariate of interest [41]. Plot (**a**) displays the sliding window and plot (**b**) displays the tail-oriented window. Fig. 79.7 The 5-year DFS outcome comparing CMF-Tam versus Tam alone along overlapping age subpopulations (Courtesy Prof. R. Gelber)

A STEPP plot shows the treatment effect estimates (or the *y*-axis) computed within the subpopulations.

For example, using the data from the IBCSG Trial IX example for postmenopausal, node-negative patients presented in Fig. 79.2, we performed a sliding-window STEPP analysis by creating subpopulations based on age. STEPP shows the pattern of 5-year DFS treatment effect across overlapping different age subgroups in one plot. As shown in Fig. 79.7, the CMF-Tam arm has slightly higher 5-year DFS compared with Tam estimated for patients under 60, but estimates cross between ages 60 and 65 and then again are higher than Tam alone for the oldest age group. Thus, there is no clear pattern that age is a covariate modifying the magnitude of treatment effect in this trial. By contrast, if we examine the sliding-window STEPP analysis for this trial exploring the relationship of CMF-Tam versus Tam alone according to level of ER expression for postmenopausal women with node-negative breast cancer, we see a clear relationship between the benefit of three courses of CMF prior to tamoxifen for the patients with the lowest levels of ER expression, in Figs. 79.8a and 79.8b. This benefit rapidly diminishes as the values of ER expression reach and exceed 10 fmol/mg cytosol protein. The pattern highlighted in the STEPP analysis is reflected in the Kaplan-Meier plots shown in Fig. 79.9 illustrating the treatment differences separately for ER-negative (<10 fmol/mg) and ER-positive (≥10 fmol/mg) subgroups.

The choice for minimum size of overlapping subpopulation (r1) and minimum subpopulation size (r2) is application specific. In order to get a good estimate, one should pick a large r2 value; if a smoother plot is desired, one should pick a larger r1 value. One may need to try a few combinations of r1 and r2 to obtain the desired STEPP plots.

A complete survival STEPP analysis provides three separate plots allowing us to see the treatment effect patterns in the two treatment arms separately, as well as evaluating the heterogeneity in treatment effect differences on an absolute and

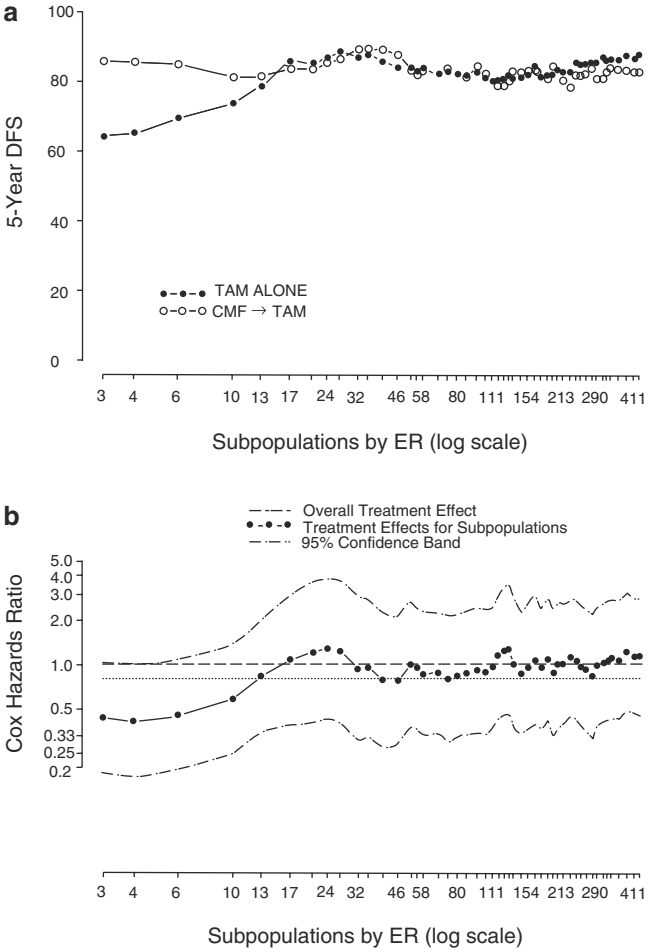

Fig. 79.8 STEPP analysis comparing CMF-Tam versus Tam alone according to estrogen receptor (ER) value in IBCSG Trial IX. It shows a much larger treatment effect for patients with low (ER-) disease. For this sliding-window analysis, each subpopulation contained approximately 200 patients, and each subsequent subpopulation was formed moving from left to right by dropping ten patients with lowest values of ER from the subpopulation and adding ten patients with the next higher values of ER. Plot (**a**) displays the absolute treatment effects in terms of 5-year DFS, while plot (**b**) displays the Cox model hazards ratio (HR) according to values for quantitative ER [28]. Reprinted from JNCI, IBCSG, Endocrine responsiveness and tailoring adjuvant therapy for postmenopausal lymph node-negative breast cancer 2002; (94) 14:1054–1065. © (2002) by permission of JNCI, Oxford University Press

on a relative scale. As an example, we evaluated the treatment effect heterogeneity using biomarker Ki-67 data from the BIG 1-98 trial [39, 45]. The three plots are shown in Fig. 79.5.

1. A treatment effect plot displays the treatment outcome of each therapy against the median of the covariate value for each subpopulation. One can visually discern if there is emerging treatment heterogeneity between the two treatment groups Fig. 79.5a.
2. A difference plot displays the absolute difference of treatment effects along the subgroups defined by the covariate Ki-67 Fig. 79.5b.

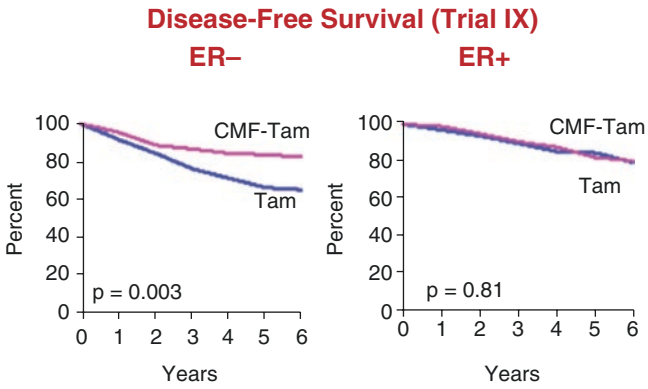

Fig. 79.9 The Kaplan-Meier comparison of the two treatment arms of CMF-Tam versus Tam on subgroups of patients with ER– and ER+ diseases in IBCSG Trial IX (Courtesy Prof. R. Gelber)

3. A relative difference plot displays the relative difference of treatment effects along the subgroups defined by Ki-67. In the survival setting, the treatment effects would be measured as hazard ratios Fig. 79.5c.

In order to assess statistical significance of the differences, STEPP performs a test by permuting the covariate values across patients in each subgroup within each treatment under the null of no heterogeneity of treatment effects. The supremum statistic which is the absolute deviation from the overall effect is computed for each permuted sample. The permutation supremum *p*-value is the percentage of results which are more extreme than the observation and is presented together with these plots so that one can meaningfully interpret the results. A significant result can imply that the observed pattern of treatment effects may not be due to sampling variation.

In large randomized controlled trials, the risk of random imbalance of the covariates is mostly negligible. However, with STEPP subgroup analysis in smaller studies, the imbalance may be substantial. To alleviate this problem, one can choose a larger minimum subpopulation size (r2) with a bigger overlap (r1). Adjustment for known confounders using regression can also reduce a biased assessment of the treatment comparison in GLM models with STEPP.

STEPP offers several advantages compared to other statistical approaches. It does not require predefinition of specific cutoff points for developing patient subgroups. Treatment effect heterogeneity is illustrated graphically, allowing for a convenient exploratory evaluation. It does not rely on the assumptions of a regression model. It provides an overall *p*-value for testing whether treatment effect heterogeneity is significant. It can be based on absolute or relative treatment effects. Also, treatment effect is defined through traditional measures computed on well-defined patient subgroups. Lastly, STEPP can be applied in various survival data analysis contexts such as Kaplan-Meier, Cox proportional hazards, cumulative incidence, and generalized linear models. A free R [45] software package, **stepp**, is available for download through CRAN. The current version of the software provides support for comparison of two treatments with the sliding window approach. The following standard models can be used with the software: Kaplan-Meier, Cox proportional hazards, cumulative incidence, and generalized linear models (Gaussian, binomial, and Poisson) with their canonical links.

STEPP analysis also has some drawbacks. It allows only one covariate of interest to be analyzed at a time, although several covariates can be combined into one composite risk score. STEPP cannot be used to identify a definitive cutoff point for clinical uses but rather illustrates patterns of treatment effect. A separate confirmatory trial or application of other methods is needed to identify the appropriate clinical cutoff point.

79.6.3 Fractional Polynomial [46]

A different approach to modeling interactions between treatment and continuous covariates in clinical trials has been proposed by Royston and Sauerbrei. Fractional polynomial (FP) is a flexible technique and has been used successfully in developing many models. The main idea is to use FP modeling of outcome and testing equality of regression coefficients between treatment groups in an interaction model adjusted for other covariates. The authors' extensive experience with this method suggests that a two-term fractional polynomial (FP2) function may describe the effect of a prognostic factor on a survival outcome quite well. They also recommend checking the results by plotting Kaplan-Meier survival curves and by estimates of treatment effects in subgroups.

Importantly, they also provide a software package, MFPI, in Stata, that can also be used to explore the heterogeneity of treatment effects along a continuous covariate.

79.6.4 Bayesian Models and Other Sophisticated Techniques

There are other subset analysis methodologies developed based on Bayesian principles. One such approach is described by Simon [47] and illustrated using a Cox proportional hazards model with independent and normal priors. The computations required for using this approach are straightforward and require no specialized software.

Some more theoretical approaches are also available. A local partial likelihood estimation (LPLE) technique can be used to estimate nonlinear interactions under a proportional hazards model [48]. A two-stage estimation procedure for subject-level treatment differences for a future patient's disease management and treatment selections is also available [49].

The few methods that we listed here are by no means exhaustive. As a general suggestion, investigators are encouraged to use multiple methods when doing subgroup/subset analysis. Consistent evidence of heterogeneous treatment effects would be reassuring. If there is a lack of consistency, understanding the differences may help to explain the underlying heterogeneity and help to identify important subgroups.

Conclusion

Subgroup analysis is a general statistical methodology, which is applicable to clinical research. It follows the targeted therapy principle—if the treatment effect varies across subgroups, then therapies can be prescribed with the most optimal therapeutic benefit for the individual patient. This would both improve patient disease outcomes and reduce harm, as well as costs, in many clinical situations. However, it is imperative that analyses are performed properly. Otherwise, they may misguide research or harm patients.

Simply abandoning subgroup analyses because of past mistakes is not acceptable. In fact, avoiding subgroups is a very steep price to pay [21]. We must have strict guidelines for conduct—be skeptical at all times, propose subgroup analyses in the protocol document, do exploratory analyses based on a variety of prespecified heterogeneous factors, and never perform "data dredging." If promising results are detected, they need to be replicated in independent series because subgroup analyses are subject to large statistical variation. Ideally, a properly designed trial with sufficient power should be conducted to confirm the result. In short, analyses must be predefined, carefully justified, and limited to a few clinically important questions, and post hoc observations should be treated with skepticism irrespective of their statistical significance. Stringent guidelines for reporting must also be followed [7].

Despite various pitfalls, many subgroup analysis methodologies have been proposed, and software have been developed in the past decade which help researchers identify proper subgroups and facilitate their analyses. STEPP, MFPI, and Bayesian approaches can now be used to investigate heterogeneous treatment effects, and some of these approaches have freely accessed software packages available for download. Unfortunately, there are still only few published papers exploring heterogeneity in breast cancer clinical trials deploying these new techniques. As increasing amounts of genomic and biomarker information becomes available in clinical studies, subgroup analyses may help bring great benefit to all cancer patients by contributing to the development of personalized medicine.

Acknowledgment I would like to thank Prof. Richard Gelber for his guidance and Shari Gelber for her many editorial suggestions in organizing the material. I would also like to thank Prof. Marco Bonetti, Prof. Stefan Aebi, Dr. Florence Yong, and Dr. Xiaoxue Li for their careful reading of the draft and suggestions.

The Methodology of Meta-Analyses and Its Potential Contribution to Patient Care

80

di Sara Gandini

80.1 Introduction

The art of meta-analysis, the combination of results from multiple independent studies, is now more than a century old. In the last 40–50 years the impact of meta-analysis has grown enormously. The increasing rate of publications of meta-analyses is exponential and by far surpasses the increase in the rate of publications of RCTs [1]. This rapid increase in the number of published meta-analyses is mainly due to a greater emphasis on evidence-based medicine and the need for reliable summaries of the vast and expanding volume of clinical research. A systematic review of the relevant external evidence provides a framework for the integration of the research, and meta-analysis offers a quantitative summary of the results, necessary for evidence-based medicine.

Meta-analysis is a process that includes results of independent studies as well as a quantifiable combination of results estimates [2]. It provides a systematic approach to selecting and integrating findings across studies and to control for chance and potential bias. It is a methodology used for contrasting and combining results of different studies, where the individual unit of the statistical analysis is the study. This approach allows hypothesis testing regarding sources of heterogeneity and quantification of biases. Meta-analysis can also help to identify gaps in knowledge found in the published literature and thus can help provide guidance for future research.

Meta-analysis differs from qualitative or narrative review because conclusions from publications are not only discussed qualitatively but also involve a quantitative assessment of the available published data. Narrative reviews may present several problems because they do not have tools to analyse and quantify results of single studies and they are easily influenced by several biases (e.g. publication bias and reviewer bias). In fact without the obligation to clearly state inclusion criteria, it is likely that researchers include studies that support their own opinion and ignore those that do not. Cooper and Rosenthal [3] showed that even with only seven studies, narrative and quantitative reviews led to different results. However in a research area with very few studies often a narrative and critical review of the studies are perhaps the more suitable approach.

Pooled analyses are special types of meta-analyses that include individual subject data obtained from authors of the papers, and it is characterized by numerous advantages. It allows analyses among exposures and confounders, not investigated in the original studies, and it required variables to be recoded across studies to make them more compatible and to make adjustments to deal more extensively with heterogeneity. A major impediment to this kind of meta-analysis is the fact that it is very time-consuming because it requires several years just to obtain the data and demands close cooperation between the authors of the studies. Therefore meta-analysis of published data is often considered a sound approach when resources and time are limited and when original study data are not available.

The Cochrane Collaboration, launched in 1993, has been influential in the promotion of evidence-based medicine. This international network of individuals is committed to preparing, maintaining and disseminating systematic reviews of research on the effects of healthcare. Their reviews are made available electronically in the Cochrane Database of Systematic Reviews, part of the Cochrane Library (http://www.update-software.com/cochrane).

Meta-analysis techniques provide a useful means of summarizing overall efficacy results of clinical trials and analysing less frequent outcomes in the overall safety evaluation. Meta-analysis also has a useful role to play in the generation of hypotheses for future studies.

80.2 Meta-analysis of Observational Studies

The need to assess risks that are small, but that may have large public interest or have important implications for public health, has amplified their use in summarizing the evidence. However the use of meta-analysis for published observational studies is less accepted than in the area of clinical trials for their intrinsic biases and differences in study designs. The most prominent arguments against meta-analyses are the fundamental issues of confounding, selection bias, as well as the large variety and heterogeneity of study designs and data collection procedures in epidemiological research. Despite these controversies, results from meta-analyses are often cited and used for decisions. They are often seen as the fundamentals for risk assessment. They are also performed to summarize the current state of knowledge often prior to designing new studies.

Conflicting results among studies may arise when sample sizes of individual studies are too small to find stable results. Actually most epidemiological studies are too small to detect anything but a comparatively large relative risk (RR) associated with a fairly common exposure. Thus meta-analyses may become a useful tool to evaluate weak risk factors that have large public health impact. An increase of risk of only 20% of certain cancers, for example, may involve millions of people, and to detect such small increases in risk, huge studies are necessary [4].

An important function of meta-analysis is the investigation of between-study heterogeneity that is an opportunity to understand study variation. Meta-analysis can lead to insights when study design, exposure assessment or exposure levels, study populations, etc. are found to relate to study outcome. Thus investigation of heterogeneity can provide interesting hypotheses for future analyses and should be viewed as strength of meta-analysis, not a barrier to its use. Actually if all of the studies show same results, meta-analysis would not be very useful because it would not provide much more information than the original studies. Furthermore between-study heterogeneity was very often found significant, even when the authors considered subsets of studies identified with strict inclusion criteria. In fact many analysts identify heterogeneity and deal with it by excluding studies until a satisfactory degree of homogeneity is achieved. Authors sometimes exclude 25% of the data and still generalize to the total population.

A systematic revision of all the literature for a comprehensive meta-analysis allowed an in-depth exploration of associations and interactions among risk factors and provided some clues towards the epidemiology of a disease by looking extensively at inconsistencies and variability in the estimates. A good meta-analysis should help to understand differences in results from the mass of papers from which they are derived.

Meta-analysis permitted questions to be debated on whether the association of a disease with risk factors may depend on the composition of the population under study, the level of exposure in the study population, the definition of disease employed in the studies or the methodological quality of the studies.

80.3 Pooled Analyses

Meta-analyses of individual patient data can play a useful role in providing evidence for future studies. However, they can be very challenging from a statistical perspective in terms of dealing with the problems that plague meta-analyses in general.

Mostly very simple methods are used, such as standard fixed effect meta-analysis model for aggregate data [5]. Sometimes within-study comparisons have been adjusted for confounding variables before application of traditional meta-analytic techniques for summary data. Alternatively, more complicated regression techniques have been applied to produce stratified estimates of a common estimate adjusting for covariates.

When a two-stage approach is adopted, the first stage involves reanalysing each study using the model appropriate for the design with study-specific confounders. The second stage then combines the study-specific estimates using standard meta-analytic techniques. When the individual studies are large, two-stage methods produce nearly unbiased exposure estimates and standard errors of the exposure estimates from a generalized linear mixed model. By contrast, joint fixed effects logistic regression produces attenuated exposure estimates and underestimates the standard error when heterogeneity is present. While bias in the pooled regression coefficient increases with within-study heterogeneity for both models, it is much smaller using the two-stage model.

Random effects meta-analyses, meta-regression and assessment of the effects of patient-level covariates across all studies have been developed [6] but appear to be seldom used in practice. However heterogeneity between studies would exist, and a random effects model is usually to be more appropriate model than a fixed effect one.

Pooled reanalyses are mostly performed by combining data from studies of the same type only. Statistical issues of pooling data from case-control studies have been investigated by Stukel et al. [7]. An overview of methodological aspects for combining individual patient data with aggregate data, to utilize all the evidence available, is presented by Riley et al. [8].

The prospectively planned pooled meta-analyses include pooling as part of the protocol in order to standardize data collection procedures and definitions of variables for the individual studies. Joint planning of the data collection and analysis increase the homogeneity of the included data sets; however, in contrast to multicentre randomized clinical trials, important heterogeneity between the study centres still may exist. This heterogeneity may arise from differences in populations, in the relevant confounding variables (e.g. race may only be a confounder in some centres) and potentially differences in ascertainment of controls [8].

80.4 Statistical Methods

Like primary research, meta-analysis proceeds by framing a research question to be addressed, by sampling a defined population of completed primary studies to be surveyed, coded for relevant methodological characteristics and analysed to test hypotheses derived from the research question.

First of all, a good meta-analysis should begin with a systematic complete review of the literature. An effort should be made to obtain studies from all sources, literature databases and reviews, from published and unpublished literature, to attempt to minimize bias. After defining inclusion and exclusion criteria, a flow diagram should be provided to describe how the meta-analyst arrives the final group of studies included in the analysis (a blank version of the flowchart can be downloaded at http://www.consort-statement.org/QUOROM.pdf).

Afterwards, the meta-analyst builds a database extracting important information from each retrieved study. From each paper we need at least to obtain a risk estimate/effect size with a measure of its precision that can be obtained from standard deviation (SD), confidence intervals, *P*-values or crude data.

Lastly, findings from individual studies can be combined using appropriate statistical methods. The different methods use a similar approach in which the estimate from each study is weighted by the precision of the estimate through fixed or random effect models.

The usual way of displaying data from a meta-analysis is by a pictorial representation (known as a forest plot). This displays the findings from each individual study as a blob or square. The size of the blob or square is proportional to the weight (precision/statistical power) of the study estimate. A horizontal line (usually the 95% CI) is drawn around each of the studies' squares to represent the uncertainty of the estimate. The summary estimate obtained by combining all the studies is usually displayed as a diamond.

Guidelines for reporting Meta-analysis Of Observational Studies in Epidemiology (MOOSE) have been published by Stroup et al. [9, 10]. Especially the detailed description of methods is required so that the analysis could be replicated by others. The proposed checklist contains specifications for reporting background, search strategy, methods, results, discussion and conclusion. Use of the checklist should improve the usefulness of meta-analyses for authors, reviewers, editors, readers and decision-makers.

Many studies will use similar but not identical endpoints, and we have to translate them into some common measure: for continuous endpoints usually mean differences with standard deviations (SD), for binary endpoints usually relative risks or odd ratios with 95% confidence intervals (95% CI). Often the distinctions among the various measures of relative risk, such as RR, odds ratios (OR) and incidence rate ratio, are ignored, because disease under investigation is rare.

Omitting study results from the meta-analysis because a measure of the SD cannot be obtained should be avoided. Meta-analysts are forced to improvise and/or use other summary measures to derive an SD estimate to include studies with missing SDs. When SDs cannot be algebraically recalculated from reported data, meta-analysts have suggested and used a myriad of methods to impute SD (fill in SDs with plausible values) to attenuate any loss in power and to avoid bias. Wiebe et al. [11, 12] review several methods of imputation and suggested with Robertson et al. [12] to use multiple imputation in a variety of sensitivity analyses for handling missing SD in meta-analyses.

For survival data, when hazard ratios are not reported, a number of methods of estimating them are presented and discussed by Parmar et al. [13].

Fixed effects models are based on the mathematical assumption that a single common (or "fixed") effect underlies every study in the meta-analysis. In other words, if we were doing a meta-analysis of odds ratios, we would assume that every study is estimating the same odds ratio. Under this assumption, if all studies were infinitely large, they would produce identical results. This means that between-study heterogeneity is not statistically significant [14].

Random effects models make the assumption that individual studies are estimating different underlying risks. The idea of a random effects meta-analysis is to learn about the distribution of risks across different studies.

When large heterogeneity is found, diversities in the designs and analyses of the various studies should be taken into account in the final model, and it can be assumed that the true effects estimated will vary among studies. There are two sources of variability that must be addressed, the usual sampling variation in the estimates and variation in the underlying parameter. To account for both sources of variation in the meta-analysis, the DerSimonian and Laird [15] method is often used, especially for clinical trials.

Besides the moment-based method by DerSimonian and Laird method, summary estimates can be obtained using likelihood-based methods [16]. Estimates based on likelihood

methods offer the advantage that they provide the option to formally test which model is appropriate for the data by applying the likelihood ratio test.

The consequence of performing a random rather than a fixed effects model is that usually the confidence intervals for the summary estimate are wider. A random effect analysis therefore suggests more conservative in estimating the underlying parameter than a fixed effects model does. Fixed effects summaries are preferable to random effects models when studies are very similar in their methods, in their populations at risk, in their exposure contrasts and in their results. However estimates from random effects models tend to be more sensitive to publication bias than fixed effect estimates, because smaller studies have larger relative weights. It follows that random effects models will be more strongly biased than fixed effects models by any tendency not to publish small statistically non-significant studies.

Analysis of heterogeneity, especially analysis of study characteristics that might explain differences among the results, provides the most important information for interpretation and decision-making than can be provided by any single summary.

80.5 Treatment Difference

Many meta-analyses concern the comparison of two treatments in terms of a selected set of outcome measures. For each chosen outcome measure, the aim is usually to estimate and make inferences about the difference between the effects of the two treatments. This involves choosing an appropriate measure (parameterization) of the treatment difference and calculating individual study estimates and an overall estimate of this difference. A traditional meta-analysis is one in which the overall estimate of treatment difference is calculated from a weighted average of the individual study estimates.

Meta-analyses may be performed on studies for which the available data are in the form of summary information from trial reports or publications or on studies for which individual patient data are available. The form of the data available from each study has implications for the meta-analysis, and here three forms which are commonly encountered are considered.

The first consists of an estimate of the treatment difference and its variance or standard error—the minimum amount of information needed. If a study provides an estimate of treatment difference which is not an estimate of the chosen parameterization, it may not be possible to include it. For example, in the context of binary data, we may wish to estimate the log-odds ratio, and so a study for which only an estimate of the probability difference is available cannot be used.

The second form of data is slightly more detailed, consisting of summary statistics for each treatment group, enabling a choice to be made between several different parameterizations of the treatment difference. For example, in the context of normally distributed data, knowing the sample size, mean and standard deviation for each treatment group allows estimation of the absolute mean difference or the standardized mean difference.

In an individual clinical trial the likelihood ratio test is frequently used to test the hypothesis concerning the treatment difference. The maximum likelihood (ML) estimate of the treatment difference is then typically presented with a standard error or confidence interval. ML estimation has the advantages of asymptotic optimality and general availability in statistical packages. This is the principal method of estimation which is presented in this book. As ML estimation involves iterative procedures and is usually performed via a statistical package, a specification of the methodology is presented together with a SAS procedure which could be utilized. The likelihood approach to a single clinical trial can be extended to the meta-analysis of all of the trials when individual patient data are available.

A simpler approach to estimation, based on the efficient score and Fisher's information statistics, has been widely used for meta-analysis. This approach, on which a number of commonly used statistical tests are based, produces approximate ML estimates.

80.6 Meta-analysis Dilemma: Heterogeneity

Meta-analysis should not be applied merely as a statistical method, which combined published results, because nonexperimental studies do not allow for the assumption that the variation between studies is only attributable to statistical sampling error. It is unlikely that this so-called homogeneity assumption is fulfilled. Part of the variation in the estimates is due to differences in definitions, in measurements of the exposure, features of the studies and of the populations. A systematic investigation of between-study heterogeneity, as a function of differences in design features, types of analyses and population characteristics, helps to explain the controversy between study results and provides interesting considerations for cancer epidemiology.

An important function of meta-analyses is the exploration of sources of variation in study results, which should be viewed as strength of this work. Investigation of biases and inconsistencies should become one of the key phases for a meta-analyst because it can lead to more insights than the mechanistic calculation of an overall measure of effect, which will be often biased. Exploration of sources of heterogeneity can lead to insights over modification of apparent associations by various aspects of study design, exposure measure and population and may allow identification of features of study design that may have implications for future research.

There may be different kinds of heterogeneity: population heterogeneity and methodological heterogeneity. The term "population heterogeneity" covers factors such as study location, age, sex and types of diseases. Methodological heterogeneity has to do with differences between study designs and analyses. When different studies give different results, the aim of the meta-analysis should be to investigate the reasons why effects differ across studies, identifying methodological discrepancies among studies, assessing the possibility of confounding factors and evaluating differences among populations under study [17, 18].

Subgroup analyses and "meta-regression" are techniques useful to work out when particular characteristics of studies are related to the sizes of the estimates. Subgroup analyses are meta-analyses on subgroups of the studies that partition the observed effect size variability into two components: the portion attributable to subject-level sampling error and the portion attributable to other between-study differences. This is obtained dividing results into different types of subjects, outcomes or study characteristics, but it requires cautious interpretation. When several outcomes are measured, but only a selected subset of them are reported and discussed, it is possible to have misleading results. Furthermore the more subgroup analyses are performed, the more likely it is that a statistically significant result will be found due simply to chance. Any subgroup analysis should be best considered as generating hypotheses for testing in the future and should have a scientific rationale [19].

"Meta-regression" models represent a useful tool to investigate possible explanations for between-study heterogeneity because they allow testing interactions between factors. The term meta-regression indicates the use of study-level covariates, as distinct from regression analyses that are possible when individual subjects data on outcomes and covariates are available. Subgroup analysis is equivalent to meta-regression with a categorical study-level covariate. Considering subgroup analysis formally as a meta-regression has advantages, since it properly focuses on the differences between subgroups, rather than the effects on each subgroup separately. Also random effects models allow for residual heterogeneity, not explained by subgrouping [19–21].

When there is a small number of studies and many differing characteristics, the risk of obtaining a spurious explanation from meta-regression is high. This is a particular problem in meta-analysis because there are many characteristics, which differ among the studies, and these can be highly correlated. Further summarizing of subject's characteristics at study level implies the risk of completely failing to detect genuine relationships between these characteristics and the size of risk factors. Meta-analysis carried out on individual subjects data can alleviate some of these problems. In particular within-study and between-study relationships can be more clearly distinguished, and confounding by individual level covariates can be investigated. However, as we have seen earlier, this kind of meta-analysis is much more expensive and time-consuming and very often not feasible [22].

Since poor-quality studies sometimes produce systematically different results, a meta-analysis may yield misleading results if the quality of the studies is poor [23]. In an attempt to cope with these problems and to control heterogeneity, many researchers restrict analysis considering some inclusion criteria. However an extensive investigation of the effect of inclusion criteria on results is recommended to avoid introduction of reviewer's own bias.

Use of quality scoring in meta-analysis is controversial because its validity is not clear and may not be associated with quality. It is very difficult to score and measure quality that is best evaluated qualitatively [24, 25]. Greenland called quality scores "perhaps the most insidious form of subjectivity masquerading as objectivity" because they modify data information by using arbitrary judgements in their assignment [26].

Sensitivity analysis is recommended rather than quality scores because it helps to establish the influence of individual study results to the overall summary estimate. The main role of a sensitivity analysis is to discuss robustness of results and determine whether the assumptions or decisions to either exclude or include studies have a major effect on the final estimates [27].

When working with observational studies, it is very likely that heterogeneity exists between the studies. After exploration of the contributions of all known or suspected factors that may have introduced variation in the estimates, heterogeneity remains very often unexplained. If appropriate statistical models are applied, then heterogeneous studies may still be pooled and statistical models that can take into account this variation, as random or mixed effects models, are essential.

Addressing statistical heterogeneity is one of the most troublesome aspects of many meta-analyses. The interpretative problems depend on how substantial the heterogeneity is, since this determines the extent to which it might influence the conclusions of the meta-analysis. It is therefore important to be able to quantify the extent of heterogeneity among a collection of studies. An obvious means of achieving this is by estimating the between-study variance of the parameters of interest. A common way of indicating the extent of heterogeneity is a statistical test (chi-squared test, i.e. Q test). A P-value is frequently quoted as an indication of the extent of between-study variability. The test has poor power with few studies and inappropriately high power with many studies, and it can therefore be difficult to decide either whether heterogeneity is present or whether it is clinically important. The test does not therefore provide a relevant summary of the extent to which heterogeneity impacts on the meta-analysis. In order to overcome the shortcomings of this

test, Higgins and Thompson [20] have proposed three indices for assessing heterogeneity in a meta-analysis. As they are interrelated, here we focus on the I^2 index, because of its easy interpretation. I^2 does not depend on the number of studies; therefore it is recommend to be presented together with the Q test. In fact this measure quantifies the impact rather than the extent of heterogeneity in a meta-analysis, and it can be compared across different effect metrics. I^2 describes the percentage of variability in point estimates that is due to heterogeneity rather than sampling error.

80.7 How to Deal with Sources Bias

One of the most crucial steps in a systematic meta-analysis is study identification. In order to control the biases, the process of identifying and selecting studies is very important. Refined methods to search for studies are fundamental to include all potentially eligible studies. The effect on the estimates of the exclusion of each study not contributing to the analysis should be investigated. In fact, if the studies included are a biased sample of all the studies conducted, then the force of any possible inference is limited.

Publication bias is the most mentioned bias in meta-analysis because when it is present the significance of results may influence whether a study is submitted, positively reviewed and eventually accepted for publication or not. Commonly meta-analysts refer to publication bias, but this is only one of the possible biases, included in the term "dissemination bias". In general when the analysis is influenced by the accessibility of research findings, we should talk of dissemination bias. This depends not only on whether a study is published but also on when, where and in which format this occurs [28]. For example, language bias is related to the fact that studies without significant results are preferably published in languages other than English, and this implies that it will be more difficult to find such "negative" studies. Authors try more likely to publish positive findings in an international, English language journal, whereas negative findings end in local journals. Therefore bias could be introduced in meta-analyses based exclusively on studies published in English [29]. Moreover if most of the major west European journals, published in languages other than English, are indexed in Embase or Medline, this is not the case for journals published in less-developed countries. Obviously it will be very difficult to find studies that are published in journals not indexed in one of the major databases.

Searches in computerized databases are usually extended examining the reference lists of other studies and reviews. When reference lists are used, citation bias may have an important role. Citation bias leads to underreporting of "negative" studies being referred to less often. On the other hand, significant results are sometimes published in more papers, increasing the probability for them to be discovered (multiple publication bias). Furthermore it is not always obvious that more publications come from a single study, and one data set may thus be included in an analysis twice.

Another source of bias comes from differences in methodological quality of studies. Methodological accuracy of smaller studies is not at the same level of larger studies, and papers of lower quality also tend to show larger effect estimates [23]. In these cases there is often an interaction between sample size and statistical significance. To publish a non-significant result, sample sizes must be very large. This is reasonable because the statistical power to detect a significant difference is low when samples are small. The real problem arises when the true relationship is modest as in the majority of epidemiological analyses [25]. In fact, for studies with small samples, the only results published will tend to be those that are significant, and this can lead to a systematic overestimation of the true effect size.

In meta-analysis, funnel plot and related statistical analyses are the most commonly used methods for assessing the possible existence of publication bias. Funnel plots are simple scatter plots of the risk estimates, on the *x* axis, versus some measure of their precision, as standard error, variance, inverse of variance and sample size, on the *y* axis. The name "funnel plot" arises from the fact that risk estimates from small studies will spread out more widely at the bottom of the graph, with the spread narrowing among larger studies that present more precise estimates (smaller standard errors). In the absence of bias, the plot should look like a symmetrical inverted funnel (see Fig. 80.1). If there is a bias, because, for example, smaller studies without statistically significant effects remain unpublished, this will lead to an asymmetrical form of the funnel plot with a gap in a bottom corner of the graph (see Fig. 80.2): smaller studies, with low power and greater standard errors, will not be published. The more the asymmetry is pronounced, the more likely it is that the amount of bias will be substantial and the pooled effect calculated from meta-analysis will probably overestimate the true risk estimate [29].

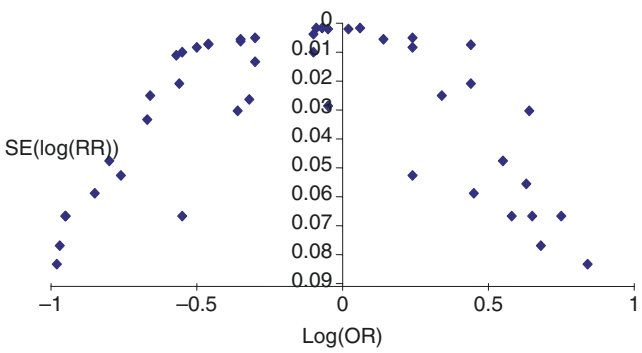

Fig. 80.1 Symmetrical funnel plot

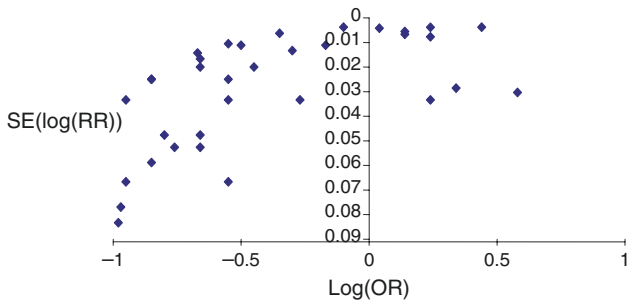

Fig. 80.2 Asymmetrical funnel plot

In absence of bias, the shape of the plot depends on the choice of the axes. Standard error was shown to be the best choice for the vertical axis because the expected shape in the absence of bias corresponds to a symmetrical funnel, straight lines to indicate 95% confidence intervals can be included, and emphasis of the plot is on smaller studies where bias is more likely. The only disadvantage, compared to other choices for the vertical axis, is that the axis has to be inverted to place the largest trials at the top of the graph [30, 31].

Visual evaluation of funnel plots may be subjective, and more formal statistical methods, to examine associations between the study effects and size, were proposed [32].

Duval and Tweedie have proposed the so-called "trim and fill" method. It is based on a rank data augmentation technique that adds studies to a funnel plot so that it becomes symmetrical [33]. Smaller studies at the bottom are omitted until the funnel plot is symmetrical (trimming). The trimmed funnel plot is used to calculate a summary estimate by standard meta-analysis approach. The trimmed studies are then replaced and their missing counterparts around the centre imputed or "filled". This provides an estimate of the number of missing studies and an adjusted summary estimate that is obtained including the "filled" studies.

Begg and Mazumdar proposed a rank correlation method that uses Kendall's tau to evaluate the association between the effect estimates and their variances [32].

Egger introduced a linear regression approach, which is equivalent to a weighted regression of the estimate on its standard error.

Egger's method is more sensitive than Begg's rank correlation approach, but the sensitivity of both methods is generally low in meta-analyses based on less than 20 trials [31]. Both Egger's regression method and the "trim and fill" method may be related to a great false-positive rate in detecting significant asymmetry of funnel plots. Furthermore Egger's method is known to be intrinsically biased [34].

Copas proposed a model in which the probability that a study is included in a meta-analysis depends on its standard error [35]. The model describes the process of study selection (publication bias) and evaluates the pooled OR for different parameter choices, which can be interpreted as the probabilities that a paper with a certain value of "standard error" is published (publication probability). For any given value of publication probability, Copas and Shi proposed a method to estimate the number of studies that were undertaken but not published and the correspondent reduction in the estimated risk. As there are not enough data to choose a single "best" model, the authors proposed a sensitivity analyses in which the value of the estimated risk factor is computed under a range of assumptions on the severity of the selection bias. The danger of the testing approach for funnel plot is the temptation to assume that, if the test is not significant, there is no problem, and hence the possibility of publication bias can be ignored. Copas and Shi argued that publication bias is endemic to all empirical research even if it is not evident from the funnel plot. Approaches, which try to estimate exactly how many studies are missing, are very hazardous, and graphical tests make assumptions that cannot be tested. The sensitivity analysis proposed by Copas and Shi monitors how sensitively the results depend on the assumptions using a model to describe the process of study selection, estimate the effect of interest for different parameter choices within this model and then check the fit of each estimate with the evidence in the funnel plot. The application of this method is quite straightforward because the authors published the S-plus routines, which is useful to carry out the calculations [35].

These statistical methods, which investigate the asymmetry of the funnel plot, try to estimate how big the impact of publication bias might be on the results. However none of them can be considered the ideal statistical method for assessing publication bias, and any method should be considered indirect and exploratory. Modelling assumptions used may heavily influence the estimates adjusted for publication bias. Many factors may be involved in the publication process, and it is difficult, if not impossible, to adequately model them. These methods may detect "missing" studies even in the absence of bias, adding and adjusting for nonexistent studies in response to funnel plot asymmetry arising from nothing more than random variation [30]. As a matter of fact their sensitivity is generally low in meta-analyses based on less than 20 trials [30, 36]. The tests are most useful for large meta-analyses and when there is a wide range of study size. However, based on the empirical type I error rates, a regression of logOR on sample size, weighted by the inverse of the pooled variance to allow for possible heterogeneity, is the preferred approach.

It was estimated that missing studies change the conclusions in less than 10% of meta-analyses, suggesting that publication bias, although widespread, may not be a major problem [37]. It is therefore wise to restrict the use of statistical methods that model selection mechanisms to the identification of bias rather than correcting it [38].

80.8 Some Examples of Meta-analyses and Pooled Analyses on Breast Cancer Risk and Survival

One of the first meta-analyses on breast cancer was published in 1988 by Longnecker et al. [39], in which the authors investigated the association between alcohol and breast cancer. They found a significant dose-response relationship both in case-control and in cohort studies, strongly supporting the detrimental effect of alcohol consumption on breast cancer risk. In contrast, in a recent meta-analysis investigating the association between serum 25-hydroxyvitamin D levels and cancer risk, we could not establish an association with breast cancer because of different results in case-control and cohort studies. In fact, we found a significant association only in case-control studies where a reverse causation could have biased the results [40].

One of the most cited pooled analysis [41] of individual patients data summarized results of 194 unconfounded randomized clinical trials of adjuvant chemotherapy or hormonal therapy for early breast cancer, assessing recurrence and 15-year survival. Owing to its large size, this study had enough statistical power to draw reliable conclusions about the long-term benefits of various breast cancer treatments.

Another widely cited pooled analysis [42] of data from 22 studies allowed a reliable estimation of the cumulative risk of breast and ovarian cancer in BRCA1 or BRCA2 mutations carriers, providing important information for genetic counselling. Information that none of the single study could have given with accuracy. As a final example, investigation of heterogeneity in another meta-analysis in BRCA1/2 mutation carriers allowed us to assess differences in the effect of oral contraceptive formulations by time. We found that formulations used before 1975 were associated with a significant increased risk of breast cancer but not more recent formulations [43].

Trial Designs and Biostatistics for Molecular-Targeted Agents

81

William T. Barry

81.1 Introduction

Prospective clinical trials are a key element in the developmental process of investigational drugs for treatment of cancer. For the past 50 years, clinical trials have largely been segmented into investigations that are defined by the cancer's site of origin. For example, treatment paradigms for breast cancer patients have developed independently from those for patients with lung cancer. Early work in cancer biology has demonstrated that the disease is heterogeneous within a given cancer type, with some common features that allow for tumors to be classified by molecular phenotypes [1]. Our increased knowledge of the molecular alterations which occur and drive disease progression has also transformed drug discovery in oncology. Today, many new compounds have been identified which target specific defects or cellular pathways that are dysregulated in tumors. The discovery of many multiple classes of drugs has opened the door to the use of personalized medicine in treatment of the disease, whereby lines of therapy can be tailored to the molecular phenotype of the individual's tumor. Furthermore, the targeted genetic mutations and molecular phenotypes often occur across multiple cancer types [2]. This has led to the application of new clinical trial designs, where patient eligibility is not restricted by the anatomical origin of the tumors and molecular assays are incorporated to establish the biomarker status of all patients and to evaluate the effectiveness of drugs under the paradigm of personalized medicine.

Formally, the term biomarker has been broadly defined by the National Institutes of Health Biomarkers Definitions Working Group as "any substance, structure, or process that can be measured in the body or its products and influence or predict the incidence of outcome or disease" [3]. The biomarkers used in clinical cancer research today were originally discovered and developed within many different disciplines of academic medicine, whether pathology, radiography, immunology, or cancer genetics [4]. When utilizing a biomarker clinically, there is the added layer of complexity that there may be more than one laboratory assay available, and standardization can improve both the quality of testing and also the consistency of application in clinical research. At the same time, the assessment of biomarkers can be improved over time with development of new biotechnologies and further analytic validation. For instance, in 2013, the American Society of Clinical Oncology (ASCO) and College of American Pathologists (CAP) updated their recommendations for human epidermal growth factor receptor 2 (HER2) testing in order to incorporate new diagnostic strategies when measured by immunohistochemistry (IHC) and/or in situ hybridization (ISH) [5].

The clinical utility of any biomarker will depend on the type of information it provides about the disease state. Biomarkers in breast cancer can be categorized as measures of the risk of development of breast cancer, prognosis of individuals diagnosed with the disease, prediction of benefit to specific therapies, or measures of response to interventions. Many of the most well-characterized molecular phenotypes in breast cancer, however, provide multiple pieces of information about the disease process. This includes the genotype of BRCA1 and BRCA2 (risk, prognosis, and possibly prediction), HER2 gene amplification (prognosis and prediction), and expression of the Ki67 gene in tumor tissue (prognosis and response to therapy). Thus, when designing a clinical trial that incorporates a molecular biomarker, one must consider context and what specific clinical utilization is under investigation.

Biomarker research was traditionally conducted as correlative science to clinical trials where the primarily objective was to investigate safety and efficacy of a new drug or

intervention. Guidelines have been issued on the collection and use of biospecimen for biomarker development and on assay requirements before their incorporation into prospective trials [6, 7]. A set of criteria, REporting recommendations for tumor MARKer prognostic studies (REMARK), was compiled in 2005 by an international committee to improve the quality and reproducibility of study results [8]. One advantage to retrospective investigations of biomarkers is that they allow for a variety of approaches common to observational studies, such as nested case-control designs that can be more efficient when trial populations are large and the clinical outcome or molecular phenotype is rare [9]. However, only prospective application of the biotechnology will fully evaluate the clinical utility of an assay [6] that depends on additional factors including accessibility of a biospecimen, quality control of specimen collection and laboratory procedures, and the feasibility of running assays in real time to make clinical decisions in a timely manner. In recognition that there are operational challenges and costs with prospective clinical trials, prospective-retrospective studies have been proposed where prospective processing of banked specimen could be run in an in silico manner to obtain high-quality evidence of clinical utility. In a report from the Institute of Medicine, *Evolution of Translational Omics: Lessons Learned and the Path Forward* [10], the validation of the Oncotype DX® assay in the National Surgical Adjuvant Breast and Bowel Project (NSABP) trial B-14 is used as a case study of a prospective-retrospective evaluation from banked specimen. The investigators found that the assay was prognostic for disease recurrence and overall survival in patients with node-negative and estrogen receptor-positive tumors [11]. Further retrospective studies indicated that the assay was also predictive of benefit from adding chemotherapy to tamoxifen treatment in patients with higher risk of recurrence [12] and that the prognostic and predictive value extended to a study population of node-positive breast cancer patients [13]. Ultimately, a large prospective trial was required to prospectively validate the assay and to further refine its clinical utility and optimal thresholds for selecting between endocrine and chemotherapy-based regimen.

In this chapter, a series of trial designs are presented in detail for prospective biomarker-driven studies where the primary objective incorporates both the marker status of the study population and the efficacy of anticancer treatments. A description of some of the analytic approaches for biomarker-driven studies is provided, including statistical methods for fixed group sequential and adaptive designs. The complexity of breast cancer studies highlighted here ranges from investigations of a single agent with a paired biomarker to multiplex assays to assess a panel of molecular alterations and treatment strategies that incorporate multiple targeted therapies.

81.2 Trial Designs for Heterogeneous Populations

In 2009, the Biomarkers Task Force of the National Cancer Institute (NCI) Investigational Drug Steering Committee provided a set of definitions for biomarkers that are incorporated in a prospective manner into cancer clinical trials [14]. Standardized criteria were established that determine whether a marker has an *integrated* or *integral* role in the study design and conduct. Specifically, an integrated marker is performed in a trial "to identify or validate assays that are planned for [future] use," where "statistical design and analysis should be pre-specified" and "include complete plans for specimen collection, laboratory measurements, and analysis." Studies with integral markers have many of the same elements, but are also designed such that the assay must be completed before patients can proceed on the trial. Examples of integral biomarkers include those used to establish eligibility, determine patient stratification and randomization, or inform treatment assignment.

81.2.1 Biomarker-Based Trial Designs

Treatment trials which incorporate integral biomarkers generally fall into one of three classes: marker-stratified designs, marker enrichment designs, or a broader class of marker-directed designs [15]. Some of the unique elements and limitations of each design are discussed below.

81.2.1.1 Marker-Stratified Designs

Marker-stratified designs are studies where the biomarker-defined subgroups are incorporated into the trial as a stratification factor used during randomization. Equivalent allocation schemes are applied within each stratum so that the expected treatment assignment does not vary by biomarker status. A representative schema is shown in Fig. 81.1 for a study population that can be segregated into three biomarker-defined subgroups; in each stratum patients are randomized to receive one of two treatments. The distinction from integrated biomarker studies is that marker status is required at study entry, which allows for other design characteristics to be considered (e.g., capping the total sample size to each marker-defined subgroup). The scientific objectives and analysis plans of a marker-stratified design can take a number of different forms, as explored later in this chapter, but must be pre-specified and justify the sample size in accordance with the hypothesized relationship between biomarker status and efficacy of the treatment.

An example of a breast cancer trial that used the marker-stratified design is a randomized placebo-controlled phase III study to investigate the addition of lapatinib to letrozole as a

targeted strategy for patients with hormone receptor-positive metastatic breast cancer [16]. The study enrolled a total of 1280 patients in order to have a subset of 218 patients with HER2-positive tumors. The sample size of the subgroup was selected to be powered to detect a 55% improvement in progression-free intervals with the combination and to secondarily test efficacy in the total study population. The study demonstrated significant improvement with the combination in the HER2-positive subset which was attenuated in the overall population but remained statistically significant. However, based on a post hoc evaluation in the HER2-negative subset, the investigators rightly concluded "lapatinib plus letrozole failed to delay endocrine resistance in more than 750 patients with endocrine-sensitive, EGFR/HER2-negative disease." This trial result illustrates that marker-stratified designs and testing strategies require careful consideration of power and clinically meaningful effect sizes within and across subgroups.

81.2.1.2 Marker Enrichment Designs

Marker enrichment designs are studies where biomarker-defined subgroups are selected for participation in the trial. Selection could be based on a predictive marker of sensitivity to protocol treatment or based on a prognostic marker to identify higher- or lower-risk patients for whom clinical benefit with the treatment is hypothesized. With predictive biomarkers, enrichment designs are most appropriate when there is sufficient prior information to indicate that efficacy will only be seen in the molecularly defined subpopulation. In Fig. 81.1, the right-most schema applies an enrichment strategy by excluding patients that determined to be in [marker subgroup] 1.

A classic example of enrichment studies leading to approval of drugs has been the investigation of trastuzumab and other anti-HER2 therapies in breast cancer. The efficacy of adding trastuzumab to standard adjuvant chemotherapy was demonstrated in two randomized phase III trials: NSABP trial B-31[1] and North Central Cancer Treatment Group trial N9831.[2] A total of 3351 patients with HER2-positive disease were treated across the two studies and showed vastly improved disease-free survival with the addition of the targeted therapy [17]. Eligibility to both studies was established by local assessment of HER2 using standard criteria. But, in a follow-on report from B-31, central confirmation of HER2 status was performed, and discordance with local assessment was seen in about 10% of cases. Furthermore, a consistent level of benefit was seen with the addition of trastuzumab in every subset defined by centralized IHC or FISH [18]. This left open a scientific question of whether benefit of anti-HER2 therapy would extend to some patients that are not HER2-positive under ASCO-CAP guidelines. To investigate this further, a randomized phase III clinical trial NSABP B-47[3] has enrolled 3260 patients with intermediate HER2 gene amplification (IHC 1+ and 2+ that are negative by FISH) to evaluate whether trastuzumab will improve invasive disease-free survival. Enrichment designs have also been adopted in three trials of PARP inhibitors as treatment of metastatic breast cancer in patients harboring BRCA mutation [19].

81.2.1.3 Marker-Directed Designs

Marker-directed designs are studies where treatment assignment is determined by the integral biomarker. This type of design encompasses a broader class of studies, including trials where either a fixed or random assignment of patients is specific to one or more of the biomarker-defined subgroups and also where unequal randomization schemes are applied within each subgroup. For instance, the rightmost schema in Fig. 81.1 directs patients in [marker subgroup] 2 to receive treatment A, while those in [marker subgroup] 3 are randomized in an imbalanced fashion to the two treatment regimen.

An example of a marker-directed design being used in breast cancer research is the Trial Assigning IndividuaLized Options for Treatment (Rx), TAILORx,[4] to prospectively validate the prognostic and predictive value of the Oncotype DX® recurrence score (RS). Specifically, patients with the lowest risk scores (RS < 11) were directed to endocrine therapy alone, and those with the highest risk scores (RS > 25) were directed to chemotherapy. Patients in the intermediate range ($11 \leq RS \leq 25$), where equipoise still existed, were randomized to receive one of the two treatment regimens. Statistical analysis plans are to test for non-inferiority of endocrine therapy and secondarily to explore whether the upper ranges of RS are modifiers of any potential benefit from chemotherapy. A total of sample size of approximately 11,000 patients was selected to have an adequate number at intermediate risk to participate in the randomized component of the study.

81.2.2 Adaptive Designs

When considering the strengths and limitations of the biomarker-based studies described above, it is important to note that only the marker-stratified design provides direct evidence of the performance of the biomarker as a predictor of treatment benefit. However, a limitation of the design is that the sample sizes can be prohibitive when the prevalence of marker positive is rare. Conversely, a marker enrichment design cannot be used to validate the performance of the

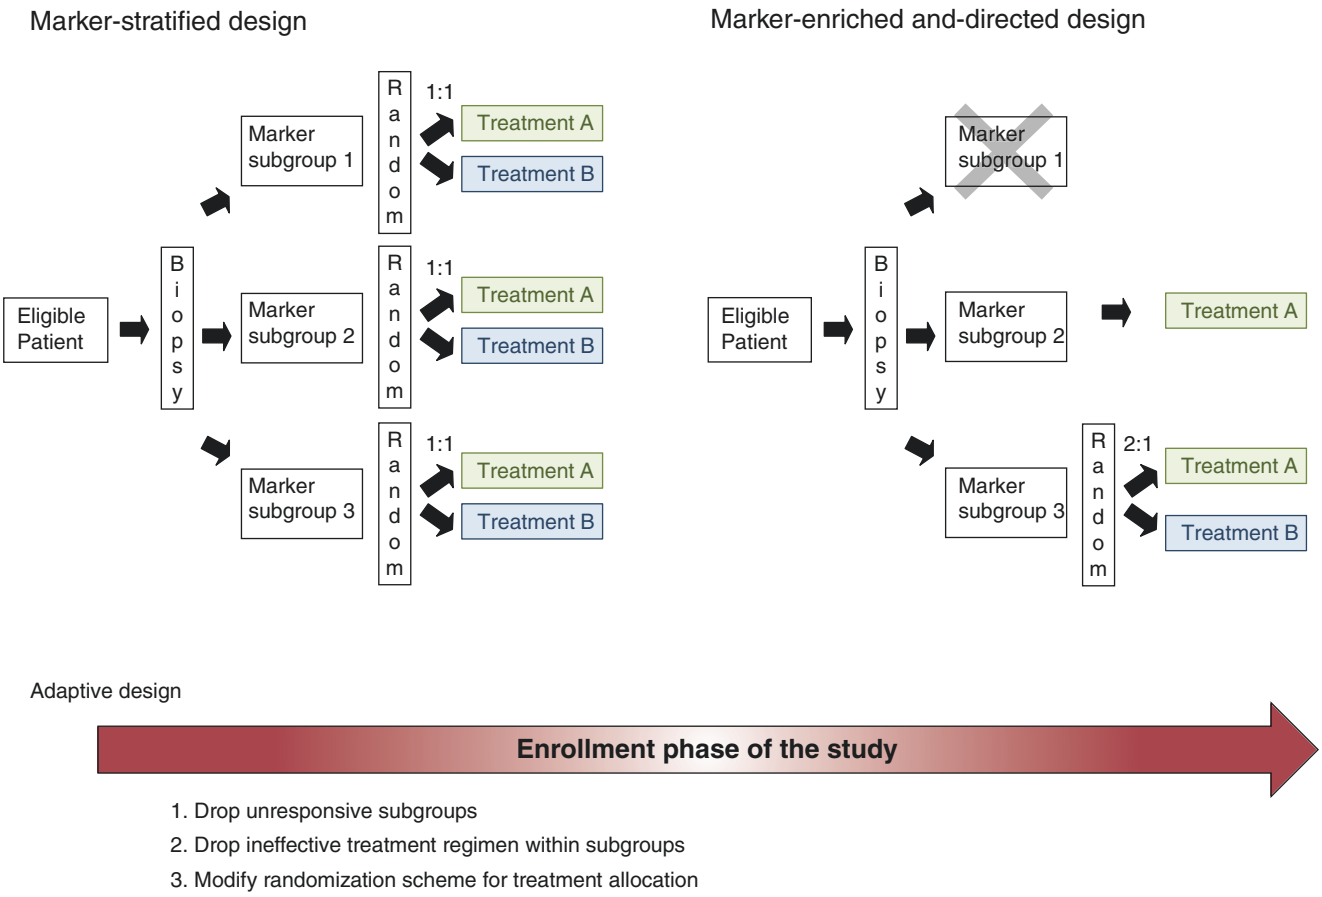

Fig. 81.1 Schema for biomarker-driven trials and elements of adaptive designs

marker, but is more efficient when treatment effects are strongly modified by the molecular phenotype [20]. Likewise, a marker-directed design can allow one to investigate different hypotheses within the marker-defined subgroups under one protocol. This distinction in operating characteristics will only hold for studies that are conducted as a single-stage analysis plan, and the theory and methodology of group sequential and adaptive designs can be applied in ways to allow a trial to transition over the course of investigation from a stratified design to an enrichment or directed design.

The designation that a trial is *adaptive* is applied whenever there is an iterative analytical plan that uses the accumulated information to make modifications to design elements. Some of the most common prospective studies with adaptive designs are phase I dose-finding studies, phase II and III studies with sample size re-estimation or response-adaptive randomization, and seamless phase II/III studies. To adapt a biomarker-driven trial, a sequential testing strategy can be used to modify a trial to (a) exclude a marker-defined subgroup where inadequate treatment benefit has been observed, (b) drop a treatment regimen in a subgroup-dependent manner, or (c) alter the ratio of randomization in a multi-arm trial. The schemas in Fig. 81.1 were selected in a way that one modification of each type would transition from the marker-stratified design to the marker-enriched and marker-directed design shown. The iterative process could be performed as a group sequential test at fixed points in the enrollment period or under a continual assessment plan.

The analytic plans to adapt biomarker-driven trials can be based on standard criteria used to evaluate the efficacy of drugs, such as the decision rules for stopping a trial early for futility. For a single-arm phase II trial without a concurrent control, the predominant approach is the Simon two-stage design that controls error rates while minimizing sample size requirements [21]. Likewise, early stopping for futility is often a required element of phase III randomized controlled trials [22]. A natural extension to biomarker-driven studies is to define staged tests of clinical activity within subgroups [23], and the study population would be enriched in the latter part of the trial if clinical activity is limited to one marker-defined subgroup. This simple extension can be burdensome when having to conduct interim tests at fixed points of enrollment within each subgroup. Thus, some designs perform unselected enrollment in stage one and evaluate efficacy in the randomly sized subpopulations [24]. Stopping rules can also be based on other parameters related to biomarker status and treatment effects, such as the predictive value of the biomarker [25]. Adaptive methods have also been developed for

a continuous biomarker without established threshold(s), where accumulated information on the predictive value is applied to a series of group sequential tests to transitioning from an all-comers design to enrolling only a marker enrichment population for final testing of efficacy [26]. The same rules can be extended to non-comparative multi-arm trials so that future patients are directed toward drugs with the greatest benefit observed.

Lastly, the use of response-adaptive randomization can also allow for a gradual and seamless transition from marker-stratified to marker-directed assignment over the course of the trial. However, such adaptive designs require careful development and monitoring to achieve desired operating characteristics [27]. This adaptive methodology has been applied in the trial Neoadjuvant and Personalized Adaptive Novel Agents to Treat Breast Cancer (I-SPY 2),[5] with the motivation that this seamless process can ultimately result in more accurate and faster drug development. To further achieve this goal, once a drug graduates from the I-SPY 2 trial to a phase III confirmatory study or drops from the study for futility, it is replaced by new investigational agent. For both response-adaptive randomization and group sequential testing, early end points of efficacy are needed to maximize efficiency in terms of number of patients enrolled and total study length. For this reason, the neoadjuvant paradigm and measurement of treatment effects using pathologic complete response has also accelerated drug development in breast cancer.

81.2.3 Basket and Umbrella Trials

With our current knowledge of the genomic diversity in cancer, and with the discovery of a variety of drugs that target specific molecular phenotypes, there has been a push to change the paradigm of how clinical cancer research is conducted. Whereas traditional drug development involved testing a single drug with or without a companion diagnostic, a number of clinical trials have recently been developed that enroll a diverse population of patients to evaluate multiple targeted treatments (Table 81.1). The motivations are both scientific, in seeking to answer broader questions of efficacy under precision medicine, and pragmatic, in gaining operational efficiencies from incorporating multiple investigations under a single protocol. The terms "basket" and "umbrella" have been used to evoke the manner in which the trial flows patients into the series of investigations, and each design requires integral biomarkers to establish the patient status at study entry.

Table 81.1 Biomarker-driven trials with multiple molecular targets or investigational drugs

Trial	Design	Study population	Target gene alterations or protein expression[a]	Investigational drugs[a]
NCT01953926	Basket (non-randomized)	Solid tumors	EGFR, HER2, HER3	Neratinib
NCI-MATCH NCT02465060	Umbrella (non-randomized)	Solid tumors or lymphomas	ALK, ROS1, BRAF, EGFR, HER2, NF2, cKIT	Afatinib, AZD9291, crizotinib, dabrafenib, sunitinib, T-DM1, trametinib, VS6063
Lung-MAP[b] NCT02154490	Umbrella (randomized)	Squamous cell lung cancer	PI3K, CDK4, CCND1, CCND2, CCND3, FGFR	AZD4547, ipilimumab, nivolumab, palbociclib, taselisib
I-SPY 2 NCT01042379	Umbrella (randomized adaptively)	Breast cancer	ER, PR, HER2, MammaPrint®	ABT-888, AMG 386, ganetespib, ganitumab, metformin, MK-2206, PLX3397, neratinib, pembrolizumab, pertuzumab, T-DM1, trastuzumab
SAFIR 02[b] NCT02299999	Marker strategy (randomized)	Breast cancer	AKT, AR, EGFR, HER2, MEK, mTOR, PARP, VEGF	AZD2014, AZD4547, AZD5363, AZD8931, bicalutamide, olaparib, selumetinib, vandetanib
SHIVA [30] NCT01771458	Marker strategy (randomized)	Solid tumors	KIT, ABL1/2, RET, PI3KCA, AKT, mTOR, RICTOR, RAPTOR, PTEN, STK11, INPP4B, BRAF, PDGFRA/B, FLT3, EGFR, HER2, SRC, EPHA2, LCK, YES1, ER, PR, AR	Abiraterone, dasatinib, erlotinib, everolimus, imatinib, lapatinib, letrozole, sorafenib, tamoxifen, trastuzumab, vemurafenib

[a]Target molecular phenotypes and investigational drugs for each trial were obtained from https://clinicaltrials.gov/ as of Jan 1, 2016
[b]Trial design and investigational drugs was obtained from updates posted at http://www.lung-map.org

[5]NCT01042379.

The label of a "basket trial" is typically applied when a single drug is under investigation, and patients from a variety of disease settings are enrolled into the study. Clinical activity is then evaluated separately in each basket defined by traditional disease characteristics. For newer classes of drugs, including immunotherapies, the basket design has become popular for early phase investigations before conducting multiple definitive randomized studies in individual disease types. For targeted drugs, a basket trial allows one to enroll a diverse study population who share common molecular phenotype thought to impart sensitivity to the agent. As one example, a non-randomized phase II study is evaluating neratinib monotherapy in solid tumors known to carry mutations or amplifications in one of the human epidermal growth factor receptor genes: EGFR, HER2, and HER3.[6] The individual baskets are defined by combinations of disease type and molecular phenotype (e.g., gastric cancers harboring a HER2 mutation, or any solid tumor with a HER3 mutation).

Conversely, an "umbrella trial" will enroll a study population defined by generic disease characteristics and then use a set of integral biomarkers to direct patients into substudies to evaluate a variety of experimental therapeutics. Two of the first umbrella trials were sponsored by the NCI: the ALCHEMIST trial[7] screens several thousand patients with operable, non-squamous, non-small cell lung cancer to select those with ALK rearrangement or EGFR mutations for randomization to targeted therapy versus standard of care. The Lung-MAP trial[8] used the genomic profile of advanced squamous tumors to match patients to randomized sub-studies of targeted therapy or to evaluate a new combination of immunotherapies in unmatched individuals. The use of umbrella designs was extended more recently in the NCI-MATCH ("Molecular Analysis for Therapy Choice") trial,[9] to perform genomic profiling of any consenting adult with a solid tumor or lymphoma and to allocate patients with a matching alteration to a drug within a portfolio of targeted investigational products. The primary evaluation of a drugs' efficacy will be in all treated patients, and not in separate baskets defined by the type of cancer. Lastly, the I-SPY 2 trial can be characterized as an umbrella trial, in addition to using outcome-adaptive randomization, because the comparisons of investigational drugs to standard of care are analyzed and reported separately. The first treatment regimens to report positive findings from the trial have been the combination of veliparib and carboplatin for triple-negative disease, neratinib for HR−/HER2+ disease, and the AKT inhibitor MK-2206 in HR− and/or HER2+ disease.

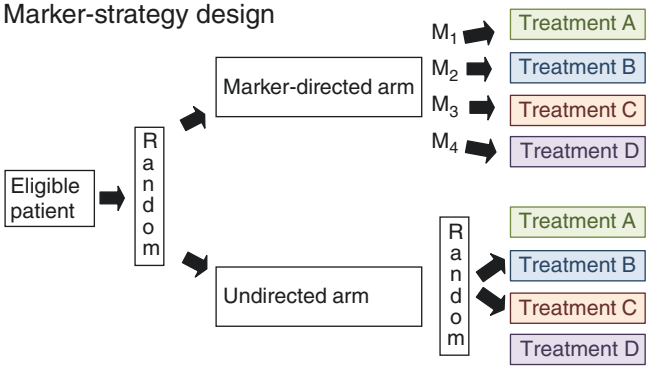

Fig. 81.2 Schema for a marker strategy design

81.2.4 Biomarker Strategy Designs

While the traditional drug development process has been to investigate a single treatment regimen with or without using a molecular biomarker to define the target population, different approaches have been proposed for evaluating the clinical effectiveness in the era of precision medicine including the biomarker strategy design (Fig. 81.2). Here, the experimental arm utilizes an algorithm for directing patients to receive one of a portfolio of drugs according to their biomarker status. A randomized controlled study could use several different strategies to assign treatment in the other arm: a different set of drugs that are standard of care, random allocation to the drugs in the portfolio, or physician's choice naïve to the patient's biomarker status. Outcome can then be compared between the two randomized populations without direct consideration of the individual treatments received in each arm. The trial could be conducted in a narrow patient population using a small number of directed therapies or in a broader setting when a suitable treatment algorithm can be constructed for a more heterogeneous population.

The marker strategy design has been implemented in the SAFIR 02 trial[10] for patients with metastatic breast cancer. Genomic profiling was first piloted in a non-randomized screening study, where investigators found that 195 of 423 patients (46%) had a target genomic alteration detected [28]. In SAFIR 02, patients who begin treatment with standard chemotherapy are screened for 51 molecular alterations which are matched to a targeted therapy. Patients with a detected alteration are then randomized after a fixed number of cycles to continue on standard of care or to switch to the target monotherapy. The primary objective is to compare the progression-free survival of patients on each arm. An example of a marker strategy design used in a broader setting is the SHIVA trial[11] which enrolled patients with any solid tumor deemed refractory to

[10]NCT02299999.

[11]NCT0177145.

standard of care for the disease type [29, 30]. Patients were screened for a number of genomic and proteomic alterations that are targeted by ten treatment regimens. When an alteration was detected, patients were randomized either to receive an agent under the protocol-specified treatment algorithm or to receive treatment by physician's choice. The study was designed to include a total of 200 patients with alterations and powered to detect a 40% improvement in progression-free survival under an assumption of a homogenous treatment effect. After screening 741 patients, targeted alterations were detected in 293 individuals and 195 were randomized to treatment (breast cancer was the most common disease type, n = 40). The primary analysis failed to identify a significant improvement in progression-free survival. For both marker strategy designs, the treatment regimens vary between the experimental and control arm which leads to confounding between randomized assignment and the effects of the individual treatments. For this reason, it is difficult to discern whether the negative results from the SHIVA trial are attributed to the marker-directed strategy, efficacy of the ten targeting drugs, or other aspects of the design and enrolled study population.

81.3 Statistical Methods for Biomarker-Driven Trial Designs

One of the challenges in developing a biomarker-driven trial is to distinguish the overall hypothesis and scientific goals of the study. This will not only drive the design but also frame the analysis plan for primary and secondary objectives. All study plans should be described in the trial protocol that governs study conduct. The section on statistical considerations should be developed according to the study objectives and provide a justification of the sample size, the statistical methods, and detail on the set of inferences planned to avoid any research biases from testing additional post hoc hypotheses.

In a treatment trial that assumes a homogenous patient population, the primary hypothesis is simply a question of whether outcomes are improved when given a new drug relative to a randomized or historical control. For biomarker-driven trial designs, the hypothesis might be reframed to (a) ask questions of improved outcomes conditioned or modified by biomarker status, (b) validate the predictive or prognostic value of the biomarker, or (c) both. To investigate the causal relationship between a drug intervention and outcomes, randomized controlled trials provide the highest level of evidence of the treatment effect and its modification by baseline factors. The same holds for biomarker-driven studies, and estimates will be unbiased assuming that complete and error-free molecular information is obtained before treatment begins. Finally, in order for randomization to provide the necessary properties for causal inference, analyses should follow the *intention-to-treat* principle and analyze all subjects according to their assigned intervention, and integral biomarker studies will prevent any systematic errors from specimen processing from introducing bias.

81.3.1 Evaluations of Biomarkers and Drugs

Before the utility of a biomarker is ready to be assessed in a prospective clinical trial, the assay must first be demonstrated to have analytic and clinical validity. Analytic validation of a laboratory test establishes that its performance characteristics meet the requirements for clinical application, including accuracy and precision. Accuracy can be quantified in terms of sensitivity and specificity from a collection of specimen where a dichotomous test result is compared to a "gold-standard" measurement of the underlying phenotype. For laboratory tests that return a continuous score, performance as a binary classifier can be displayed using a receiver operating characteristic (ROC), and indexes such as Youden's J statistic, $J = \text{sensitivity} + \text{specificity} - 1$, can be used to select an optimal threshold.

The precision of a laboratory assay be can be evaluated under two scenarios: *repeatability*, when all efforts are made to keep conditions constant (e.g., instruments, operator, and time point of processing), and *reproducibility* across conditions (e.g., laboratories, platforms, or experiments). In developing the MammaPrint® assay based on the original 70-gene signature discovered with Agilent microarrays, a paired experiment was performed using a collection of banked specimens demonstrating a Pearson correlation >0.99 between the two platforms [31]. For cancer biomarkers, additional sources of variation need to be considered that may affect precision, such as spatial heterogeneity of the tumor, environmental factors (e.g., fasting), or time-varying effects of the disease and/or natural process as hypothesized for Ki67 expression levels across menstrual cycles [32]. For experiments with a variable number of unordered replicates, the intraclass correlation coefficient (ICC) is a useful statistic for quantifying the agreement in continuous marker levels, and Donner and Eliazew provide a sample size calculation for designing studies to assess reliability which depends on the number of replicates per sample and desired type I and II error when testing against a null ICC [33].

The clinical validity of a biomarker extends from the accuracy and precision of the assay versus a gold standard to the association with health outcomes that are related to the drug efficacy and treatment decisions. For outcomes that can be represented as a binary variable (e.g., radiographic response), the probability of an event can be parameterized as π_j where $j = 1, 2 \cdots m$ represents each biomarker subgroup. The null hypothesis of no association between outcome and biomarker status is $H_0 : \pi_1 = \pi_2 = \ldots = \pi_m$. The observed data from a study can be summarized in a $2 \times m$ contingency

table, and inferences can be made using Fisher's exact test. In cancer, clinical outcomes are frequently measured as the time interval until a disease event occurs, whether a disease-free interval until recurrence, time to radiographic evidence of progressive disease, or overall survival until death from any cause. In a clinical trial, the study timeline and data collection and the underlying disease process will not allow for all patients to be followed until an event occurs. For patients where an event is not observed, the end point is right censored at the time point at which the subject was last known to be event-free. Methods in survival analysis allow one to estimate the distribution of time-to-event data as a survivor function, $S(t)$, and to compare the outcomes in either a randomized trial or marker-defined subgroups against a null hypothesis, $H_0: S_1(t) = S_2(t)$ for all $t > 0$. Analysis plans can utilize parametric methods to estimate $S(t)$ and conduct hypothesis testing, such as the exponential model with the assumption of a constant hazard, λ, over time such that $S(t) = e^{-\lambda t}$. However, nonparametric methods are more commonly used in the analysis of breast cancer trials, including the Kaplan-Meier product-limit estimator for $S(t)$ and the log-rank test for two-sample comparisons with the null hypothesis stated above.

When evaluating the prognostic value of a biomarker, the association to disease outcome is estimated using a regression model. REMARK criteria include the recommendation to use multivariable models to discern the independent prognostic effect of a biomarker after adjusting for other known prognostic disease and patient characteristics. For time-to-event end points, the semi-parametric Cox proportional hazard model can be used to specify the functional relationship between covariates in the model, but underlying hazard function, $\lambda_0(t)$, remains distribution-free. As part of the validation of the Oncotype DX assay, the prognostic value of the recurrence score remained significant after adjusting for clinical factors including tumor size and nodal status [34]. The first set of results from the TAILORx trial demonstrated that the low-risk cohort had a very low rate of recurrence 5 years out from study entry [35]; however, as a marker-directed design, these data do not allow for the prognostic value of the classifier to be validated until outcomes are reported for the patients in the intermediate-risk cohort that were randomized to endocrine therapy.

For a predictive biomarker to be evaluated as a companion diagnostic to a targeted treatment, the FDA recommends prospective validation using a test of interaction between treatment effects and biomarker status. This approach could be conducted with an integral biomarker as part of a marker-stratified design, as an integrated biomarker to a study that enrolls all-comers, or a retrospective-prospective study using archived specimen, but requires a randomized controlled study of treatment. Reporting guidelines should follow the CONSORT with additional issues relating to the marker assays incorporated from the REMARK criteria. The parameter of interest in an interaction test is a multiplicative term in the linear predictor a multivariable regression model. In the simplest case of a categorical marker with two levels and a two-arm randomized trial, the parameter is given as β_3 in the following linear predictor:

$$\log(\lambda(t)) = \log(\lambda_0(t)) + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1 x_2,$$

where covariates for the treatment assignment and biomarker status are x_1 and x_2, respectively. The test is constructed against the null hypothesis, $H_0: \beta_3 = 0$. One challenge with an analysis plan to test for an interaction is that a larger sample size is needed to establish statistical significance relative to a main effect of the same magnitude, by a factor of $(p_1\, p_2)^{-1}$ where p_i is the proportion of patients in the i-th marker subgroup. Thus the minimum fold increase is under an idealized situation that the prevalence of marker-positive patients is exactly half of the study population [20, 36]. For this reason, alternative testing strategies have been proposed which perform multiple comparisons of treatment effects conditional on biomarker status, but it should be remembered that the inferences drawn from these analysis plans do not validate the predictive value of a biomarker for specific treatment benefit.

81.3.2 Multiple Comparisons

One of the important considerations for a biomarker-driven study is the consequence of any multiple testing driven by the complexity of the research question. For a simple biomarker enrichment design, this is less relevant because the primary evaluation of the treatment effect is in the entire study population. Likewise, for biomarker-directed designs, the basis for accounting for multiple testing will depend on how primary and secondary objectives are specified. If hypothesis is framed as co-primary objectives about the efficacy of each marker-directed therapy, the common procedure to control the family-wise error rate (FWER) of at least one false-positive finding is to make a Bonferroni correction to the p-values of each test: $p_j \le \alpha/m$ for all $j = 1, 2 \cdots m$. For biomarker-stratified designs, alternative testing procedures to the Bonferroni correction have been proposed to control study-wise false discovery. Freidlin et al. review the different methods of sequential or parallel assessment in the overall population and biomarker subpopulations and comment on the strengths and limitations of each [37]. This includes the testing method used in the phase III of lapatinib to letrozole in hormone receptor-positive metastatic breast cancer mentioned above, where the testing method was to evaluate sequentially efficacy in the HER2+ subgroup and then in the overall study population [16].

Other experimental approaches have been developed for when a biomarker is not sufficiently established to be integral or to be prospectively validated. For instance, the "biomarker-adaptive threshold" design has been proposed for when an assay has been analytically validated, but there is not a cut point defined for clinical utilization [38] and an "adaptive signature" design when a classifier remains to be developed from a multiplex assay [39]. In spite of the naming conventions to each method, analysis plans are conducted retrospectively once clinical outcomes are known for the study population.

81.3.3 Bayesian Statistics for Adaptive Designs

For adaptive designs, the use of Bayesian statistics is a natural approach to model the desired flexibility in design as parameters and to compute their posterior probabilities based on the accumulated data. Bayesian inference plans for clinical trials, whether fixed or adaptive, have used hierarchical models to evaluate treatment effects across a heterogeneous population. Under the formulation of Kass and Steffey [40], disease outcomes in a study population can be modeled as a random vector, y_n, which is conditionally independent given the parameters, θ. By conditioning on hyperparameters, φ, at the next level of the hierarchy, the individual $\{\theta_i\}$ are identical and independently distributed. Then, the elements of y_n will have a common probability model, p:

$$p(y_n|\theta) = \prod_{i=1}^{n} p(y_i|\theta_i)$$

$$p(\theta|\varphi) = \prod_{i=1}^{n} p(\theta_i|\varphi)$$

This hierarchical model was used in single-arm cancer clinical trials in order to borrow information across subgroups when evaluating efficacy [41, 42]. Likewise, the model has been implemented in randomized phase II studies investigating multiple experimental drugs [43]. In I-SPY 2, an experimental drug, say treatment A, "graduates" in a given marker-defined subgroup, x_j, if there is at least an 85% predicted probability of success in a future phase III trial that randomizes 300 patients with phenotype x_j between A and a standard of care, treatment B. The Bayesian probability of future success depends on the posterior distribution $P(\pi_{A,j} - \pi_{B,j} \mid \text{data})$ derived from the information accumulated in I-SPY 2. Conversely, if there is less than a 10% predicted probability of success in every biomarker subgroup, a drug can be dropped from I-SPY 2 for futility. The trial also performs response-adaptive randomization, using as input the posterior probability a drug is superior to all others within the j-th subgroup $P(\pi_{A,j} > \pi_{B,j}\ ,\ \forall B \neq A \mid \text{data})$. A key design feature of the I-SPY 2 trial which can improve efficiency of global drug development in breast cancer is that new drugs can be brought into the study.

Conclusions

In summary, with the number of genomic alternations that have been identified in cancer being targeted by novel therapies, we are undergoing a dramatic paradigm shift in the drug development process. Biomarker-driven trials are necessary to identify the subset of a heterogeneous population that will be sensitive to each targeted drug and to develop strategies for treating individuals under the paradigm of personalized medicine. The design and statistical analysis plans of every biomarker-driven trial should be framed around a hypothesized relationship between treatment effects and molecular phenotypes and establish how study-wise error will be controlled with any multiple comparisons. Umbrella and basket trials allow for efficient approaches to testing new therapies and bridging across the anatomic types of cancers to build study populations with similar molecular phenotypes. Adaptive designs play a specific role in biomarker-driven trials for transitioning from stratification of a general population to enrichment when assays are shown to accurately predict treatment benefit. Integral biomarker studies have an increased operational burden of performing assays and collecting results in real time, but more closely mirror the utilization of biomarkers for making treatment decisions in a personalized manner.

Bioinformatics for Clinical Use in Breast Cancer

82

Fabrizio Bianchi

82.1 Background

Bioinformatics embraces a multitude of fields including informatics, computer science, statistics, mathematics, and engineering, which are focused on the analysis and interpretation of biological data. In the recent years, bioinformatics steadily acquired a prominent position in cancer research due to the massive amount of data produced by genomic screening studies (i.e., microarray and next-generation sequencing based) of tumor samples [1]. For example, the Tumor Cancer Genome Atlas (TCGA), which is one of the biggest and most comprehensive effort to the understanding of the cancer molecular profile, performed gene expression, mutation, copy number variation, methylation, and protein profile analysis, for a total of 11,077 cases spanning 34 different tumor types (December 2015 update) [2]. This is a massive amount of *-omics* data which required the development of large computing infrastructures, software, and ad hoc databases, in order to manage data and make it publicly available to research community.

With the advent of next-generation sequencing (NGS), the amount of data produced in a single sequencing experiment expanded up to a ~10,000-fold. For example, the sequencing of BRCA1/2 genes using standard Sanger method produces ~15 MB of data, while in an NGS analysis, the amount of data produced are in the range of 8 GB for a whole-exome sequencing analysis (WES) to ~150 GB (30× coverage; 3.6 billion reads; 90 billion nt; FASTA format) for a whole-genome sequencing (WGS) analysis. Therefore, for running an NGS profile study of ~200 samples, the space required is about 1.6 terabytes (TB) for WES and 30 TB for WGS, which is far beyond the actual capabilities of data storage and computational power in a personal computer. As an example, the "Hawkey" stand-alone software developed by Michal Schatz in 2005 [3], which allows researchers to investigate mutations in the genome to confirm a specific phenotype, literarily collapsed when the massive sequencing information coming from an NGS sequencer was loaded into PC memory before visualization [4]. This prompted computer programmers and bioinformaticians to rethink about the way to manage large *-omics* datasets and perform analyses by skipping as much as possible local computing resources. The Galaxy platform is an excellent Web-based platform developed by Penn State, Emory University, and other institutions that allows uploading of *-omics* data to a public server and use remote computational power to perform a multitude of bioinformatics analyses [5], including NGS data alignment, genetic variation analyses, and downstream analysis to dissect molecular mechanisms (https://galaxyproject.org). Another powerful Web-based platform is the Cancer Genomics Browser (https://genome-cancer.ucsc.edu; [6]) that hosts an intuitive Web interface to interrogate several large *-omics* datasets of cancer samples (including TCGA), to look for cancer-relevant molecular alterations. A list of tools available for all level -omics data analysis can be found in the "Omics Tools" website (http://omictools.com) that include technologies, applications, and analytical steps, for a total of 10,738 tools. Importantly, most of these are freely available and do not require particular bioinformatics skills.

A new emerging technology that allows intensive computational analyses without a sizeable computer infrastructure is cloud computing. Cloud computing relies on external powerful IT infrastructures that offer the user the possibility to hire, at competitive costs, the required computational power and data storage and also to configure shared computing resources for custom data analyses [7]. Consequently, cloud computing represents an important partner of *-omics* data analysis software. For these reasons several computer scientists are now adapting existing tools and developing

new ones to perform bioinformatics on remote cloud computer clusters [8]. However, a critical aspect for cloud computing is the Internet speed connection that could become a bottleneck during data transfer, particularly when dealing with big dataset [7]. A way to skip such limitation is to physically send the hard disk drive (HDD) to third-party computer infrastructures, but this may be complicated when data contain sensitive information (such as in the case of clinical and genetic information). Privacy and data protection remains a relevant issue in cloud computing, despite most cloud-computing services providers offer encrypted data transferring protocols to safeguard data during upload from remote Internet server.

82.2 Bioinformatic Approaches to Interpret Breast Cancer Molecular Heterogeneity

Breast cancer has been one of the first tumor types to be analyzed using high-throughput screening technologies, such as microarray. In the early 2000s, landmark papers described the first high-density microarray gene expression profiles of cohorts of breast cancer patients and the discovery of diagnostic/prognostic gene expression signatures [9–11]. Concomitantly, numerous bioinformatic approaches for the analysis of microarray data were proposed either by adapting previous mathematical/statistical methods or by developing new ones. For example, hierarchical clustering analysis is one of the most frequently used method for interpreting molecular profile data, which was introduced in 1960s by Ward, J. H. Jr. in a pioneering study [12]. Joe H. Ward developed a method that allowed clustering of elements based on their maximal similarity considering their characteristics, thus forming groups in a hierarchical structure that may be useful to define novel types/subtypes [12]. The method was suggested for use in large-scale studies ($n > 100$) which fits well in a typical experiment of microarray expression profile screening. Indeed, after nearly 40 years using a very similar hierarchical clustering procedure, Perou et al. discovered that breast tumors could be subdivided in different subtypes based on the expression profile of a set of genes, i.e., the "intrinsic gene subset" [10]. The existence of breast cancer subtypes was then validated by other studies [11, 13] which confirmed at least four subtypes: the luminal A, luminal B, triple negative/basal, and HER2. Importantly, these subtypes display different metastatic behavior, from rather indolent tumors (luminal A) to very aggressive disease (basal/HER2) [11, 14]. Based on these discoveries, a prognostic model named "PAM50" was developed. PAM50 is a qRT-PCR /nCounter-based prognostic test [15, 16] which, by measuring the expression profile of a 50-gene signature, stratifies breast cancer patients in the four tumor molecular subtypes. PAM50 is used and commercialized as prognostic test to identify patients at high risk of recurrence (basal, luminal B, and HER2) who may be treated by adjuvant chemotherapy [17–19]. A similar prognostic test based on another gene expression signature is Oncotype DX [20]. Oncotype DX is a 21-gene qRT-PCR assay (16 cancer related and 5 used as reference) involved in cell proliferation, invasion, and signaling. Scientists developed an algorithm to calculate a "recurrence score" (RS) which combined gene expression data of the 16 cancer-related genes, weighted considering their expression correlation (calculated by hierarchical clustering and principal component analysis), to identify "who needs more than 5 years of tamoxifen among women diagnosed with axillary node-negative and estrogen receptor-positive breast cancer" [21]. This genomic test stratifies breast cancer patients in three main groups: patients at high risk of recurrence (treated by chemotherapy followed by hormonal therapy), low-risk patients (treated with hormonal therapy), and intermediate-risk patients. A recent study found that PAM50 and Oncotype DX test results are in partial agreement particularly in those patients classified as "intermediate-risk" patients [22]. Therefore, it would be mandatory a refinement of such genomic tests before their application in the clinical routine; indeed, no clinical decisions can be taken when a patient is classified as an "intermediate risk."

Beyond hierarchical clustering, several other gene-clustering methods were developed in the last years for gathering more insights in genomics data [23, 24]. A limit of these clustering algorithms is their trend to consider genes/proteins as independent entities, not taking into account that biological functions are the results of complex molecular interactions. Thus, a variety of bioinformatics tools and databases of biological information were shaped to join set of genes sharing similar functions and altered in a particular pathological condition. This is relevant when the research goal is not "merely" the identification of diagnostic/prognostic cancer biomarkers, but also the identification of molecular functions that are potentially druggable.

82.3 System Biology Approaches for the Inference of Gene Regulatory Networks

Recently, system biology approaches to *-omics* data were shown to be accurate enough to identify gene regulatory networks (GRN) that represent molecular mechanisms involved in human disease [25]. System biology is a research field focused on computational and mathematical modeling of complex biological systems. The current availability of large datasets of genomic information is bolstering the identification of complex interactions of genes/proteins using gene regulatory network inference (GRNi). In cancer research, the

application of GRNi using microarray expression datasets resulted in the discovery of mechanisms that explained the onset and progression of different tumors, including breast cancer [26]. This has led also to the identification of novel potential druggable targets [27]. Different mathematical and statistical methods were successfully applied to infer GRN from gene expression data [28–33]. All of these methods assume that gene/protein functional relationships are characterized by linear or nonlinear correlations in the experimental data. A linear correlation is observed when the ratio of change among variables is constant; conversely, a nonlinear correlation is observed when the ratio of change is not constant (Fig. 82.1a). Of course, the identification of nonlinear functional relationship is more difficult. Recently, bioinformatic tools for GRNi based on mutual information (MI) has been successfully applied in cancer research [30, 32]. MI captures nonlinear relationships between variables (genes) in addition to positive and negative linear correlations [32, 34, 35], by measuring the amount of information (i.e., entropy) gained about a random variable (gene X) when considering another random variable (gene Y). In the case of two independent genes, the expression profile of X does not give any information about the expression profile of Y, so MI is equal to zero. On the contrary, in the case of dependency of two genes, knowing the expression profile of X, it is possible to determine the expression profile of Y and vice versa (X is a deterministic function of Y; Y is a deterministic function of X); thus MI is equal to one. In another embodiment, the way a gene X is regulated in a particular condition has the same uncertainty (i.e., entropy) after gene Y is known. The first attempt to build GRN by using MI was pursued by Butte and Kohane [36]. Two genes were graphically linked using edges only if they have an MI score above a specified threshold. Statistical significance of MI scores is then calculated using permutation test [37]. A critical aspect in GRNi could be the case of indirect relationship among genes which is a frequent condition in molecular mechanisms (i.e., a signaling cascade). In the ARACNE algorithm, the problem of indirect interactions was elegantly tackled using the data processing inequality (DPI) measure [32]. The ARACNE algorithm starts assigning pairwise connections to genes according to the computed MI scores. Before assigning connections a threshold of significance of the computed MI score is established. Then, the algorithm compares all the possible triplets (gene X, gene Y, and gene Z) and removes the edge with the smallest MI value representing an indirect interaction (Fig. 82.1b). Using ARACNE, highly interconnected genes in GRNs, also called as "gene hubs," were proposed to function as master regulators of cancer-relevant signaling pathways (Fig. 82.1b) [38, 39]. Of note, NGS screening studies are adding additional information which could help to identify cancer driver genes within these GRNs and design novel molecularly targeted therapies.

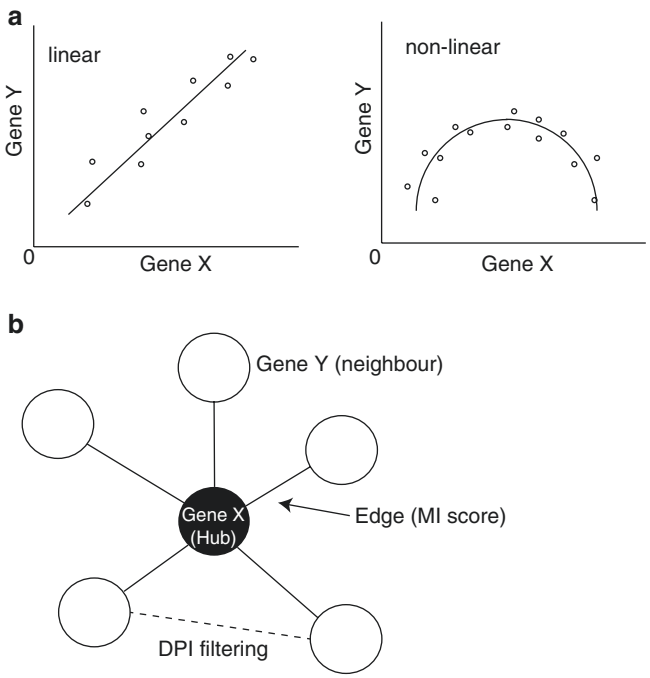

Fig. 82.1 Inference of gene regulatory networks (GRNi). (**a**) Examples of linear and nonlinear correlation between two genes. (**b**) A gene regulatory network

Conclusions

Besides the so-called inter-tumoral variability which characterizes the four breast cancer molecular subtypes, it is now evident that a high heterogeneity is present within the same tumor, i.e., the "intra-tumoral" variability. Navin et al. elegantly demonstrated by single-nucleus sequencing that in primary breast tumor there are distinct clonal subpopulations of cancer cells with different patterns of genomic alterations [40]. Importantly, only a fraction of cells in the primary tumor were found to be genetically similar to other cancer cells collected in metastatic sites [40]. Thus, a complete genomic characterization of all subpopulations of cancer cells will be mandatory to identify the entire repertoire of cancer driver mutations. In line with this, Gerlinger and De Bruin [41, 42] proposed genomic/bioinformatic protocols for the in-depth molecular characterization of distinct subpopulation of cells. In this scenario, bioinformatics and cancer genomics are becoming key elements for the success of personalized medicine.
