This book is dedicated to Umberto Veronesi, to his memory, and especially to his scientific and medical heritage.

Preface

The scientific and patient care communities have witnessed significant improvements in the diagnosis and treatment of breast cancer. Breast cancer is the leading cause of cancer morbidity and mortality in women worldwide. Screening, early diagnosis, and personalized treatments have provided better patient management, improved efficacy of therapies, and reduced mortality. Additional knowledge has been obtained by improving histopathological testing and conducting molecular and genetic investigations, which have also resulted in better therapies.

Progress in care of breast cancer patients has been achieved due to the clinical trials designed and conducted to demonstrate the efficacy and safety of therapies. This accumulation of evidence from randomized trials has resulted in a substantial improvement in patient care. Clinical trials can provide evidence indicating treatment efficacy but do not provide direct extrapolation on "how to treat the Individual Patient." The required intellectual step for extrapolation of useful details needed for adapting information from clinical trial results for the purpose of patient care is the multidisciplinary approach, a relatively novel methodology for discussion and negotiation involving several professional perspectives to define a common modality of diagnosis and treatment. With this spirit in mind, this book has been created, touching on all aspects of innovation in the care of patients with breast cancer. The editors and authors of each section and chapter are scholars in the field of breast cancer and are experts in conducting multidisciplinary discussions.

Professor Umberto Veronesi, who conceived the idea of this book to summarize modern developments in the diagnosis and treatment of breast cancer, was an internationally renowned innovator of diagnosis and all modalities of therapy for women with breast cancer. In the 1960s, he introduced the concepts that breast cancer is a disease with widespread extension of micrometastasis, and that the least extensive treatment (either surgical, radiation, or systemic) might suffice for obtaining the optimal therapeutic result. This approach involves specifically maintaining efficacy while reducing the burden of side effects of therapeutic and diagnostic interventions. Clinical research was conducted by him and others to intensively investigate this personalized approach for women with the disease. Areas of these clinical trial investigations included use of quadrantectomy instead of mastectomy, partial intraoperative radiation therapy instead of whole breast irradiation, sentinel node biopsy instead of full axillary dissection, and assigning systemic therapies according to features that predict responsiveness to different treatments instead of using the "same therapy for all" approach. His dedication to prevention was also methodologically remarkable, from pioneering work in early diagnosis to investigating chemoprevention in clinical trials. This book is a comprehensive presentation of breast cancer research and treatment, describing past and present information and including thoughts about the future.

Professor Umberto Veronesi passed away on November 8, 2016. Although he did not survive to see the book's birth, he was intensively involved in the editing until the last days of his life. He remained an example for all of us, insisting that the work should go on. This book is dedicated to him, to his memory, and especially to his scientific and medical heritage.

Special appreciation is extended by all editors and authors to Mrs. Lucia Racca, the backbone of Professor Veronesi's office for many years, who maintained the coordination of the editorial office until the completion of the work, well beyond her retirement.

This book is an important resource covering all aspects of breast cancer carcinogenesis, prevention, diagnosis, and surgical, radiation, and systemic therapies. It is particularly suited for those who seek exposure to a broad spectrum of knowledge of a multidisciplinary approach to understand the disease and facilitate optimal patient care.

Fundamental Pathways in Breast Cancer 1: Signaling from the Membrane

1

Yekaterina Poloz, Ryan J.O. Dowling, and Vuk Stambolic

1.1 Introduction

Breast cancer (BC) is the most frequently diagnosed cancer in women worldwide, with 1.7 million new cases diagnosed in 2012 [1]. In the United States alone, 231,840 new cases and 40,290 related deaths are expected to be seen in 2015 [2]. This heterogeneous disease is classified into several molecular subtypes, depending on the presence of specific cell surface receptors, including the estrogen receptor (ER), the progesterone receptor (PR), and the human epidermal growth factor 2 receptor (HER2) [3]. Luminal A BCs are ER^+ and/or PR^+ but $HER2^-$. These are the most commonly seen BCs and have the best prognosis. Luminal B BCs are ER^+ and/or PR^+ and sometimes $HER2^+$. These tumors have a higher proliferative index and are more aggressive. $HER2^+$ BCs are ER^- and PR^- but $HER2^+$. This subtype usually presents at a younger age with a poorer tumor grade and lymph node involvement, but the prognosis has improved dramatically since the clinical implementation of Herceptin, an anti-HER2 antibody. About 20% of BCs are triple negative (TNBC) or basal-like, that is, they are ER^-, PR^-, and $HER2^-$. These tumors are often aggressive, have poorer prognosis, and lack any targeted therapies.

Research has focused extensively on the role of cell surface receptors like HER2 in the pathobiology of BC. There are numerous families of cell surface receptors, like receptor tyrosine kinases (RTKs), one example being HER2, and G protein-coupled receptors, that sense extracellular cues and transmit them into intracellular messages that regulate cell growth, proliferation, survival, migration, and differentiation. These receptors are often deregulated in BC and lead to tumor growth and metastasis. This chapter will focus on the identification of the receptors most often deregulated in BC, the common signaling pathways they activate, and the crosstalk that links them to one another.

1.2 RTKs and Their Downstream Signaling Targets

RTKs are cell surface receptors found on a diversity of cell types. All RTKs comprise an N-terminal extracellular ligand-binding domain, a single-pass transmembrane domain, and a C-terminal tyrosine kinase domain. Ligand binding induces a conformational change leading to the receptor homo- or heterodimerization and the consequent autophosphorylation of a series of tyrosine residues in the C-terminal tail. The phosphorylated tyrosines then act as docking sites for the SRC homology 2 (SH2) and phosphotyrosine-binding (PTB) domain-containing proteins, many of which are shared by the different RTKs. The RTK signaling program converges on the two major signaling pathways, namely, the phosphoinositide 3-kinase-protein kinase B/AKT (PI3K-PKB/AKT) and the rat sarcoma-mitogen-activated protein kinase/ERK (Ras-MAPK/ERK), that go on to regulate critical cellular processes like cell growth, proliferation, differentiation, migration, and apoptosis (Fig. 1.1).

One of the SH2 domain-containing effectors of RTKs is the regulatory subunit of the class I PI3K (p85), which when bound to the activated RTK or one of its tyrosine phosphorylated adaptors relieves its inhibition of the p110 catalytic subunit of PI3K, thereby leading to its activation [4]. PI3K p110 then phosphorylates a resident membrane lipid, phosphatidylinositol 4,5-bisphosphate (PIP2), to generate phosphatidylinositol 3,4,5-trisphosphate (PIP3), a major lipid

second messenger [5]. The phosphatase and tensin homolog deleted on chromosome 10 (PTEN) counteracts the action of PI3K and converts PIP3 back to PIP2 [6, 7]. PIP3 recruits the pleckstrin homology (PH) domain-containing proteins to the membrane, of which there are more than 250 in the human genome, including AKT and the 3-phosphoinositide-dependent protein kinase 1 (PDK1) [8]. AKT is phosphorylated by PDK1 on threonine 308 (T^{308}) and consequently by the mammalian target of rapamycin complex 2 (mTORC2) on serine 473 (S^{473}), leading to its full activation [9, 10]. AKT then activates the mammalian target of rapamycin complex 1 (mTORC1) through two distinct pathways. AKT phosphorylates and suppresses the GTPase-activating protein (GAP) activity of the tuberous sclerosis complex 2 (TSC2) toward the Ras homolog enriched in the brain (Rheb) [11–13]. On the other hand, AKT phosphorylates and inhibits proline-rich AKT substrate of 40 KDa (PRAS40), which is implicated in the regulation of mTORC1 [14, 15]. mTORC1 regulates cell growth by controlling mRNA translation, via direct phosphorylation of the S6 kinase (p70S6K) and the 4E binding proteins (4EBPs) [16, 17]. AKT also phosphorylates the forkhead box O transcription factors (FOXOs), which results in their nuclear exclusion and proteasomal degradation, thus releasing cells from the FOXO-mediated cell cycle arrest [18–20]. The deactivation of FOXO, along with another target of AKT, the B-cell lymphoma 2 (BCL2)-associated agonist of cell death (BAD), coordinately represses apoptosis [21]. Finally, the AKT-mediated inhibition of glycogen synthase kinase 3 (GSK3) inhibits nuclear export and proteasomal degradation of cyclin D1, thus leading to its nuclear accumulation and induction of cell proliferation [22]. Thus, the PI3K-AKT pathway mainly regulates the cellular growth, proliferation, and survival programs in cells. Other than RTK deregulation, activating mutations in PI3K or deletion of PTEN is often found in BCs and further drives the oncogenic program in cells [23].

The Ras-ERK pathway is the other major signaling network that is modulated by the RTKs. The Src homology 2 domain-containing (SHC) and the growth factor receptor bound 2 (GRB2) are the main adaptor proteins that link the activated RTKs to the Ras-ERK pathway [24]. The RTKs interact with and activate SHC directly, which then recruits GRB2 to the cell membrane. Alternatively, GRB2 can also interact with RTKs directly or through another adaptor protein, like one of the insulin receptor substrates (IRSs) [25, 26]. GRB2 associates with the son of sevenless (SOS), which then recruits and activates Ras, by acting as a guanine nucleotide exchange factor (GEF), converting the GDP-bound Ras into the active GTP-bound form [27]. In a sequential manner, Ras activates Raf, which phosphorylates and activates MEK, which in turn phosphorylates and activates ERK [28, 29]. ERK is a serine-threonine kinase that has hundreds of cytoplasmic and nuclear targets. For example, ERK translocate to the nucleus and activates transcription factors like Ets-like gene 1 (Elk1) and c-Myc [30, 31]. In the nucleus, ERK also activates the mitogen- and stress-activated protein kinases (MSKs), which activate transcription factors like the cyclic AMP-responsive element-binding protein (CREB) and the activating transcription factor 1 (ATF1) [32]. In the cytoplasm, ERK phosphorylates the p90 ribosomal S6 kinases (RSKs), which inhibit apoptosis by phosphorylating BAD, but also translocate to the nucleus and activate transcription factors like CREB and c-Fos [33–36]. ERK-mediated phosphorylation of the MAPK-interacting kinases (MNKs) induces mRNA translation through phosphorylation of the eukaryotic initiation factor 4E (eIF4E) [37, 38]. The Ras-ERK pathway thus controls diverse cellular processes including cell growth, proliferation, differentiation, migration, and apoptosis.

In addition to the parallel activation immediately downstream of the receptors, coordination between the PI3K-AKT and the Ras-ERK signaling pathways can also be achieved by the interaction of activated Ras with the PI3K p110 catalytic subunit, independently of p85, leading to the PI3K-AKT pathway activation (Fig. 1.2) [39]. Like AKT, ERK and RSK can also phosphorylate and inhibit TSC2, leading to mTORC1 activation [40, 41]. The two pathways are also subject to the multiple levels of feedback inhibition. MEK promotes the membrane localization of PTEN, which downregulates the PI3K-AKT signaling pathway, while AKT can phosphorylate and inhibit Raf [42–44]. Furthermore, mTORC1, S6K, and ERK can downregulate both pathways by phosphorylating RTK substrates, like IRS1, on multiple inhibitory serine residues [45–47]. Thus, multiple feedback loops and crosstalk between the PI3K-AKT and the Ras-ERK pathways orchestrate the dynamic and intricate, context-dependent effects of multiple growth factors through their cognate RTKs.

1.3 RTKs Often Deregulated in BC

The deregulation of RTK signaling plays an important role in the pathophysiology of many cancers, including BC [48]. Several mechanisms lead to the deregulation of RTK signaling, including RTK gene amplifications, activating mutations, protein overexpression, ligand overexpression or hyperactivation, and crosstalk with other cellular signaling components. Members of the ERBB family, MET, the insulin receptor (INSR), and the insulin-like growth factor receptor (IGF1R) are RTKs that are most often deregulated in BC.

1.3.1 HER2

The amplification of the *HER2* gene, a member of the ERBB family of RTKs, is seen in approximately 20% of BCs, and HER2 overexpression correlates with a worse BC prognosis [49–51]. In these patients, HER2 overexpression correlates with tumor size, grade, proliferative index, aneuploidy, lack of steroid hormone receptors, and metastatic disease. HER2 (also named ERBB2 or NEU), belongs to the ERBB family, with three additional members: the epidermal growth factor receptor (EGFR, also named ERBB1), ERBB3, and ERBB4, all of which have been shown to be overexpressed and/or hyperactivated in BC to varying degrees. For example, EGFR is often overexpressed in basal-like TNBC [52].

There are 11 ligands that activate this family of RTKs, and they can be subdivided into three groups [53]. The first includes the epidermal growth factor (EGF), the transforming growth factor α (TGFα), and amphiregulin, which bind specifically to EGFR. The second includes betacellulin, heparin-binding EGF (HB-EGF), and epiregulin, which bind EGFR and ERBB4. Neuregulins (NRGs) make up the third group of ligands and are further subdivided into two subgroups, based on the ability to activate ERBB3 and ERBB4 (NRG1 and NRG2) or ERBB4 alone (NRG3 and NRG4). All ligands exist as membrane-anchored precursors, often co-expressed and even overexpressed with the ERBBs in the same cancer cells. Metalloproteases, mainly of the a disintegrin and metalloprotease (ADAM) family, cleave the precursors, leading to ectodomain shedding and activation of ERBB signaling in an autocrine or paracrine fashion [54].

Like other prototypical RTKs, all ERBBs can form functional homo- or heterodimers, with the exception of HER2, which does not appear to bind a ligand, and ERBB3, which is impaired in the intrinsic kinase activity and thus cannot form functional homodimers [55, 56]. Though HER2 is not self-autonomous, its extracellular domain conformation mimics that of the ligand-bound receptor, thus allowing HER2 to form functional heterodimers with other ERBBs [57]. HER2 is in fact the preferred binding partner of other ERBBs, and intriguingly the HER2-ERBB3 heterodimer is the most mitogenic and transforming of all the receptor combinations [58–61]. The C terminus of each of the ERBBs is unique (11–25% identity) and is able to bind to a diversity of intracellular targets. All of the ERBB members activate the Ras-ERK signaling pathway by directly interacting with the adaptor proteins SHC and GRB2 [62]. The regulatory subunit of PI3K (p85) directly interacts with ERBB3 and ERBB4. ERBB3 has the most [6] binding sites for p85, while EGFR and HER2 lack them all together, thus the HER2-ERBB3 heterodimer is the most potent activator of the PI3K-AKT signaling pathway, promoting cell growth, proliferation, and survival [63, 64]. Alternatively, ERBBs can activate the PI3K pathway through Ras. Together with the multitude of ligands, the different combinations of receptor dimers, and the unique C-terminal tails, this family of RTKs is capable of regulating diverse cellular processes implicated in cell growth, proliferation, differentiation, migration, and apoptosis.

1.3.2 MET

The hepatocyte growth factor receptor or MET is another RTK that is overexpressed in about 20% of BCs, particularly in the basal-like TNBCs [65]. Hepatocyte growth factor (HGF) is the only known ligand of MET, and it is often co-expressed with its receptor in the same tumor cells, particularly in the leading edge of the tumor [66, 67]. The expression of both, the receptor and the ligand, correlates with tumor grade, proliferative index, metastatic disease, and poor prognosis [68–74]. The HGF-mediated activation of MET leads to activation of the Ras-ERK pathway through the direct interaction of SHC and GRB2 with the receptor or through the recruitment of an insulin-like substrate (IRS)-like adaptor, the GRB2-associated-binding protein 1 (GAB1). The p85 regulatory subunit of PI3K also interacts with MET directly or through GAB1 and leads to activation of the PI3K-AKT pathway [75].

1.3.3 INSR

The INSR is overexpressed in as many as 80% of BCs and is associated with poor survival [76, 77]. The INSR is encoded by a gene composed of 22 exons found on chromosome 19. From this single gene, two receptor isoforms, INSR-A and INSR-B, are expressed as a result of alternative splicing. These two isoforms differ in inclusion/exclusion of exon 11, a 36 bp region encoding a 12 amino acid peptide located at the C-terminal end of the INSR alpha subunit [78]. INSR-B represents the full-length isoform and is expressed in insulin-responsive tissues including the liver, muscle, and adipose tissue. Conversely, INSR-A is expressed from the spliced transcript that lacks exon 11 and plays a significant role in fetal development by regulating cell growth and proliferation [79, 80]. The INSR-A and INSR-B isoforms display unique ligand specificity and downstream signaling potential. INSR-A exhibits an almost twofold higher affinity for insulin as compared to INSR-B and has a much stronger affinity for the insulin-like growth factor II (IGFII) [81–83]. INSR-A is the prevailing isoform overexpressed in both BC cells in culture and patient tumors [77, 84]. Therefore, increased INSR-A expression may negatively impact BC development, particularly in the context of hyperinsulinemia, as in the cases of diabetes or obesity. Indeed, hyperinsulinemia is an adverse prognostic factor in BC that is associated with increased risk of recurrence or death [85]. INSR-A expression is also elevated beyond that of the related IGF1R in some BCs suggesting INSR-A plays a role in mediating the growth-promoting effects of IGF-II in breast tumorigenesis [84, 86].

On the cell surface, the INSR exists as a heterotetrameric protein comprised of two extracellular alpha subunits and two transmembrane beta subunits. The beta subunit of the receptor possesses tyrosine kinase activity, which is stimulated upon binding of the ligand to the alpha subunit [87, 88]. Upon activation, INSR phosphorylates a number of substrates including IRS1–4, SHC, and GAB1 [89]. IRSs and GAB1 recruit the p85 regulatory subunit of PI3K, leading to

the PI3K-AKT pathway activation. The Ras-ERK pathway is activated by the recruitment of GRB2-SOS complex by SHC or IRSs [26, 90]. INSR-B regulates the metabolic effects of insulin mainly through the PI3K-AKT pathway, while INSR-A activates the mitogenic program through both, the Ras-ERK and the PI3K-AKT pathways [91, 92]. Consequently, inhibition of INSR-A is actively being explored as a therapeutic option in breast and other cancers with clinical trials focusing on testing small molecule inhibitors and monoclonal antibodies directed against key components of these signaling networks [93]. Systemic modification of receptor ligands represents another strategy for targeting INSR signaling in cancer. For example, reduction in circulating insulin levels via administration of the antidiabetic drug metformin is being explored as a treatment option for cancers associated with obesity and hyperinsulinemia, especially BC. Indeed, administration of metformin to early-stage, nondiabetic BC patients led to reductions in circulating insulin and cancer cell proliferation, as well as suppressed INSR activity as indicated by reductions in AKT and ERK signaling [94].

1.3.4 IGF1R

Close to 50% of human breast tumors express the activated form of IGF1R, and gene expression signatures consistent with IGF1R activation are associated with poor outcome in BC patients [95, 96]. The IGF1R is homologous to the INSR but exhibits preferential binding to IGFI and IGFII over insulin. It is also a heterotetrameric protein complex consisting of two extraceulluar alpha subunits and two transmembrane beta subunits but plays a more significant role in the regulation of mitogenic signaling. The IGF1R shares numerous binding partners and effector proteins with the INSR, including IRSs and SHC adaptors, and is known to stimulate cell growth and proliferation via activation of the PI3K-AKT and Ras-ERK signaling pathways [93, 97]. A second IGF receptor, namely, IGF2R, is also commonly expressed by numerous cells; however, it lacks catalytic activity and is not involved in intracellular signaling [98]. Instead, IGF2R exhibits a high affinity for IGFII and is thought to sequester the growth factor from stimulating IGF1R [97, 99]. As a result, IGF2R may exhibit tumor suppressor properties by decreasing the bioactivity of IGFII and indirectly modulating signaling by IGF1R.

Due to their homology and strong structural similarities, the INSR and IGF1R have the ability to form hybrid receptors composed of one hemireceptor of each type. In addition, the two INSR isoforms can also combine to form hybrids, generating the potential for multiple insulin and IGF-sensitive receptors (INSR-A, INSR-B, INSR-A/B, IGF1R, INSR/IGF1R) to be expressed by a single cell. Hybrid receptors appear to bind IGFI with a higher affinity than insulin, and they exhibit different ligand specificities depending on the INSR isoform present. For example, INSR-A/IGF1R hybrids bind IGFI, IGFII, and insulin, while INSR-B/IGF1R hybrids typically bind IGF1 [91]. Since cancer cells frequently express high levels of both INSR and IGF1R, it is not surprising that they also overexpress hybrid receptors. Indeed, human breast tumors express high levels of hybrid receptors, and most of the effects of IGF1 are believed to be mediated by INSR-A/IGF1R hybrids. Furthermore, BC cells are known to secrete IGFII, creating the potential for autocrine stimulation of tumor cell growth and proliferation via activation of INSR-A, IGF1R, and INSR/IGF1R hybrid receptors [84, 100]. Consequently, human BC cells are highly sensitive to the growth-promoting effects of insulin and IGFs, and INSR/IGF1R expression may be a key event in tumor development and growth.

1.4 GPCRs and Their Downstream Signaling Targets

The G protein-coupled receptors (GPCRs) are the largest group of cell surface receptors that regulate cell motility, growth, proliferation, differentiation, and survival. The discovery of the Mas oncogene, a GPCR, in 1986 provided the first direct link between GPCRs and their role in cellular transformation [101]. Since then, many GPCRs where shown to be overexpressed or mutated in a diversity of cancers, including BC.

GPCRs are seven-pass transmembrane domain-containing receptors with an intracellular C-terminal tail that interacts with the heterotrimeric G proteins [102]. Upon ligand binding, the receptor undergoes a conformational change that allows it to act as a GEF, converting the GDP-bound G protein α subunit to the GTP-bound, active form. This causes the G protein α subunit to dissociate from the βγ subunits, initiating a multitude of signaling cascades. There are numerous G protein subtypes, each with unique signaling abilities. For example, the $G\alpha_{12/13}$ activates several Rho GEFs leading to activation of Rho, a small GTPase that regulates cytoskeletal dynamics and cell motility, largely implicated in cancer metastasis. $G\alpha_{q/11}$ activates the phospholipase C beta (PLCβ), which initiates the calcium and diacylglycerol (DAG) signaling cascades that regulate cell motility, proliferation, and gene expression. The GPCR signaling also crosstalks to the PI3K-AKT and the RAS-ERK pathways. The DAG-activated protein kinase C (PKC) phosphorylates and activates Raf, thereby leading to the activation of ERK [103]. The Gβγ subunits bind directly to PI3Kγ and activate the PI3K-AKT signaling pathway [104].

1.5 GPCRs Often Deregulated in BC

1.5.1 PAR1

The protease activated receptor 1 (PAR1) is a GPCR that is overexpressed in TNBC and correlates with metastatic disease and poor prognosis [105, 106]. The zinc-dependent matrix metalloprotease 1 (MMP1), thrombin, and other proteases cleave the extracellular domain of PAR1 exposing a new N terminus that binds to and activates the receptor [107, 108]. PAR1 then couples to multiple G proteins ($G\alpha_{q/11}$, $G\alpha_{i/o}$, $G\alpha_{12/13}$) to regulate cell migration and proliferation, in part through the activation of Rho and ERK, respectively. PAR1 has been shown to be required and sufficient for the regulation of growth and invasion of BC cells in a mouse xenograft model [107, 109].

1.5.2 GPR161

The GPR161 is another GPCR that is overexpressed in TNBC and correlates with cancer relapse [110]. Overexpression of GPR161 in mammary epithelial cells transforms them via a yet unidentified mTORC1-dependent signaling pathway [110].

1.5.3 Wnt

The Wnt signaling pathway is hyperactivated in basal-like BCs and correlates with poor survival [111, 112]. The canonical Wnt signaling pathway results in nuclear accumulation of β-catenin, where it acts as a transcriptional coactivator for the T-cell factor/lymphoid enhancer factor (TCF/LEF) family of transcription factors [113]. In the absence of the Wnt signal, β-catenin is sequestered in the cytoplasm by a destruction complex, containing GSK3β, which targets β-catenin for proteasomal degradation. Frizzled (FZD) is the GPCR for the Wnt family of ligands. When FZD is activated by the Wnt ligand, it acts together with the co-receptors, the low-density lipoprotein receptor-related protein 5 and 6 (LRP5/6), to disrupt the β-catenin destruction complex. This allows β-catenin to accumulate in the cytoplasm and translocate to the nucleus to activate its transcriptional program. The knockdown of FZD7 in TNBC cell lines reduces expression of β-catenin target genes, the transformation of these cells *in vitro*, and their ability to form tumors *in vivo* [114]. In addition, more than 40% of invasive breast tumors have a hypermethylation of the promoter, and therefore a strong downregulation of expression of the secreted frizzled-related proteins (sFRPs), the negative regulators of the Wnt signaling pathway [115, 116].

1.6 Crosstalk Between RTKs and GPCRs

The RTKs crosstalk with each other through multiple feedback and transactivation mechanisms. For example, MET can interact with and be transactivated by ERBBs, thus synergizing in the regulation of the downstream pathway components [117, 118]. Furthermore, RTK signaling often parallels or synergizes with GPCR signaling. The GPCRs can be upstream or downstream of the RTKs, and GPCRs are under the transcriptional regulation of RTKs and vice versa [119]. Furthermore, GPCRs and RTKs can transactivate each other. For example, GPCR activation regulates ectodomain shedding of the ERBB ligands. The PAR1 and the Wnt pathway have been shown to transactivate EGFR and HER2 in this manner [120–123]. Thus, GPCRs can activate the PI3K-AKT and the Ras-ERK pathways directly or through transactivation of the RTKs. In addition, EGFR-mediated activation of ERK induces nuclear translocation of the pyruvate kinase (PKM), which regulates β-catenin transcriptional activity [124]. The expression of β-catenin target genes can further be induced through the AKT- or RSK-dependent inhibition of GSK3β or the direct phosphorylation of β-catenin by AKT [125–127].

1.7 Other Receptors Deregulated in BC

The tumor microenvironment is a complex milieu of cell surface and secreted factors that affect BC development and progression. Tumor-associated fibroblasts (TAFs), endothelial cells, and inflammatory cells comprise the majority of the tumor microenvironment and express factors that affect tumor progression. Tumor cells express a number of non-RTK and/or non-GPCR receptors, the discussion of which is beyond the scope of this chapter, that sense signals from the microenvironment and often integrate them into the common pathways described above. For example, plexins, the receptors of semaphorins, originally described for their role in axon guidance, have now been implicated in BC metastasis, in part due to their ability to be transactivated by HER2 and MET and to activate Rho signaling [128, 129]. Tumor cells also express a number of cytokine receptors that interpret the pro-inflammatory signaling from leukocytes, tumor-associated macrophages (TAMs), TAFs, and autocrine loops. Cytokine receptors can activate several pro-survival and proliferation pathways but can also transactivate RTKs [130]. Lastly, integrins and cadherins, the cell adhesion mediators, are often deregulated in metastatic BC and play a central role in the epithelial-to-mesenchymal transition as well as in the activation of oncogenic signaling. Integrins can feed into both the PI3K-AKT and the Ras-ERK signaling pathways [131, 132]. Integrins also regulate ERBB expression at the mRNA translation level, as well as interact directly with

ERBBs and regulate their tyrosine kinase activity [133, 134]. Further insight into the complexity of these intracellular crosstalk networks will aid in the identification of effective therapeutic targets and the mechanisms of therapeutic resistance.

1.8 Outlook

BC is one of the most common cancers worldwide and the second leading cause of cancer-related death in women [135]. It is a heterogeneous disease with a complex molecular etiology. A great deal of research has focused on the mechanisms underlying BC development, growth, and progression. Dysregulated RTK signaling has been identified as a critical event in breast tumorigenesis. For example, HER2 and IR are overexpressed by 20 and 80% of BCs respectively, and mutation of PI3K, a key mediator of RTK signaling, is mutated in 35% of human breast tumors [77, 135, 136]. Identification of such oncogenic proteins has led to a deeper understanding of BC and allowed for the development of targeted therapies for the treatment of this disease. Nevertheless, additional research is required to characterize mechanisms of tumor initiation as well as therapeutic resistance. Indeed, crosstalk between different RTK pathways and the existence of signaling feedback mechanisms are poorly understood processes that play critical roles in BC development and resistance to therapy. In the future, fundamental studies focusing on these issues *in vitro* should be combined with clinical research and early phase clinical trials to further characterize the role of RTKs in BC and identify new targets for anticancer therapies.

Fundamental Pathways in Breast Cancer 2: Maintenance of Genomic Stability

2

Chiara Gorrini and Tak W. Mak

2.1 Introduction

Mammalian cells preserve their genomic integrity by counteracting DNA damage [1]. DNA damage can originate from exogenous and endogenous insults. Exogenous insults involve environmental stress that originates from exposure to chemicals, UV light, tobacco smoke, chemotherapy, and radiotherapy. Endogenous DNA damage can arise from impaired DNA metabolic processes, intracellular oxidative stress, and oncogene activation. Cells respond to DNA damage by activating sensors, transducers, and effectors that jointly coordinate the so-called DNA damage response (DDR). When the amount of DNA damage is manageable, DDR activates cell cycle checkpoints that arrest cell cycle progression and allow DNA repair to correct the lesion thus preventing replication of damaged DNA. When DNA damage reaches levels beyond repair, cells activate self-destruction mechanisms that include apoptosis, autophagy, senescence, and necrosis.

There are five different mechanisms of repair designed for specific types of DNA lesions [2]:

- Base excision repair (BER) removes base damage. BER is mainly involved in the surveillance, recognition, and repair of oxidative DNA.
- Mismatch repair (MMR) corrects replicative errors and mismatched base pairs caused by faulty proofreading of DNA polymerases. MMR ensures low mutation rates in replicating cells.
- Nucleotide excision repair (NER) operates on a spectrum of helix-destabilizing bulky DNA lesions (global genome NER or GG-NER) or eliminates lesions in the transcribed strand of active genes (transcription-coupled NER or TC-NER). For example, NER removes bulky DNA adducts caused by exposure to various chemicals, alkylating agents, and UV radiation.
- Single-strand break (SSB) DNA repair corrects DNA breaks on one strand of the DNA double helix arising directly on the deoxyribose moieties or indirectly as intermediates of BER. SSBs are among the most frequent DNA lesions and are major threats to genetic stability and cell survival.
- Double-strand break (DSB) DNA repair resolves lesions that appear on both DNA strands. The DSB is the principle lesion deriving from ionizing radiation and radiomimetic chemicals. It is also caused when a replicative DNA polymerase encounters a DNA single-strand break or other type of DNA lesions. DSBs are intermediates in various biological events, such as V(D)J recombination in differentiating B cells. There are two major pathways of DSB repair: homologous recombination (HR) and nonhomologous end joining (NHEJ). During HR, the repair of the damaged strand occurs by retrieving genetic information from the undamaged complementary DNA sister strand. In contrast, NHEJ brings about the ligation of two DNA DSBs without the requirement for sequence homology between the DNA ends.

Although these mechanisms are tightly regulated, DNA repair defects occur thereby promoting the acquisition of mutations. Genomic instability results from a high frequency of DNA mutations ranging from nucleotide changes to chromosomal translocation, and it is a common feature of many cancers. De novo genetic alterations can initiate tumorigenesis, augment aggressiveness, and ultimately affect the overall prognosis of cancer patients. Recent studies have shown that different tumors have specific DNA repair defect signatures that involve more than one repair pathway [3]. A more comprehensive analysis of these signatures has shown that DNA repair mechanisms are not parallel distinct entities but are intimately interconnected and can influence each other. While a normal cell coordinates DNA repair to preserve its genomic integrity, cancer cells modify DNA repair hubs to

maintain genomic instability without compromising survival. In fact, cancer cells are subjected to many stressful conditions including nutrient starvation, oxidative stress, hypoxia, chemotherapy, and radiation that ultimately result in genotoxic damage. Therefore, a cancer cell must rely on a certain level of functional DNA repair to cope with these additional sources of damage.

Regulation of DDR and DNA repair has a critical role in the development and treatment of breast cancer. Expression and genomic profiling studies have shown that breast cancer is a very heterogeneous disease [4]. There are different subtypes of breast cancers, and each type exhibits a range of biological and clinical behaviors (discussed more in detail in Chap. 1.4). Luminal subtypes A and B both express markers of the luminal epithelial layer of normal breast tissue such as keratins 8/18 and are estrogen receptor (ER) positive. The ERBB2 subtype is characterized by the amplification and overexpression of ERBB2 (HER2) and neighboring genes at 17q12-q21 locus. The basal-like subtype expresses markers of the basal epithelial layer of normal breast tissue such as keratins 5/6. Cancer cells of this subtype do not express ER, progesterone receptor (PR), and HER2 and are therefore referred to as triple negative (TN). Other TN types include "normal-like" and the recently described "claudin-low" subtype, showing that most but not all TN are basal-like cancers. There are two main hypotheses that can explain the existence of different subtypes: (1) each subtype arises from a distinct tumor-initiating cell and (2) all subtypes share a common cell of origin that eventually acquired different somatic DNA mutations leading to different biological phenotypes. Although a definitive answer is lacking and both phenomena can coexist, it is clear that breast cancer subtypes are the results of distinct evolutionary processes. The genomic profile of breast cancers spans from a relatively simple landscape in luminal A subtype to a highly complex scenario in basal-like/TN subtype (Fig. 2.1). In this chapter, we will consider the role of genomic instability underlying the different biological and clinical features of each breast cancer subtype.

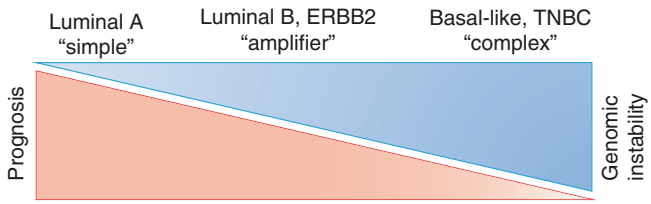

Fig. 2.1 Correlation between tumor aggressiveness and genomic instability in the different subtypes of breast cancer. Luminal A subtype tends to have good prognosis and a "simple" genomic landscape with few genetic alterations. Luminal B and ERBB2 subtypes have an "amplifier" genome with high frequency of gene duplications. As a consequence, their prognosis is less favorable than luminal A. Basal-like and TN breast cancers have a highly unstable "complex" genomic profile and have very poor prognosis

2.2 Genomic Instability in Luminal A/B Subtypes of Breast Cancers

Luminal A and B subtypes share similar biological characteristics. However, luminal B tumors are more genetically unstable and highly proliferative and have less favorable prognosis. Luminal A subtype tumors have few chromosome rearrangements that define a "simple" genomic landscape. The main feature of this pattern is gain of chromosome 1p and 16p with loss of 16q [5]. Luminal B subtype has a different pattern of genomic alterations called "amplifier" or "firestorm." This pattern is characterized by focal high-level DNA amplifications, clustered on one or more chromosome arm [6]. Most of luminal B DNA rearrangements affect the expression of genes involved in signaling, cell cycle regulation, and nucleic acid metabolism such as FGFR1, MYC, CCND1, MDM2, ERBB2, and ZNF217. In these tumor cells, the amplified DNA can exist either as repeated units within chromosomes called homogeneously staining regions (HSRs) or as extrachromosomal copies called "double minutes."

Several studies have demonstrated the presence of genomic instability in luminal A/B cancers. Cyclin D1, one of the most amplified genes in luminal B cancer, contributes to tumor progression by activating a transcriptional program that promotes chromosomal instability (CIN) [7]. The analysis of a large dataset of human specimen has shown that 52% of luminal A/B tumors overexpress the gene ESPL1 that encodes for a separase, a protease that cleaves the chromosomal cohesin during mitosis [8]. Indeed, overexpression of ESPL1 in the mouse mammary gland induces chromosomal instability and aneuploidy [9]. Genomic data from over 1000 luminal A tumors has identified four major subtypes defined by distinct copy number and mutation profiles. Among these types, this group has characterized an atypical luminal A subtype characterized by higher genomic instability, TP53 mutations, and increased aurora kinase signaling associated with worse clinical prognosis [5]. Moreover, a recent study has shown that in early-stage luminal breast carcinoma, genomic instability, defined as a high number of chromosomal breakpoints, is a stronger prognostic marker than proliferation [10].

Overall, these studies suggest that genomic complexity is a feature of luminal breast cancer and can be used to predict the outcome of these tumors.

2.3 Genomic Instability in ERBB2 Subtype of Breast Cancers

ERBB2 tumor subtype has a genomic landscape that is similar to luminal B subtype. It is characterized by an "amplifier" genomic pattern with focal high-level DNA amplifications [6]. However, different from luminal B subtype, amplification

of 17q12 (ERBB2) is the most prominent amplification event in ERBB2 subtype. The amplification of ERBB2 gene seems to derive from a sister chromatid breakage-fusion-bridge process based on the analysis of an ERBB2-amplified breast cancer line [11].

Several studies have revealed a direct link between ERBB2 oncogene and factors involved in the maintenance of genomic integrity. For example, the analysis of a collection of ERBB2-positive breast cancer cells suggests the presence of centrosome amplification with increased protein expression of the centrosome kinases Nek2 and Plk4 [12]. Also, expression of ERBB2 in immortalized breast epithelial cells downregulates the DNA damage sensor protein histone H2AX and a number of other components of the HR and NHEJ double-strand DNA break repair pathways [13]. Overall, these preclinical models indicate a role for ERBB2 signaling in initiating CIN and defective cell cycle control.

2.4 Genomic Instability in Basal-Like and Triple Negative Subtypes of Breast Cancers

Basal-like and triple negative (TN) breast cancers have an extremely complex genomic pattern. Their genome includes numerous gains, losses, and small tandem duplications resulting in a highly segmented profile with many copy number transitions. In this landscape a prominent place is occupied by the tumor suppressor BRCA1. The gene BRCA1 is one of the most important DNA repair factors and controls HR-directed DNA repair [14]. Strong similarities exist between breast cancers bearing BRCA1 mutation and sporadic basal-like breast cancers, underlying the inherently genomic instability of this particular cancer subtype.

Germline mutations that inactivate BRCA1 predispose women to breast cancers with basal-like/TN features [15]. In these tumors, dysfunction of HR repair leads to increased error-prone repair, which results in chromosome rearrangements and copy number transitions. Although BRCA1 is mainly known for its role in DNA repair, it has several other biological functions that contribute to tumor predisposition. BRCA1 controls breast epithelial differentiation, regulating the differentiation of ER-negative breast epithelial stem cells into ER-positive luminal progenitors [16]. This study has opened a debate on the cell of origin of BRCA1-associated breast cancers. For example, the breast tissue of women carrying BRCA1 mutations are characterized by abnormal accumulation of luminal progenitors, supporting the idea that basal-like tumors may originate from a cancer-initiating cell with luminal features [17]. Indeed, deletion of BRCA1 in mouse mammary epithelial luminal progenitors produces tumors that phenocopy human BRCA1 breast cancers [18].

Recently, we identified BRCA1 as a novel regulator of cellular antioxidant response [19]. In this study, cells carrying BRCA1 loss-of-function mutations accumulate oxidative stress that affects survival. This is counteracted by the activation of one of the most important pro-survival programs in the cells, the PI3K pathway (see Chap. 1.1 for details), and controlled by estrogen that restores antioxidant defense and promotes survival and malignant transformation [20]. These data clarified the role of estrogen in BRCA1/TNBC as suggested by other mouse and human studies [21, 22].

BRCA1 is not the only DNA repair factor associated with basal-like breast cancers. Other proteins involved in DDR and DNA repair have been identified. These factors are transducers (ATM and ATR) or effectors (Chk2) of DDR and repair factors (Rad51 and PALB2).

Because basal-like and TN breast cancers are associated with a very complex genetic landscape, effective treatment of this particular subtype of breast cancer still represents a challenge for clinicians. Therefore, scientists are devoting their efforts to identify specific vulnerabilities that guide to more targeted therapeutic approaches. For example, basal-like and TN breast cancers seem to rely on the activation of PI3K signaling pathway for cell growth and survival [23]. The loss of PTEN, the negative regulator of PI3K, is a very frequent genetic event in these tumors [24]. Indeed, basal-like and TN breast cancers are particularly sensitive to PI3K inhibitors, such as BKM120 [25]. The activation of PARP-mediated DNA repair (SSB and BER) is another mechanism of adaptation that occurs in BRCA1-mutated cancers that are HR defective [26]. PARP inhibitors have proven to be particularly effective in these tumors, mainly in combination with PI3K inhibitors [27]. Our group has identified another dependency of basal-like and TN breast cancers that involves the activity of the serine/threonine protein kinase PLK4 [28]. This work has led to the identification of CFI-400945, a potent and selective PLK4 inhibitor, particularly effective in tumors with PTEN deficiency. Overall, basal-like and TN breast cancers are characterized by high degree of genomic instability compared to other breast cancer subtypes. Although genomic instability can produce alterations that are beneficial for tumor growth, it can also create vulnerabilities. Importantly, genomic instability can generate "synthetic lethal" interactions that can be exploited therapeutically.

Conclusions

As discussed in this chapter, breast cancer is a very complex disease with different biological and genetic features. The study of breast cancer genomes and genomic instability is advancing rapidly thanks to more advanced genomic technologies, but much remains to be learned. For example, it is unclear which role genomic instability has in the clonal evolution of breast cancer. Genomic instability can be the general driving force of breast cancer or simply a conse-

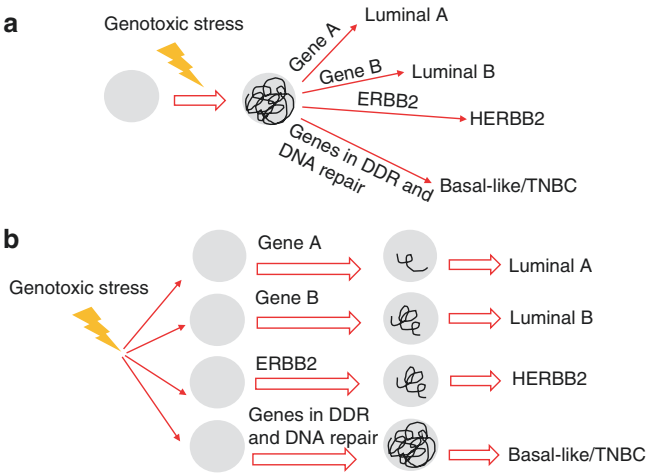

Fig. 2.2 Hypothetical model of the evolution of breast cancer in relationship with genomic instability. (**a**) All breast cancer subtypes originate from a common cancer-initiating cell. Upon endogenous or exogenous genotoxic insult, a genome becomes unstable and stochastically generates the mutational event/s that drive/s the development of each subtype. (**b**) Each cancer subtype derives from a specific cell of origin. In condition of genotoxic stress, each cell type acquires specific genetic mutations that drive different subtypes. Accordingly to which pathway is affected by the mutation, each tumor type will acquire different degrees of genomic instability

quence of the specific mutations that characterize each subtype (Fig. 2.2). In the first hypothesis, all subtype would share a common cell of origin that acquires a certain level of genomic instability upon genotoxic damage. This mutator landscape would favor stochastic acquisitions of mutations in specific genes such as ERBB2 that would give rise to each subtype. In the second hypothesis, each subtype would originate from a different cell that will stochastically acquire mutations in specific genes such as ERBB2. Based on which pathway will be altered, each subtype will show a different degree of genomic instability. Both hypotheses well support the heterogeneity of breast cancer disease. The recent development of single-cell sequencing may reveal another layer of complexity, that is, intra-tumoral heterogeneity. This analysis can be used to identify and characterize hidden subpopulations and shed light on the clonal evolution of breast cancer. Clonal dynamics should be studied in response to cancer therapy to further evaluate mechanisms of adaptations. Currently, computational biologists and bioinformatics have developed tools that are able to handle huge amount of data. The task for cancer research scientists is to develop biological models suitable to reveal "drivers" and "vulnerabilities" in the overwhelming landscape of cancer complexity. Although advantageous, living with genomic instability is a challenge that cancer cells face by triggering mechanisms of adaptation. The identification of these mechanisms will reveal novel vulnerabilities for better-tailored therapies.

Fundamental Pathways in Breast Cancer 3: Estrogen Biology

3

Luca Magnani and Darren K. Patten

3.1 Introduction

Over the last two decades, it has become evident that breast cancer should be considered as a family of diseases rather than as a unique malignancy. Pathological, molecular, and genetic analysis have revealed the existence of five to ten main subgroups [1–3]. Over 70% of all patients are generally classified by the tumor dependencies on estrogenic compounds [4]. These dependencies are principally mediated by the nuclear receptor estrogen receptor α (ERα) [5, 6]. For all these reasons, ERα remains the key driver in the majority of breast cancers and is commonly used as a molecular biomarker for stratification while serving as the main target for systemic adjuvant chemotherapy. In this chapter we will discuss the molecular mechanisms of ERα activation, focusing on integrative analysis that have recently exposed the intimate link between ERα and chromatin structure.

3.2 Estrogen Signaling and the ERα Underlie a Large Fraction of Breast Cancer Hallmarks

A critical shift in the approaches to studying estrogen biology has occurred in the last decade. The field has gradually moved from the investigation of single genes to the study of model cell lines and finally moving to patient-derived samples. This broadening involved also the molecular toolkit used by scientists through the development of next-generation sequencing and allowed the development of unbiased, genome-wide assays [7]. This transition was critical to refine our understanding and overtake long-standing dogmas. Since then, the field has become aware of the complexities of estrogen signaling and began examining the association between DNA, the scaffolding DNA structure (chromatin), epigenetic and genetic factors, and ERα. Using system biology approaches and genome-wide annotations, we now have also linked ERα to the majority of breast cancer hallmarks thus reemphasizing the importance of this dogmatic transcription factor.

The involvement of estrogen signaling in breast cancer biology was recognized over a century ago, when a causative link between ovariectomy and breast cancer progression was made [4]. Several studies have also linked estrogen and breast cancer etiology. Some of the best-characterized predisposing factors predisposing factors leading to breast cancer breast cancer reflect endogenous estrogenic exposure (reviewed in [8]). In addition, additional exogenous estrogen exposure can also favor the development of luminal breast cancer [9]. Over 5×10^3 studies (source, PubMed) have evaluated the role of estrogen signaling in MCF7 cells, one of the preferred tools to investigate the dynamics of estrogen signaling at a molecular levels. The most investigated aspect of estrogen signaling is without any doubt the sustained growth promoted by activated ERα. Nonetheless, estrogen signaling is also involved in many other cancer hallmarks [10] (Fig. 3.1). Some of the molecular details of how this happens will be discussed in more detail in other sections of this chapter and other chapters as well.

Estrogen signaling has been extensively associated with evasion of cell death [11], invasion and metastasis [12, 13], and inflammation [14] phenotypes. More recently estrogens and ERα have also been associated with angiogenesis [15], genome instability and mutations [16], and deregulation of cellular energetics [17, 18]. It is important to understand that most of these biological features are modulated by activated ERα at the DNA level. In the next sections, we will discuss how breast cancer cells can access such a wide array of cellular response via a single transcription factor.

3.3 This Must Be the Place: A Brief Introduction of the Chromatin Environment

ERα signaling can be broadly classified into canonic (genomic) and noncanonical (non-genomic). Noncanonical signaling involves ERα activation in the cytoplasm and the subsequent activation of complex signal transduction cascades mediated mostly by kinases. For an in-depth review of the subject, see [19]. An example is provided by EGF-EGFR signaling converging on ERα phosphorylation. Even in these scenarios, ERα ultimately acts via DNA binding [20, 21]. A more controversial line of investigation has addressed the potential role of ERα in the cell membrane [22], the data though have been challenged [23] and the field has not matured a consensus. On the other hand, a large fraction of ERα molecules constantly shuffle between the cytoplasm and the nucleus where they alternate between a free-floating state and a DNA bound state [24, 25]. More importantly, canonic ERα signaling has been associated with the majority of the breast cancer hallmarks discussed above. For all these reasons, we will focus the discussion on canonical signaling.

The full-length ERα contains a ligand binding domain (LBD) and a DNA binding domain (DBD) separated by a hinge domain [26]. Once the ligands contact the LBD, conformational changes occur throughout the entire protein and allow for dimerization and DNA binding [27, 28]. ERα then quickly contacts the DNA at genetically defined DNA sequences called estrogen-responsive elements (EREs) [29]. More than 70,000 EREs are scattered throughout the human genome in addition to regions that harbor half or degenerate EREs which are also permissive to ESR1 recruitment [30]. This poses the question of how many regions ERα binds throughout the genome, how ERα finds these ERE, what are the molecular determinants of ERα binding, and how many ERα are actually functional.

The human genome consists of around 3×10^9 base pairs. Eukaryotes have evolved strategies to compact this vast array of information in the nucleus via higher-ordered packaging (the chromatin). 147–148 bp of the DNA string wrapped around histone proteins is the minimal repeating unit of the chromatin (the nucleosome) [31]. ERα, similarly to 94% of all DNA binding proteins, has higher affinity for nucleosome-free DNA [32, 33]. Thus, chromatin accessibility represents the first barrier to ERα binding. ERα binding is the primary driver of gene expression. Activation of ERα induces the strong transcriptional response that drives breast cancer cell proliferation [34]. ERα orchestrates transcription by binding at critical DNA regions known as regulatory elements [35]. These regions can be broadly classified as promoters and enhancers based on the relative distance from the gene that is controlled (Fig. 3.2). The chromatin environment at regulatory regions is defined by several well-characterized epigenetic features [36]. For example, active promoters and enhancers are typically nucleosome-free and accessible to transcription factors [33]. The nucleosomes surrounding regulatory regions carry special chemical modifications on the histone tails depending on their activity status [36–38]. These modifications, known as histone post-translational modifications (HPMTs), have been extensively used to annotate regulatory regions in the genome by several international consortiums [36, 39, 40]. Promoters are characterized by histone 3 lysine 4 tri-methylation (H3K4me3), while enhancers are generally enriched for histone 3 lysine 4 mono-methylation (H3K4me1) [38]. On the other end of the chromatin spectrum, inactive/repressed regulatory regions carry H3K27me3 and H3K9me3 modifications [41]. Collectively, chromatin accessibility and histone modifications are a constitutive part of the epigenome. Several integrative studies have now dissected the relationship between ERα and the epigenome.

Fine mapping of ERα DNA interaction and integration with epigenetic data were central to remodel a long-standing dogma in ERα biology. For a long time, it was hypothesized that ERα controls transcription by binding to primarily the promoters of target genes. It is now well established that 97% of ERα binding occurs at distal enhancers [35, 42, 43] (Fig. 3.1). These regions are typically enriched for active epigenetic modifications (H3K4me1, H3K27ac) and devoid of repressive marks (H3K27me3 and H3K27me9). These unex-

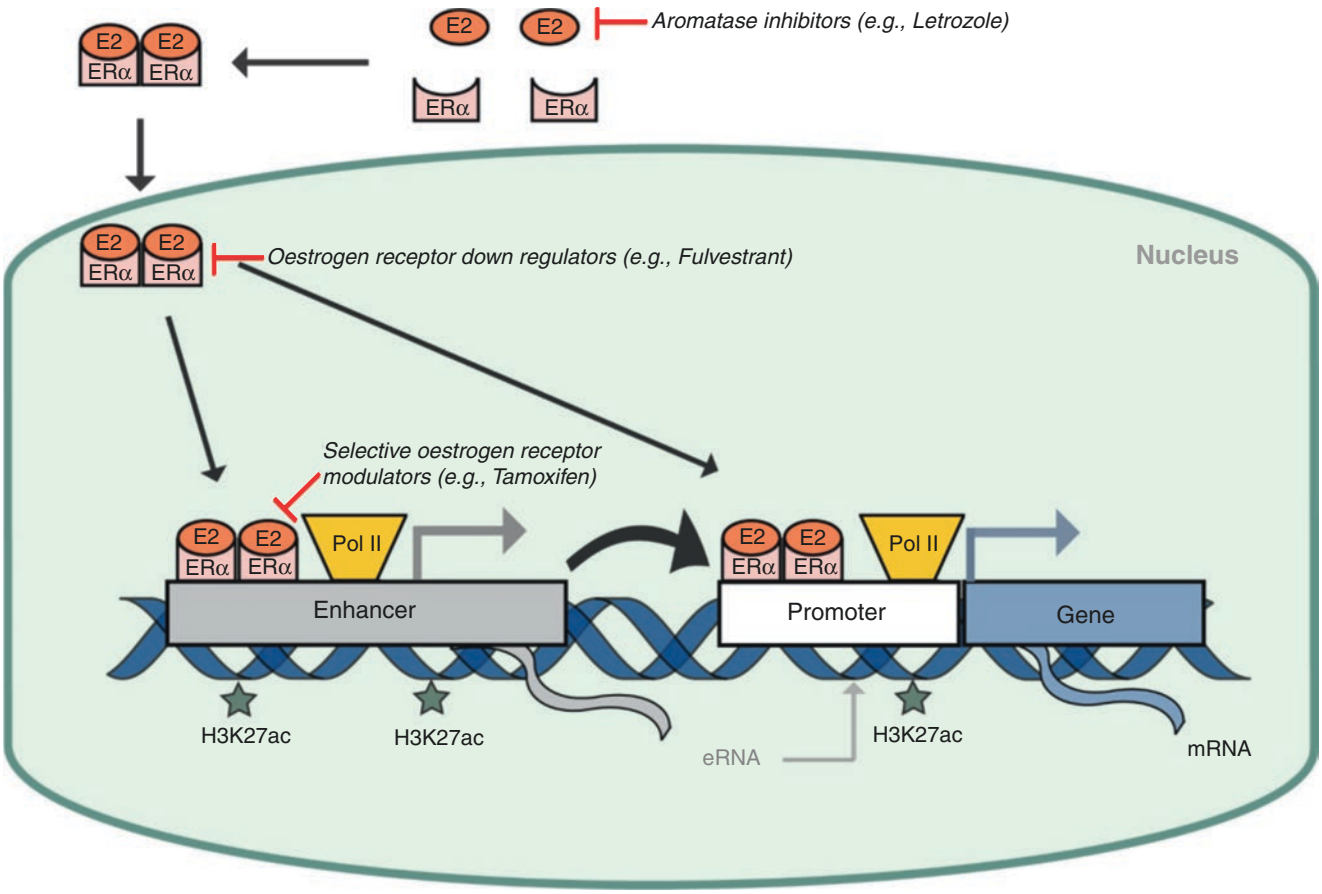

Fig. 3.2 ERα interacts with the chromatin to regulate gene expression. ERα is found both in the cytoplasm and in the nucleus prior to estrogen-mediated activation. Estrogen activation is the main target of endocrine therapies. Once activated, the receptor binding regulatory regions (enhancers and promoters) that contain ERE motif are bookmarked by specific histone modifications. ERα binding potentiates gene transcription by Pol II and leads to the activation of many genes involved in proliferation, invasion, and other cancer hallmarks

pected landmark discoveries have provided the foundations for the last ten years of research looking for the modalities by which ERα mechanistically modulate gene expression.

3.4 Pioneer Factors Are Critical Regulators of ERα Binding to the Chromatin

ERα can bind the DNA only when activated; otherwise, it remains unbound within the cytoplasm/nucleus. Several groups have examined the dynamic properties of ERα binding to the DNA. Biochemical investigation using the average signal from millions of cells have established a paradigm whereby once activated, ERα cyclically binds to target DNA at 45-min intervals [35, 44–46]. Nonetheless, ERα requires nucleosome-free regions for efficient DNA binding. Recent studies have shown that ERα binding sites are maintained in an open chromatin conformation by a specialized set of transcription factors called pioneer factors [47, 48]. While ERα interaction with the DNA is ligand and time dependent, pioneer factors bind near EREs in the absence of external stimuli and are thought to maintain more stable interactions with the chromatin. Two of the best-characterized pioneer factors are FOXA1 [35] and PBX1 [24]. Depletion of FOXA1 and PBX1 results in a dramatic reduction in chromatin accessibility at local EREs [24]. In contrast with other transcription factors, pioneer factor can interact with nucleosomes and bind nucleosome-dense DNA [49] thus increasing chromatin accessibility *de novo* [50]. Pioneer factors also appear to be the link between the epigenome and ERα via nucleosome modifications. Several evidences indicate that pioneer factors might be able to interact with nucleosome modifications. For example, overexpression of a protein involved in erasing the H3K4me2 mark corresponds to a loss of PBX1 and ERα from several enhancers [24]. Furthermore, pioneer factors are found mainly at H3K4me1/2 rich regions [24, 51]. In summary, pioneer factors act as the gatekeepers of potential ERα binding sites by modeling chromatin accessibility and bookmarking a discrete number of genomic locations for ERα (Fig. 3.3).

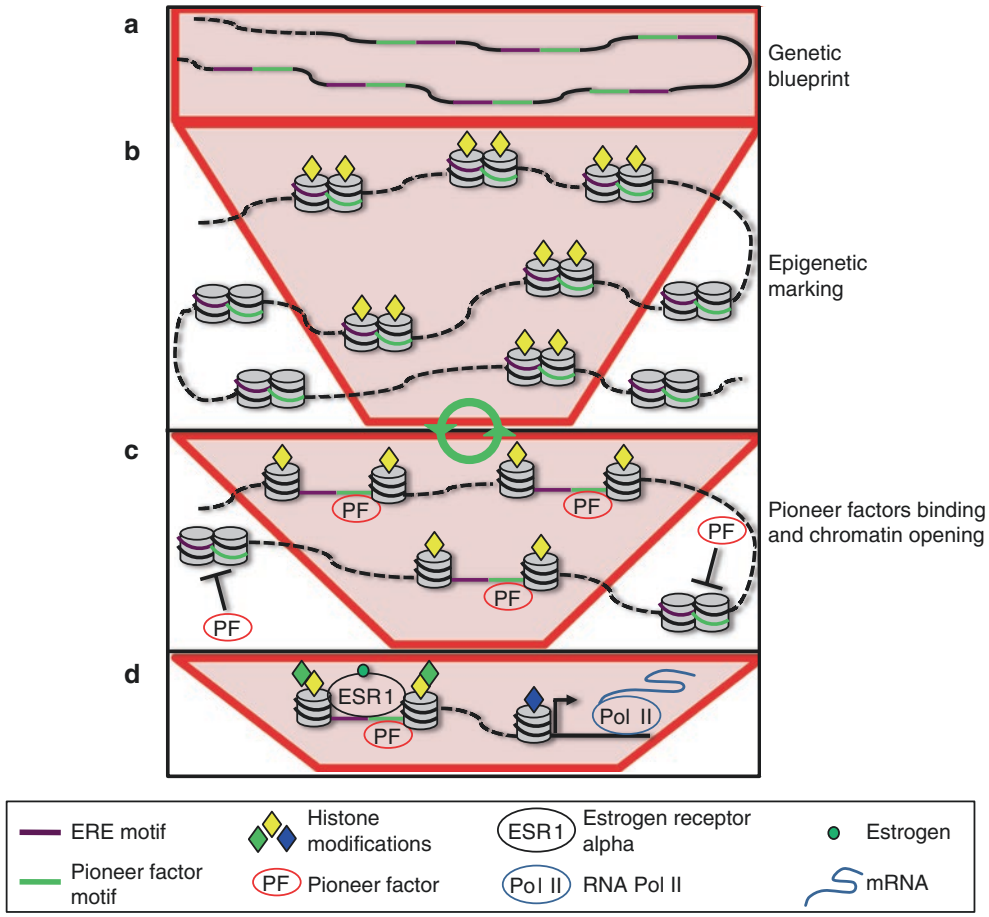

Fig. 3.3 (**a**) The chromatin template mediates ESR1 signaling activity. ERE elements are distributed across the genome and can co-localize near pioneer factor motif elements. (**b** and **c**) Histone modifications (e.g., H3K4me1/2) and pioneer factors cooperate to increase chromatin accessibility at a subset of genomic ERE. (**d**) These events promote competence for successful ESR1 binding in response to external stimuli and mediate ESR1 transcriptional program (reproduced with permission from [6])

3.5 ERα Regulates Transcription via Chromatin Looping

The vast majority of ERα binding occurs at distal regulatory regions (enhancers). How does ERα then activate gene transcription? It is well established that activated ERα is essential to promote efficient RNA polymerase II release from gene promoters and enhancers as well [52–54]. Recent advances in chromatin conformation capture assays have highlighted the tremendous complexity of the 3D organization of the chromatin [55, 56]. These genomic assays characterized thousands of enhancer-promoter interactions partially explaining how distal regulatory regions can mediate transcription. Not surprisingly, ERα was one of the first transcription factors found at interacting chromatin loops [57]. There are, however, some unresolved questions about the formation of these loops. One model postulates that estrogen-activated ERα can drive loop formation [57–59]. However, there is also an indication that ERα might exploit preformed loops that have been set up by pioneer factors with the contribution of epigenetic modifications (reviewed in [60]). It is conceivable that future studies will find that ERα chromatin looping is very context dependent and could include both models of transcriptional activation.

3.6 ERα Regulates Transcription via Protein Recruitment

ERα regulates transcription by modulating RNA polymerase II release from the 5′-prime end of the gene body. Yet, ERα alone is not sufficient for full transcriptional activation. It soon became apparent that ERα recruits several other proteins to promote transcription [46, 61]. These studies also explained how ERα could modulate repression. The proteins recruited by ERα are commonly referred to as coactivators or corepressors. Interestingly, two among the first coactivators to be identified (SRC1 and BRG1) are critical chromatin modulators, further highlighting the strong link between ERα and the chromatin environment. Steroid receptor coactivator-1 (SRC1) is a histone acetyltransferase [62] (Histone 3 lysine 9/14 acetylation), while BRG1 is a chromatin remodeler [63, 64]. Histone 3 lysine 9 acetylation is yet another HPMTs strongly associated with active transcription and has been shown to be important for chromatin relaxation and improved DNA accessibility [65]. On the other hand, histone acetylation provides a docking station for bromodomain proteins, including the chromatin remodeler BRG1. These proteins interact with acetylated histones and are essential to remodel and reposition nucleosomes [66]. These

cofactors mostly lack DNA binding abilities and rely on ERα for recruitment at the correct regulatory regions. Several lines of evidence support this model. For example, it has been noted that BRG1, SRC1, and other cofactors parallel ERα cyclical pattern of recruitment onto the DNA [44]. More importantly, blocking ERα binding is sufficient to abrogate binding for several cofactors [67]. The list of cofactors has been growing dramatically in the last few years. Proteomic-based approach has now identified hundreds of potential coactivators and corepressors [68] including several ERα target genes themselves. Collectively, these examples emphasize the complex transcriptional machinery driving growth in breast cancer cells while underscoring the central role of ERα in coordinating all genomic actions.

3.7 Alternative ERα Binding Programs Correlate with Differential Patient Outcome

ERα binding is modulated by chromatin accessibility, epigenetic modifications, and cofactor recruitment. The combination of these regulatory layers shapes cell type-specific ERα binding. But are alternative ERα binding combinations reflective of different biology? Could alternative ERα binding be used to stratify breast cancer patients *in vivo*? A recent study from the Carroll group have examined, for the first time, the collection of ERα binding (known as cistrome) in several luminal breast cancer patients characterized by distinct outcome [43]. The data suggest that while a lot of ERα binding seems to be patient-specific, there are also clusters unique to good outcome patients and clusters unique to poor outcome patients in addition to a core ERα cistrome common to patients and cell lines as well [43]. Of note, differential ERα binding is potentially correlated with alternative transcriptional programs. Gene expression profiling using putative ERα target genes can also identify subgroups of patients with dramatically different outcome suggesting that ERα can guide both aggressive and nonaggressive breast cancers. An explanation for these patterns can be found in alternative usage of pioneer factors. For example, it was shown that when ERα interacts with PBX1, it can guide transcription of genes associated with aggressive phenotype [24]. On the other hand, ERα interaction with GATA3 [47, 69, 70], another breast cancer pioneer factor, seems to be associated with less aggressive tumors ([43]).

Genetic alteration can also impact ERα recruitment in vivo. Genomic analyses have revealed that about 20% of all luminal breast cancer patients have copy number loss at the progesterone receptor (PGR) locus [71]. PGR is one of the best-characterized ERα target genes and is commonly used to stratify luminal breast cancer patients into luminal A (ER+/PGR+) and luminal B (normally ER+/PGR− or ER+/PR+ and HER2+) subtypes [72]. Nevertheless, PGR has been also described as an ERα cofactor capable of hijacking ERα upon native progesterone stimulations [71]. More importantly, the ERα cistrome obtained from progesterone-treated cells correlate with milder phenotypes and improved outcome. Indeed, patients with PGR copy number loss are characterized by a poorer outcome [71]. In summary, ERα genomic localization has significant effects on tumor biology. These data can be then harnessed clinically by finding practical strategies to reprogram ERα. For example, it has been postulated that native progesterone (but not synthetic progestin) treatment in PGR wild-type patients might carry significant benefits.

3.8 Alternative Means of ERα Activation

Estrogen signaling plays an essential role in driving breast cancer growth at early stages. All approved adjuvant systemic therapies are in fact designed to block estrogen signaling (for an updated review see [73]) (Fig. 3.2). Targeting estrogen signaling lowers the rate of relapse by about 50% in ERα-positive patients [74]. However, it is becoming apparent that estrogen signaling remains central at later stages of the disease as well. In the last three years, it has been shown how ERα-positive breast cancer cells develop alternative strategies to activate the receptor in later stages of the disease. There are two main mechanisms through which this can happen. The first involves activating mutations targeting the LBD [75, 76]. Two independent studies found that metastatic breast cancer patients with a history of luminal disease have a significant prevalence (~20%) of mutations targeting the LBD of ERα. These mutations appear to activate the receptor in the absence of estrogens through conformational changes. This results in a constitutively active form of the receptor that cannot be turned off by conventional chemotherapy. It remains unclear at what stage of the disease these mutations arise, since the patients in which they were identified received an extensive array of treatments [75, 76].

The second mechanism involves the activation of cholesterol biosynthesis in estrogen-independent ERα breast cancer (i.e., letrozole resistant) [18]. In this case, ERα cancer cells develop the ability to synthesize *de novo* an alternative ERα ligand (27-hydroxycholesterol) [77]. This in consequence allows estrogen-independent, ERα-dependent proliferation [18]. Moreover, 27-hydroxycholesterol was previously shown to stimulate an invasive phenotype in ERα breast cancer mouse models [12]. Ultimately, estrogen signaling might become redundant as the disease approaches the later stages despite breast cancer cells remaining frequently ERα positive [78]. This is also reflected clinically by the limited benefit of ERα downregulators such as Faslodex [79]. In summary, estrogen signaling and ERα continue to play a key role throughout the patients' entire journey.

3.9 Novel Insight in the Genomic Activity of ERα

Estrogen signaling is essential to promote growth, invasion, and survival of breast cancer cells. In addition, recent studies have also linked ERα and estrogen signaling to genetic instability and mutational burden. One of the most recently identified ERα cofactors is the cytosine deaminase APOBEC3B [16]. APOBEC3B was previously linked to a specific mutational signature (C to T) in breast cancer patients [80, 81]. Interestingly, APOBEC3B is temporarily co-recruited on the chromatin along with ERα and depletion of ERα results in loss of APOBEC3B recruitment [16]. One of the key findings however is that APOBEC3B is essential for ERα transcriptional activity. Moreover, estrogen stimulation in ERα-positive cell lines was sufficient to jump-start DNA repair mechanisms and the accumulation of double-strand breaks at ERα binding sites [16]. Why estrogen activity induces risky double-strand breaks? Mechanistically, these findings fit with the idea of chromatin remodeling at ERα regulatory regions. While the transcriptional machinery advances, it might require relax and unwounded DNA [82, 83]. Nonetheless, cells with inefficient DNA repair might then have an increased mutational burden at regulatory elements. Altogether these data suggest that estrogen signaling and ERα might also contribute to the mutational signature found in ERα breast cancer patients.

Conclusions

In this chapter, we have discussed some of the critical roles of estrogen signaling in breast cancer cells. By using integrative analysis, we are finally addressing the question we are finally addressing the question as to why ERα is so dominant in breast cancer cells. Yet, some aspects remain uncertain. For example, is ERα binding important in the context of breast cancer predisposition? A recent study found that single nucleotide polymorphisms (SNPs) associated with increased breast cancer risk have a significant tendency toward EREs and FOXA1 binding sites [84]. Possibly, these SNPs act by modulating ERα and other pioneer factors binding to DNA [85]. It is fascinating how then the ERα might evolve during the patient journey. If ERα is involved in increasing the mutational burden, it is then easy to speculate that some of these mutations might increase affinity for ERα, while others might decrease it. Consequently, the ERα cistrome might change at high frequency allowing the tumor to transform during progression and activate or adapt many of the cancer hallmarks in response to change in tissue, therapy, and many other physiological parameters.

Fundamental Pathways in Breast Cancer 4: Signaling to Chromatin in Breast Development

4

Luca Mazzarella and Pier Giuseppe Pelicci

4.1 Breast Development and Its Relationship with Cancer

4.1.1 Normal Breast Development and the Identification of Mammary Stem Cells

Development of the breast has important differences compared to other organs, as it is mostly completed in the postnatal life (for extensive review of breast development, see [1]). At birth, the breast consists only of a rudimentary ductal structure populating the area around the nipple. During puberty and in response to ovarian hormones, a branched ductal architecture develops, driven by highly proliferative "terminal end bud" (TEB) cells. This process is macroscopically and molecularly similar to the epithelial-to-mesenchymal transition (EMT) that occurs earlier in embryonal development and implies infiltration of epithelial cells into the underlying fibroadipose stroma. Postpubertal mammary ducts so formed consist of a bilayer of polarized **luminal** cells surrounded by myoepithelial **basal** cells; small milk-producing alveoli with apocrine **lobular** cells develop; lastly, a specialized stroma with trophic function surrounds the mature gland. Ductal and alveolar cells undergo periodic waves of apoptosis and regeneration at each estrous cycle. During pregnancy and then lactation, duct arborization and alveolar volume increase dramatically through active cell proliferation.

The cell types and molecular mechanisms governing breast regeneration are still incompletely understood. Early experiments showed that any portion of the mammary gland transplanted into a suitable environment (cleared mammary fat pad for mouse-to-mouse transplants, kidney capsule for human-to-mouse) is able to regenerate a functional mammary gland [2, 3]. However, it was unclear whether this ability is shared by most cells or is restricted to few mammary stem cells (MaSCs). The latter view is now supported by a large body of experimental evidence (reviewed in [1, 4, 5]), but the heterogeneity of the experimental systems employed has fueled debate about the features of MaSCs. Earlier transplantation-based experiments revealed that single individual cells able to completely regenerate a functional gland and give rise to all mammary lineages can be prospectively identified in the mouse as $CD24^{+}$ or $CD29^{hi}/CD49f^{hi}$ [6–8]. In humans, $CD49^{+}/EpCAM^{low}$ cells or aldehyde dehydrogenase (ALDH)-active cells are enriched for regenerative activity when transplanted in immunocompromised mice [9, 10]. Furthermore, in vitro mammosphere formation assays revealed that regenerative activity is highly enriched in a rare population that cycles infrequently [11, 12]. This led to a dominant model in which mammary regeneration is carried out by few and slow-cycling stem cells with the ability to give rise to all mature breast lineages, in clear resemblance to models of hematopoiesis. However, transplantation is a highly nonphysiological setting in which the revealed developmental potential may not reflect the actual contribution to normal mammary homeostasis. More recent in vivo lineage tracing experiments have established the existence of cells with "true" multipotency but also revealed that multiple reporter alleles can identify multipotent cells with different expression profiles, frequency, and cell cycle dynamics, suggesting a higher than expected heterogeneity [13–15]. A significant part of adult mammary lineages is replenished by self-renewing "progenitor" cells whose contribution is restricted to the luminal or basal lineages [16, 17]. A subset of self-renewing cells is retained through rounds of pregnancy-induced alveolar remodeling and re-initiates alveologenesis at subsequent pregnancies in mice ("parity-induced mammary epithelial cells," PI-MEC) [18–21], although the existence of such cells has never been demonstrated in humans [4]. It is still unclear whether multipotency is a fixed feature of cells which are multipotent by transplantation *and* by lineage tracing, or whether unipotent

progenitors might become multipotent upon strong changes in environmental signals, like physiological hormonal changes or transplantation.

4.1.2 Relationship Between Normal Breast Development and Breast Cancer

The study of normal developmental dynamics can provide important information to understand breast cancer natural history. What is the cell of origin of breast cancer? Multiple cumulative genetic abnormalities are required to transform a normal cell. In the breast, on average one mutation per coding megabase are identified in large-scale sequencing projects [22, 23]. As the rate of mutation accumulation at each cell division is low [24], cells of cancer origin are likely to have a long proliferation history: MaSCs or progenitors surviving multiple cycles of gland regeneration are the likeliest candidates.

But does this also imply that the developmental potential of the cell of origin can shape cancer phenotype? This was strongly suggested by the landmark expression microarray studies of the early 2000s [25, 26], which showed that groups of commonly expressed genes that define normal lineages are also able to define clusters of cancers with common natural history ("intrinsic" subtypes). However transcriptional similarities do not necessarily extend to the cell of origin, implying for instance that a basal-like cancer had to originate from a basal-restricted cell. In fact, more recent studies on BRCA-deficient mice and humans suggest that basal-like cancers derive from luminal-committed progenitors [9, 27]. The emerging consensus is that luminal progenitors are the likely cell of origin for both luminal and basal-like tumors, whereas MaSCs and/or basal progenitors are the initiators of the rarer claudin-low subtype. The origin of HER2+ tumors is less well understood; data in mice suggest that parity-induced stem cells might be the culprit as their ablation inhibits tumorigenesis in MMTV-neu mice [28], but to what extent this model really mimics human HER2+ tumors is disputable since the murine expression profile is more akin to human luminal tumors [4, 28, 29]. Almost completely undetermined is the cell of origin of lobular and rarer breast cancer subtypes. Transcriptome analysis of "special" subtypes (like mucinous and micropapillary) all clustered in a separate group, revealing transcriptional homogeneity despite morphologic differences, but little about a possible common cell of origin [30]. Lobular cancers showed heterogeneous signatures resembling ductal subtypes (including luminal-like and basal-like signatures) [30]; transcriptome signatures within lobular cancers have been recently studied in more depth by the TCGA, with the definition of three new subgroups "reactive-like," "immune-related," and "proliferative" [31]. Again this reveals little about the cell of origin, but the only available genetically engineered mouse model showed that lobular tumors can be obtained from basal cells expressing cytokeratin 14 [32].

4.2 Signaling Pathways Controlling Breast Development and Their Alterations in Cancer

Several authors have proposed that molecular mechanisms specific for stem cells might also be responsible for malignant behavior, in a declination of the "cancer stem cell" theory [33]. Specifically, the same pathways allowing stem cells to maintain multilineage potential resist to physiological death and invade the stroma to (re)generate the organ, might also allow cancer cells to adapt their transcriptome, resist to treatment-induced death, and become invasive and metastatic. We will now review the most important developmental and stem cell-related pathways in breast. Then, we will review how these signals converge on chromatin (the ensemble of normal DNA and DNA-bound proteins) to modulate transcription. Chromatin can directly (by physical compaction) or indirectly (through differential recruitment of effector proteins) control DNA accessibility to transcription factors and stabilize phenotypic traits by restricting the degree to which transcriptional signatures can be further modified by competing signals. Hence, proteins directly governing chromatin architecture are particularly important in developmental processes and are often disrupted in cancer.

4.2.1 NOTCH/NUMB and p53 as Regulators of Symmetric vs Asymmetric Cell Division

4.2.1.1 NOTCH Pathway in Breast Development

The NOTCH pathway governs cell lineage determination and body patterning in all metazoans [34–36]. NOTCH was classically identified as a regulator of neuroectodermal development in *Drosophila* but then emerged as a functional module repeatedly exploited in heterogeneous developmental contexts to execute binary cell fate choices, generating and maintaining phenotypic "boundaries" within organs. The four NOTCH receptors are functionally redundant [37] transmembrane proteins with homology to eGFR; once activated by short-range ligand binding, usually requiring cell-to-cell interaction, the receptor is cleaved by the gamma-secretase complex and transported into the nucleus. Here, it induces the assembly of a highly conserved protein complex that canonically includes CBF-1 and RBP-J, plus additional chromatin-modifying enzymes [38]; this drives transcription of NOTCH target genes, most notably the HES and HERP families of bHLH transcription factors [39, 40].

The half-life of the activated receptor is normally very short due to efficient proteasomal degradation, which is dependent on the C-terminal PEST (rich in proline (P), glutamic acid (E), serine (S), and threonine (T)) domain common to all NOTCH receptors. The NOTCH molecular circuitry is reinforced by multiple layers of intrinsic and extrinsic feedback mechanisms ("lateral inhibition") that amplify small variations in ligand/receptor concentrations between adjacent cells; this allows the emergence of discontinuities among cell populations with prior equal potentials. A particularly important regulatory role is played by NUMB, a membrane-associated protein that targets NOTCH receptors to proteasomal degradation and is a key determinant of asymmetric cell division: in several NOTCH-dependent lineage choices, NUMB is unequally partitioned between daughter cells, leading to differential inactivation of the NOTCH pathway. Numb also independently regulates the stability of p53 [41], which in itself is implicated in stem cell self-renewal and (a) symmetric cell division [11].

These general functional properties also apply to NOTCH role in breast biology. NOTCH pathway receptors are expressed in the luminal compartment [42–44], and its target genes are upregulated in luminal progenitors in the adult gland [42]. This expression pattern is mutually exclusive with that of ΔNp63, which promotes and maintains basal cell gene expression; in fact, NOTCH and p63 appear to be functional antagonists [45]. Hyperactivation of NOTCH pathway by overexpression of the active form [42] or conditional ablation of NUMB [44] leads to ductal hyperplasia with luminal differentiation. On the contrary, ablation of NOTCH function by conditional deletion of the common transcriptional mediators CBF1 or RBP-J led to expansion of the basal cell pool during pregnancy [46]. Collectively, these results suggest a model in which NOTCH pathway activation promotes the commitment of dividing stem cells and progenitors to the luminal lineage at the expenses of the basal/myoepithelial lineage [47]. However, this model is complicated by the presence of low levels of NUMB and NOTCH receptors also in basal and other cell types [42, 44]; the precise mechanism of action of NOTCH in normal mammary gland biology remains an active field of research.

4.2.1.2 Modes of NOTCH Pathway Alterations in Breast Cancer

Although altered NOTCH receptors have been found to act as tumor suppressors in some circumstances [48, 49], in breast cancer and in most other tumors (most notably T-ALL), they behave as classical proto-oncogenes that become constitutively activated through loss of extrinsic or intrinsic regulation [49, 50].

Loss of extrinsic regulation is achieved by genetic ablation of the N-terminal extracellular domain. Early on in the history of breast cancer experimental research, this mechanism was identified as a consequence of insertional mutagenesis of the mouse mammary tumor virus; breast-specific expression of the truncated form induces expansion of luminal progenitors and mammary tumors in experimental animals [51–53].

Among human tumors, alterations in NOTCH receptors are present in around 5% of all cases in different patient populations. Unlike MMTV insertions in the mouse, the generation of an extracellular domain-defective protein is uncommon in humans; this was observed as the result of chromosomal translocations in a recent study [54, 55]. More common are point mutations that frequently (around 60% in the TCGA cohort) are truncating and clustered at 3′ exons, resulting in a disrupted PEST domain and predicted to lead to increased protein half-life. The PEST can also be lost through deletions or translocations [54, 55]. The remaining point mutations are scattered throughout the gene body with no detectable pattern but tend to occur in highly conserved residues important for receptor heterodimerization associated with increased activity in T-ALL [54]. NUMB is frequently downregulated at the protein level in breast cancer, although the mechanism leading to downregulation has not been extensively studied. Deletions can be observed in 0.6% of all TCGA breast cancer patients.

NOTCH/NUMB alterations are strongly associated with HER2/ER/PgR negativity [41, 54, 56] and, as expected, with unfavorable outcome in invasive carcinoma [41, 43, 56–59] and with higher recurrence rate in DCIS [60]. This makes NOTCH pathway an attractive target for drug development. Inhibiting NOTCH through genetic [61, 62] or pharmacological [60, 63] means results in a loss of in vitro self-renewal ability in mammosphere assays.

NOTCH inhibitors are currently undergoing early phase clinical evaluation in breast cancer and other tumors. Two main approaches are being explored: the use of antibodies that disrupt ligand-receptor interaction and inhibitors of the gamma-secretase activity first explored in Alzheimer's disease [64–66].

4.2.2 The Wingless (WNT) Pathway

4.2.2.1 Wnt Pathway in Breast Development

The Wingless (WNT) pathway plays a crucial role in mammary development; similarly to NOTCH, it acts prevalently at short range as a functional module that is repeatedly used in highly different contexts to give rise to variable outputs, including the regulation of asymmetric cell division. Signals are instructed through paracrine cellular communication between the lipidated Wnt ligands and the Frizzled transmembrane receptors. This results in the phosphorylation of the canonical WNT mediator beta-catenin by casein kinase I (CKI) and glycogen synthase-3β (GSK-3β), resulting in its stabilization and nuclear translocation. In the nucleus,

beta-catenin activates transcription of conserved targets, namely, telomerase, Axin2, and LGR5, through TCF/LEF factors. Signal strength is intrinsically regulated through proteasomal degradation of Frizzled receptors by Rnf43/Znrf3, which is in turn inhibited by LGR5; LGR5 marks WNT-responsive cells in a variety of epithelial tissues [67], and in the breast it marks a subset of bipotential stem cells able to give rise to luminal and myoepithelial cells as defined by lineage tracing experiments [13]. PROCR is another WNT target that also marks multipotent mammary stem cells, although intriguingly, PROCR$^+$ cells appear distinct from LGR5$^+$ [14].

Another level of WNT modulation is through sequestration of beta-catenin to adherent junctions by E-cadherin: this peripheral pool of beta-catenin is unavailable for nuclear translocation and is thought to play a role in epithelial-to-mesenchymal transitions [68, 69].

4.2.2.2 Modes of WNT Pathway Alterations in Breast Cancer

Similarly to NOTCH, the Wnt1 receptor was found early on as a common MMTV integration site [70], and the oncogenic potential of Wnt hyperactivation subsequently demonstrated by MMTV-induced overexpression of several Wnt receptors or of beta-catenin [71–75]. This leads to anticipated lobuloalveolar overgrowth, morphologically similar to that induced by pregnancy but with an expansion of poorly differentiated cells [73]; importantly, this is also true in male mice and upon transplantation into ovariectomized recipients, suggesting that Wnt pathway lies downstream of ovarian hormones and that Wnt-aberrant cells might become estrogen independent [76, 77]. As mice age, invasive ductal tumors develop with a penetrance of 100% by 1 year. The long penetrance suggests that additional mutations are required to achieve the invasive phenotype, but importantly ablation of Wnt signaling is still required after the invasive tumor has formed, although loss of p53 facilitates the transition to WNT independence [78].

WNT-hyperactivated mouse models have been used extensively in basic research, but their relevance to clinical practice might be questionable, since components of the canonical Wnt pathway are not frequently mutated in breast cancer [76, 79]. However, aberrant beta-catenin staining patterns (i.e., prevalence of nuclear pattern) is observed in about 20% of ductal carcinomas and, as it might be expected, is correlated with triple-negative histology and poor prognosis [79, 80]. Aberrant beta-catenin expression is also correlated with lobular histology, given its association with E-cadherin loss [79, 80].

The absence of a clear targetable alteration made WNT an attractive but difficult pathway for drug development. Recently, casein kinase 1d (CK1d) was found to be amplified and overexpressed in strong correlation with WNT pathway genes in 36% breast cancers, particularly in luminal B and triple-negative ones. The CK1D inhibitor SR-3029 was highly effective in preclinical models (orthotopic cell line transplantation) [81].

4.2.3 Inducers of Epithelial-to-Mesenchymal Transition

Invasion of epithelial cells into connective and adipose tissue is a physiological phase of pubertal breast development and is governed by signaling pathways that have also been implicated in the acquisition of metastatic potential. This process bears resemblance to the physiological epithelial-to-mesenchymal transition (EMT) that occurs during crucial phases of embryogenesis like gastrulation. Whether tumoral invasion is truly an aberrant form of EMT has been a matter of dispute, mostly due to the fact that normal EMT implies dramatic morphological and molecular transitions that have not been consistently observed in breast and other tumors. However, a recent study showed that highly sensitive analysis of pathological specimens can identify cells with mixed epithelial/mesenchymal markers in invasive but not noninvasive breast cancers. These cells correlate with primary histology (mostly triple negative) and can be found circulating in proportions that vary according to treatment response [82].

The exact wiring of the signaling circuits responsible for EMT-like responses in breast cancer has not been fully worked out. Overexpression of specific individual transcription factors (SNAIL, TWIST, SLUG, and ZEB1/2) is able to initiate EMT and increase invasiveness in noninvasive breast cells [83–87]. Several extracellular signals are also implicated, most notably transforming growth factor beta (TGFb), WNT, and Sonic Hedgehog, the latter in turn activated by FOXC1/2 and the basal cell-specific p63 [88]. A common outcome of EMT response is the loss of E-cadherin expression, which results in a weakening of cell-to-cell adhesion and the release of a cytoplasmic pool of beta-catenin, which can now enter in WNT-dependent regulation. A second, recently discovered output of EMT activation is the activation of the Hippo pathway, which in breast cancer is correlated with metastatic behavior and resistance to chemotherapy [89, 90].

All these pathways are rarely affected by genetic aberrations in breast cancer but appear frequently deregulated through nongenetic mechanisms in poor-prognosis breast tumors, especially of the basal and claudin-low subtype [91, 92]. As such, they have attracted attention as drug targets [93] but are still limited to preclinical development.

4.2.4 GATA3, FOXA1, and Lobular vs Ductal Tumors

GATA3 and FOXA1 are both implicated in the regulation of estrogen-mediated transcription (see chapter by Magnani), and their expression is strongly associated with estrogen positivity in tumors [94]. If conditionally deleted during puberty or adult life, they abrogate or severely distort

mammary gland development, with loss of luminal cell identity in the case of GATA3 [95, 96] and a block in terminal end bud formation and invasion during puberty for FOXA1 [97]. Their functional similarities extend to their molecular mode of action, as both are so-called "pioneering" factors able to condition chromatin structure and subsequent binding of other transcription factors [98]. FOXA1, ER, and GATA3 physically interact with several other chromatin regulators in a "mega transcription factor complex" nucleated by the estrogen receptor in response to estradiol stimulation. As FOXA1 directly promotes ER expression, these three factors form a regulatory network able to stabilize estrogen-dependent transcription [99].

Intriguingly, the mutational pattern of GATA3 and FOXA1 has recently emerged as mutually exclusive in the two forms of strongly ER+ breast cancers: GATA3 is frequently mutated in ductal luminal cancers, while FOXA1 is as frequently mutated in lobular cancers [31].

Mutations in GATA3 are the third most common alteration in breast cancer globally [100]. SNVs are invariably heterozygous and cluster in three specific categories: splice site mutations at the junctions between exons 4/5 and 5/6 (20%), frameshift mutations in exon 6 (50%), and frameshifts in zinc finger 2 (10%). Also, GATA3 is frequently amplified (28% of all GATA3 alterations in the TCGA dataset), but this has received little attention. Mutation type 3 is the only type that has been characterized molecularly [101, 102]. Although SNVs cause apparent GATA3 loss of function, they appear to stabilize the non-mutated allele, leading to an intriguing model that can explain the requirement for maintaining heterozygosity [103]. The frequently mutated MAP3K1 is also a target of GATA3, and recently a germline variant in its GATA3-bound promoter was discovered in a genome-wide association study [104]. Loss of GATA3 expression correlates with acquisition of metastatic potential in the MMTV-PyMT mouse model of luminal cancer [105].

Mutations in FOXA1 cluster on lysines located on the wings of the Forkhead domain. These residues, when acetylated by EP300, prevent DNA binding; thus, their loss creates a strongly bound FOXA1 at sites of ER binding, amplifying a normally estrogen-dependent response on the absence of the hormone [31].

4.3 Chromatin Marks in Normal and Neoplastic Breast

The study of chromatin factors in breast development and cancer is probably less advanced than in other systems. In hematopoiesis and its malignancies, where mutations in chromatin factors were identified first, targeted drugs have already made it to the clinic and are routinely used [106]. We will skip lengthy discussions on basic chromatin structure, for which the reader is addressed to extensive reviews [107, 108] Proteins involved in interactions with chromatin have been functionally divided in writers, erasers, and readers [109], a useful classification that will be maintained here. We will focus on those aspects of chromatin regulation not specifically related to estrogen receptor biology, which is extensively covered by L. Magnani in this book (ref).

4.3.1 DNA Methylation

DNA methylation dynamics and the role of DNA methyltransferases in normal breast development have not been extensively investigated. In most breast tumors, primitive techniques could identify gross aberrations in DNA methylation as compared to normal tissues. Locus-specific analyses carried out at relevant genes (e.g., estrogen receptor) could also show aberrant methylation, but the relevance of this information has remained questionable; only recently genome-wide investigations have been systematically applied to large patient cohorts in the TCGA [100] and other studies [110, 111]. Unfortunately, even these systematic studies are complicated by the still poorly understood relationship with gene expression, and by significant heterogeneity in the techniques employed, none of which is truly able to fully cover all potentially methylated cytosines. In the TCGA, basal-like tumors tended to be globally hypermethylated, and, importantly, BRCA1 hypermethylation appeared to be a frequent mechanism (24%) for gene downregulation, potentially suggesting an involvement of BRCA functional loss in the absence of genetic alterations. A group of MSKCC performed a bioinformatically more refined analysis on 171 samples of heterogeneous histology and identified a cluster of tumors with methylation profile similar to that identified in colon cancer ("breast CpG island methylator profile," B-CIMP), which was associated with significantly lower propensity to metastasize. Different results were obtained by an Australian group focusing on triple-negative cancers; here, hypomethylated tumors were associated with better prognosis.

4.3.2 Histone Modifications

Histone modifications in normal breast cell populations have been systematically studied by Polyak et al. [112], who focused on the two marks that define actively transcribed and repressed genomic regions: trimethylation of H3K4 and H3K27. Regions where both signals overlap ("bivalent chromatin") are considered to be epigenetically plastic and

enriched in multipotent stem cells at genes with strong lineage-defining activity [113, 114]. $CD24^+$ and $CD44^+$ cells showed a different distribution of these marks, and many lineage-defining genes, especially transcription factors, were shown to maintain chromatin bivalency, suggesting a basis for phenotypic plasticity. In particular, ZEB transcription factors are bivalent in some tumor cell lines and regulate the expression of CD44, a marker of cancer stem cells with increased invasiveness. Robert Weinberg and colleagues demonstrated that cells in which ZEB1 is bivalent (but CD44 is repressed, like in luminal cancer cell lines) are able to resolve bivalency and lose the repressive H3K27me3 in response to TGFb, resulting in CD44 upregulation and acquisition of invasive traits [115], directly linking an extracellular stimulus with a chromatin-mediated phenotypic change. The Polyak lab investigated further the role of chromatin in phenotypic reprogramming. Using elegant cell fusion experiments between cell lines with luminal or basal features, they showed that the basal phenotype is dominant over the luminal and can be induced by even short-term exposure of luminal cells to basal cell total extracts; reprogramming correlated with the acquisition of epigenetic traits of the parental basal cell, in particular the super-enhancer profile defined by elevated H3K27ac [116]. It might be interesting to explore whether luminal-to-basal epigenetic reprogramming is at the basis of estrogen expression discordance between primary and relapsed tumors, which more often become estrogen receptor negative from positive than vice versa [117].

4.3.3 Chromatin Writers

Members of the Polycomb family (so called from the developmental phenotype observed in *Drosophila* mutants) are the best-studied chromatin writers in breast development. Polycomb proteins are organized in two sets of complexes which induce histone modifications associated with gene repression, namely, H2AK119 ubiquitylation (Polycomb repressive complex 1, PRC1) and H3K27 methylation (PRC2). Members of both complexes have been found to play a role in breast development and cancer [118–122]. Polycomb factors are involved in the maintenance of pluripotency in most if not all stem cells in adult and embryonal life; their genetic disruption leads to increased transcriptional plasticity at lineage-specific genes, resulting in a failure to coordinately execute differentiation programs. The ultimate outcome of Polycomb ablation is highly variable depending on the examined system and can result in cell death. Polycomb inhibitors, especially those directed against the PRC2 catalytic subunit EZH2 that is overexpressed and correlated with poor prognosis in breast cancer [123, 124], have shown responses in preclinical studies [125–127].

4.3.4 Chromatin Erasers

Factors that remove histone acetylation and methylation maintain chromatin in a dynamic state, making it more or less amenable to transcriptional changes. Many cancer cells depend on persistent deacetylase or demethylase activity for survival, and their ablation can lead to cell death or differentiation. Given their favorable chemical properties for drug design, chromatin erasers have been identified as interesting targets for drug development. Histone deacetylases (HDACs) were identified first as playing a role in breast cancer [128], especially by virtue of their negative effect on estrogen receptor expression [129]; thus, they have been mostly studied as sensitizers to endocrine therapy [130–132]. Of the several inhibitors with different degree of specificity synthesized so far, entinostat has reached the furthest clinical development, showing efficacy in a randomized phase II trial against placebo in combination with exemestane in aromatase inhibitor-refractory advanced ER+ breast cancer [133].

Recent research also revealed important roles for histone demethylases. The H3K4 demethylase JARID1B (also known as KDM5B), involved in mammary gland development and GATA3 recruitment to FOXA1 promoter [134], was found frequently amplified and overexpressed in multiple breast cancers, particularly in luminal cancers where overexpression of JARID1B target genes identified a subset of patients with poorer survival [135]. Another demethylase, LSD1 (also known as KDM1A), which targets H3K4 mono- and di-methylation and is involved in enhancer "decommissioning" during cell differentiation [136], was found to regulate breast cancer metastasis [137]. LSD1 inhibitors are in early clinical trials but have not been yet tested in breast cancers.

4.3.5 Chromatin Readers

Chromatin "readers" are proteins with domains able to recognize specific chromatin modifications and guide locus-specific assembly of transcription regulator complexes. A relevant example in breast biology is the Pygo2 factor that contains the PHD finger domain able to recognize H3K4me3. Pygo2 is a crucial transducer of WNT signals in breast development [138] and is essential for the survival of several breast cancer cell lines [139]. Disruption of chromatin interaction is a novel pharmacological strategy that has yielded intriguing results when targeted against bromodomain-containing proteins. These interact with acetylated histones and are important factors for super-enhancer activity. As super-enhancers are associated with highly tissue- or cancer-specific transcription [140], their targeting might benefit from an elevated therapeutic index. BET inhibitors, of which JQ1 is the progenitor, are undergoing rapid drug development and have recently shown particularly promising activity in triple-negative breast cancer [141].

Conclusions

Full understanding of the molecular pathways described in this chapter will require an elevated degree of integration between developmental biology, biochemistry, and epigenomics. The benefits that can be reaped for patients are high, as targeting differentiation and stem cells may lead to durable responses or even disease eradication, unachievable with drugs targeting proliferation or genome stability. Technological advancements of the last decade have made this endeavor realistic.

Breast Cancer Microenvironment and the Metastatic Process

5

George Sflomos and Cathrin Brisken

5.1 Introduction

Breast cancer is the most frequently diagnosed cancer, the second leading cause of cancer-related death in women worldwide, and the leading cause of cancer-related death in less developed countries [1]. Overall prognosis is favorable with 85% survival chances in developed countries [2]. Most of the remaining 15% of patients succumb to sequelae of metastasis, the spread of cancer from one part of the body to another (Dictionary of Cancer Terms, NCI), as their disease becomes drug resistant. In poorer countries, women are more likely to die of their metastases because they are diagnosed at later stages of the disease and have less access to costly treatments [3–5].

In general, breast cancer cells that escape from the primary tumor take the lymphatic and/or venous route and home most frequently to the bones, the lungs, the brain, and the liver. The WHO distinguishes more than 20 different histologic subtypes [6], and global gene expression profiling has revealed at least 5 molecular subtypes of breast cancer [7–9]. Some of these subtypes have distinct clinical features and show different metastatic behaviors. Luminal/estrogen receptor-positive (ER^+) tumors disseminate more frequently to the bones than TN tumors do, and human epidermal growth factor receptor 2-positive ($HER2^+$) and TN tumors have a predilection for the brain [10]. Lobular carcinomas typically metastasize to the peritoneum and the ovaries [11].

Metastasis is a complex pathological process, and seven distinct steps have been defined at the cellular level. It begins with increased cell motility and cell migration followed by stromal invasion. Subsequently, tumor cells intravasate into lymphatic and/or blood vessels; they adapt to survive in the circulation; they extravasate, colonize distant organs, and eventually, sometimes after many years of dormancy, grow to overt metastases [12–15].

For decades, most research efforts concentrated on the cancer cell-intrinsic factors that drive this process. In recent years, the tumor microenvironment (TME) defined as the normal cells, molecules, and blood vessels that surround and feed a carcinoma (Dictionary of Cancer Terms, NCI) has moved to the center of attention. Both at the primary and at the metastatic sites, numerous noncancerous cells, cancer-associated specialized cell types, and matrix molecules interact with the tumor cells and affect their biological properties [16–18]. Heterotypic cell contacts, exosomes, cytokines, and other soluble factors produced by cancer and stromal cells are now known to support tumor initiation, progression, and metastatic spread [19]. In conventional breast cancer xenograft models, breast cancer cell lines are typically injected either subcutaneously or orthotopically in the mammary fat pad of immunocompromised mice [20]. Intriguingly, the site of injection affects metastatic capability with increased metastasis observed upon orthotopic engraftment [21, 22].

Throughout the multistep metastatic process, tumor cells rely on epithelial-mesenchymal transition (EMT) [12, 23]. This well-characterized process is repeatedly required during development as for the formation of the mesoderm from epithelial epiblasts during gastrulation, neural crest formation, and formation of muscle cell precursors from epithelial somite walls. In adulthood, it has a role in wound healing [12, 24–27]. All these processes have in common that epithelial cells dedifferentiate, lose cell adhesion, become more migratory, and acquire stem cell properties. Cancer cells hijack this developmental program to detach from the epithelial tissues of which they are part, to reach vessels, and to

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_5

acquire the self-renewal properties and the cellular plasticity important in the metastatic process [28]. At the distant organ, the reverse process called the mesenchymal-to-epithelial transition (MET) is commonly found at metastases [27, 29]. Intriguingly, recent in vivo studies of murine tumors are arguing for a role of EMT and MET transitions in breast cancer drug resistance [30].

Here, we review how the cancer microenvironment affects the spread of cancer cells to distant sites and discuss how the microenvironment at the distant sites contributes to colonization and to the growth of the metastases. The important role of the normal tissue microenvironment as a barrier to tumorigenesis has been extensively described elsewhere [31]. Most of our insights into the metastatic process stem from experimental models, which do not distinguish between different clinical subtypes. Hence, wherever possible, we refer to clinical observations that provide clues of subtype-specific properties.

5.2 Cancer Cell: Nonautonomous Traits and Breast Tumor Microenvironment

Cancer-associated stromal cells react to the morphological and molecular changes the tumor cells undergo by epigenetic changes and alterations of their secretome [32]. The released factors can affect tumor progression directly and/or indirectly through recruitment of other cells, nonindigenous to the breast tissue. Examples are bone marrow-derived, mesenchymal stem cells and innate and specific immune cells, which in turn participate in stimulating a vicious cycle of cell-to-cell and factor-to-cell interactions.

5.2.1 Cell Types and Secreted Factors

5.2.1.1 Fibroblasts and Mesenchymal Stem Cells

The fibroblasts are the most abundant cell type in the breast stroma [33] and can both inhibit [31, 34] and promote tumor growth [31, 33–36]. During tumor progression, fibroblasts are converted cells to activated fibroblasts or cancer-associated fibroblasts (CAFs) by transforming growth factor β1 (TGFβ1) [37], Wnt7a, and other factors secreted by the tumor cells [33, 38, 39]. CAFs are characterized by high-level expression of fibroblast-specific protein 1 (FSP1), fibroblast-activating protein (FAP), alpha-smooth muscle actin (α-SMA), and TGFβ1 [40]. They orchestrate and promote the metastatic process in two ways; first, they induce EMT through activation of TGF-β receptor signaling and extracellular matrix (ECM) remodeling [34]. Second, they recruit innate and specific immune cells to the TME and subsequently activate them. The activated immune cells, in turn, stimulate the metastatic potential of cancer cells [18, 33, 35]. More specifically, CAFs release immune-modulatory molecules including interleukins, interferons, and tumor necrosis factor α (TNFα) to attract macrophages. The tumor-associated macrophages (TAMs) are the dominant portion of the leukocyte population within the tumor [41]. They can modify the cancer cell phenotype generally leading to a more aggressive behavior in breast cancer, through factors that have not been clearly identified yet, but hypoxia has been implicated [42]. TAMs in turn, at least in models of skin carcinoma, support tumor angiogenesis [39]. Moreover, CAFs recruit regulatory T cells (Tregs) through the secretion of various chemokines including CCL5, as shown in GEMMs of mammary carcinogenesis [43].

Experiments in the TN MDA-MB-231 xenograft model showed that CAFs control organ specificity of metastases by secreting two cytokines that are mainly expressed by stromal cells in the bone marrow, the stromal cell-derived factor 1 (SDF1/CXCL12) and the insulin-like growth factor 1 (IGF-1) [44, 45]. Activation of the cognate receptor, CXCR4, on the cancer cells activates AKT thereby increasing tumor cell survival in the bone [46]. Bioinformatic analysis of primary tumor gene expression profiles revealed that Src activity correlated with late bone metastasis, and Src activity was shown in the MDA-MB-231 model to indeed enhance tumor cell survival in the bone by facilitating CXCL12-CXCR4-AKT signaling and by increasing resistance to TRAIL-induced cell death [46].

Mesenchymal stem cells (MSCs) are recruited to damaged and ischemic tissues. More recently, they were also shown to be drafted to the TME following calls by numerous factors such as growth and angiogenic factors as well as chemokines and ECM proteases, all released by cancer and stromal cells as reviewed in [47, 48]. The MSCs present in invasive human breast carcinomas can be differentiated into various cell types including fibroblasts and pericytes, and their effects on tumor growth are complex. They were shown to promote tumor growth and angiogenesis through elevated SDF1 secretion [49]. Experiments in subcutaneous breast xenografts showed that once recruited to the TME, MSCs in turn secrete the chemokine CCL5, which increases the motility and invasiveness of the cancer cells, which express the cognate receptor CCR5, and promote lung colonization [50].

5.2.1.2 Adipocytes

Another prevailing cell type in the TME is the adipocyte that also interacts in different ways with the tumor cells [51, 52]. Analyses of human clinical samples and *in vivo* experiments with mice have shown that adipocytes are frequently found at the invasive front of human breast tumors. Here a dialogue between the cancer cells and adipocytes occurs; the invading tumor cells are able to modify the adipocytes,

which in turn stimulate cancer cells to a more aggressive phenotype [53].

Furthermore, the fat cells promote tumor progression through systemic effects by secreting hormones, such as oestradiol (E2) and prolactin, as well as paracrine factors like the major fat tissue-derived adipokines such as leptin and adiponectin which promote breast cancer progression through activation of proliferation and survival [54–56]. A series of in vitro coculture and in vivo experiments suggest that secretion of interleukin-6 (IL-6) by adipocytes makes tumor cells more invasive and increases their metastatic potential [53]. Similarly adipocytes promote breast cancer progression through secretion of pro-inflammatory cytokines such as TNFα, which increase stem cell numbers and enhance metastasis in cell coculture and animal models [57, 58].

In this regard, the tumor-promoting effects of obesity, which are observed in postmenopausal women, relate to increased levels of E2 and of pro-inflammatory cytokines released by the adipose tissue [59, 60]. Elevated systemic E2 levels result from increased aromatase activity not only the adipocytes of the TME but in various fat depots in the body. To what extent these effects are important for the metastatic process systemically versus locally remains to be teased apart experimentally. Interestingly, when human breast adipocytes from obese patients were grafted to immunocompromised mice to model the inflammatory environment of the human breast, the mouse tumors were enriched with adipocytes secreting CCL2/IL-1β. This recruited macrophages, which in turn stimulated CCL2-associated angiogenesis [61].

5.2.1.3 Vasculature

The vasculature in the TME is another key player in the instigation of metastasis. It consists of an inner layer of endothelial cells, pericytes that wrap around the endothelial cells, and, in the case of larger vessels, smooth muscle cells. During tumor progression, the normally quiescent vasculature is activated by VEGF released by tumor and stromal cells, and new vessels sprout to sustain tumor growth [12, 62]. Critical to the metastatic process is vessel integrity, which deters cancer cell migration and prevents tumor spread into the circulation. Pericytes are responsible for vessel integrity. Consistently, many studies in mouse models have shown that low pericyte coverage is associated with invasive breast cancer, decreased survival, and lung metastasis [63–65].

5.2.1.4 Immune Cells

It was realized a long time ago that the white blood cells, which constantly patrol normal breast tissue, also closely interact with breast tumor cells [66]. Their role is ambiguous; frequently, differentiated tumor-infiltrating immune cells and "tumor-educated" macrophages further the multistep metastatic cascade by promoting tumor cell invasion, intravasation, and their survival in the bloodstream. They also assist in tumor cell arrest, extravasation, and overt growth at metastatic sites [67]. In specific clinical scenarios, however, an immune cell infiltrate is indicative of a good prognosis [68].

Studies with the MMTV-Erbb2-transgenic mouse mammary carcinoma model [43] showed that tumor-infiltrating regulatory T cells promoted lung metastasis through expression of the receptor activator of nuclear factor kappa-B ligand (RANKL), a protein implicated in epithelial cell proliferation of the normal breast [69]. Consistently, RANKL overexpression stimulated the metastatic progression of RANK-expressing and HER2-overexpressing mammary tumors [43, 67].

Recent studies in a mouse model of invasive lobular carcinoma generated by targeted deletion of E-cadherin and p53 in the mammary epithelium indicate that neutrophils induce the release of several cytokines in the TME that increase lung metastasis without affecting primary tumor growth [70, 71]. Moreover, neutrophils support lung colonization of metastasis-initiating tumor cells in the metastatic MMTV-polyoma middle T antigen (PyMT) mammary tumor mouse model [72].

Initially, macrophages were implicated in the antitumor immune reaction [73, 74]. However, recent studies indicate that TAMs promote angiogenesis, cell migration, invasion, and intravasation, thereby increasing the propensity of the cells to leave the primary site [75]. In the PyMT mammary tumor model, macrophage infiltration is seen early during tumor development when hyperplasias are present [76]. The recruitment of TAMs into TME is principally regulated by cytokines, chemokines, and growth factors secreted by both tumor and stromal cells [77]. In breast cancer patients, TAMs abundantly produce the chemokine CCL18, and its expression in cancer stroma and blood is associated with increased metastasis and reduced patient survival [78]. Mechanistically, CCL18 promotes the invasiveness of cancer cells by triggering integrin clustering and enhancing their adherence to extracellular matrix [78].

5.3 Breast Tumors in Transient and Metastatic Microenvironments

Breast cancer cells enter the lymph vessel in the TME and ultimately reach the blood vessels. Anytime after intravasation in the bloodstream, they may encounter antitumor immune cells and metabolic and oxidative stress and be exposed to extensive shear forces in the bloodstream. Once in the vessels, circulating tumor cells (CTCs) need to exit from the lumen of blood and/or lymphatic vessels and penetrate to the distant tissue. This process is highly inefficient with an estimated 1 out

of 10,000 cells successfully extravasating and homing to a distant site [16, 79, 80]. Many different cell types can be found in the blood including immune cells, fibroblasts, and platelets with important roles in the metastatic process [32].

5.3.1 Platelets

Platelets have emerged as essential "protective" escort of the carcinoma cells on the move; they appear to constitute a special type of mobile "local" microenvironment [81, 82]. Physiologically, platelets are activated when the continuity of the endothelial layer is disrupted and the underlying subendothelial matrix is exposed [83]. In the breast tumor setting, they can be activated through physical contact with tumor cells [84]. At the primary site, platelets along with macrophages and MSCs contribute to EMT of the cancer cells. In the bloodstream, platelets have dual role in the fitness of disseminated breast tumor cells both through direct physical contact and through secretion of paracrine factors both of which increase tumor cell survival and extravasation by maintaining or/and inducing an EMT status [84]. In vivo experimental evidence indicates that the paracrine effects can be ascribed to the secretion of bioactive growth factors stored in α-granules, such as EGF, PDGF, TGFβ, and VEGF, as well as inflammatory cytokines and chemokines also stored in α-granules [84, 85]. Within the peripheral tissues, activated platelets contribute to the recruitment of monocytes and granulocytes thereby helping to establish pro-metastatic and metastatic niches [83, 85, 86].

5.3.2 Metastatic TME (MTME)

Metastatic sites are generally considered inhospitable microenvironments and present a challenge to cancer cell fitness and survival [16]. Consistently, many of the CTCs that successfully extravasated from the bloodstream to a distant tissue remain dormant for months or, in the case of ER^+ tumors, even decades. Only some get reactivated and go on to form clinically apparent tumors. Several lines of evidence indicate that secreted factors, produced by tumor and stromal cells in the TME, promote the progression of tumor-specific organ colonization. Heparanase endoglycosidase secretion by primary breast tumors promotes bone resorption in a GEMM model [87]. Furthermore, tumor cell-derived exosomes may represent the postal code on a letter and lead to distinct organ colonization depending on the integrins they carry [88]. Noteworthy, the microenvironment at the distant site can induce epigenetic changes that enhance proliferation and reduce apoptosis of the metastatic cancer cells as was elegantly illustrated by xenograft mouse models [89]. Intriguingly, metastatic breast cancer cells that have lost phosphatase and tensin homolog (PTEN) are primed for the brain most probable through the induction of the chemokine (C-C motif) ligand 2 (CCL2) [89]. Moreover, immunohistochemical analysis of clinical samples for PTEN and CCL2 revealed significantly higher CCL2 expression in brain metastases than in matched primary tumors. Mechanistically, epigenetic regulation is implicated; astrocytes secrete exosomes that cause adaptive PTEN cancer cell loss [89]. Moreover, metastatic cancer cells can directly interact with stromal cells. This heterotypic dialogue with the distant stroma can provide support to the cancer cells at the early steps of colonization and promote metastasis as nicely illustrated experiments in a xenograft model of intrailiac artery injection [90]. In this model, the ER^+ breast cancer cells, MCF7, colonized efficiently the bones and made physical contacts with osteogenic stromal cells through adherens junctions. This led to increased cell proliferation of cancer cells and growth of metastasis through the activation of mTOR pathway [90]. On the other hand, cancer cells activate bone cells. For example, bone metastatic breast cancer cells promote osteolytic lesions by stimulating the formation and activity of osteoclasts via production of colony stimulating factor 1 (CSF1) as well as parathyroid hormone-related protein (PTHRP) and tumor necrosis factor-α (TNFα) [91]. The secretion of these cytokines and hormones activates the RANK pathway and inhibits the synthesis of the osteoprotegerin, thereby increasing the number and activity of osteoclasts. Finally, xenograft experiments have revealed ER^+ breast cancer-mediated systemic instigation by supplying circulating platelets with pro-inflammatory and pro-angiogenic proteins, supporting outgrowth of dormant metastatic foci [92].

5.3.3 Hypoxic Conditions in the TME

As tumors grow, lack of adequate oxygen supply leads to hypoxia. Hypoxic breast cancer cells are more prone to invade and metastasize, and they also respond less efficiently to drug treatment [93]. Central in the cellular response to hypoxia is the transcription factor hypoxia-inducible factor 1α (HIF1α); it upregulates cytokines, extracellular matrix proteins, and secreted proteins such as lysyl oxidase (LOX).

The HIF1α target LOX is highly expressed in primary breast tumors and is significantly associated with metastasis in ER^- patients [94]. Moreover, LOX is a critical mediator of bone marrow cell recruitment during the formation of the pre-metastatic niche [95]. HIF1α facilitates the initiation of EMT by inducing the expression of the master mesenchymal regulator, the transcription factor TWIST [96]. Hypoxia also triggers the release of exosomes. Studies using the 4 T1-BALB/c syngeneic animal model of metastatic mammary carcinoma showed that LOX activates normal bone-constituent cells called osteoclasts, which in turn enhance bone breakdown, favoring the formation of a pre-metastatic niche where disseminated circulating breast cancer cells find the appropriate microenvironment to form metastasis [94]. Preparation of the niche [97] is a key regulator of angiogenesis [98].

5.4 Cancer Cell-Autonomous Traits

5.4.1 Genetic Aberrations

Tumor cell-intrinsic factors that contribute to metastasis include genetic and epigenetic alterations with the ensuing changes in gene expression and biological properties. Numerous somatic mutations, gene fusions, gene amplifications, and cancer predisposing single-nucleotide polymorphisms are well documented in breast cancer [55, 99–102]. Some of these are thought to drive tumorigenesis by bestowing essential tumor cell properties on normal cells [12]. However, despite many efforts to identify mutations specific to metastases that could trigger a metastatic switch, evidence for such failed to come forward. Hence a model began to prevail in which the ability to metastasize is inherent to the primary breast tumor. In line with this view, gene expression signatures were identified in primary tumors that are associated with higher likelihood to metastasize [14, 103–105].

Recent findings, however, have challenged this view. Advances in sequencing technology have led to the realization that tumors can be composed of a myriad of different subclones [106], and xenograft models combined with DNA bar coding technology have revealed unexpected dynamics during tumor evolution [107]. With the in-depth comparisons of DNA sequences from primary tumors and their matched metastases, examples of metastasis-specific mutations are beginning to emerge. The most prominent example is mutations in the estrogen receptor α (*ESR1*). They were originally identified two decades ago by S. Fuqua and colleagues who screened metastatic samples for *ESR1* mutations [108] but largely dismissed as a very rare event. This changed when deep sequencing revealed that they occur in as many as 32% of metastases [109] and in as many as 42% of circulating tumor DNA (ctDNA) samples from women with metastatic ER$^+$ disease who had been treated with aromatase inhibitors for their metastatic disease [102]. In primary breast carcinomas, these mutations either failed to be detected at all or were found in less than 0.6% only [102, 109, 110]. Most of the mutations are found at the C-terminus in the ligand-binding/AF2 domain and lead to estrogen-independent growth in vitro [111]. This suggests that metastatic cells require constitutively active ER signaling for the survival and growth in the metastatic microenvironments in the absence of estrogens.

Recently, whole-exome sequencing of 86 brain metastases and matched primary tumors including 21 breast tumor samples identified metastasis-specific mutations [112]. Specifically, analysis of breast cancer brain metastases revealed that 47% of genetic aberrations were not detected in the same patient's primary tumor. Patients with HER2-amplified breast cancer who developed brain metastasis under trastuzumab showed amplification and activating point mutations in epidermal growth factor receptor (*EGFR*) (L858R) and fibroblast growth factor receptor (*FGFR1*) amplification specifically in the metastatic sample but not in the primary tumor DNA. The findings from this study are of important clinical implications, as both the *EGFR* and the *FGFR* mutations are druggable. The mutations that appear only in the metastatic sites may relate to the therapeutic responses and the way the cancer cells interact with the TME [113].

Mutations in GATA binding protein 3 (GATA3) interfere with its DNA-binding ability, reducing or diminishing its binding, and are commonly found in NST luminal-like molecular subtype in human breast cancers [100] with high frequency (13%) [99, 114]. Moreover, loss of GATA3 expression in breast tumors has been linked to aggressive tumor development, poor patient survival, and increased metastatic potential [115–119]. In a spontaneous metastasis experimental model using the LM2 lung-tropic breast cancer cells that were derived from MDAMB231, increased expression of GATA3 specifically inhibited metastasis to the lungs without affecting extravasation [116]. Mechanistically, GATA3 induces *microRNA-29b* expression, which in turn inhibits metastasis by targeting a network of pro-metastatic regulators involved in angiogenesis [115].

Mutations in phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (*PIK3CA)* are found in 40% of ER$^+$ breast cancers. A study of 292 clinical samples derived from independent international cohorts analyzed for the presence of mutations showed that they are correlated with lymph node metastasis suggesting that PI3K/AKT activation may enhance invasion of cancer cells to lymph nodes [120]. Of note, *BRCA1* germline mutations, which typically lead to aggressive breast cancers, have been linked to increased probability of cerebral metastases [121]. In particular, 67% ($n = 15$) of *BRCA1* mutation carriers were found to develop metastases in the brain compared to 0 and 6% of *BRCA2* mutation carriers ($n = 12$) and noncarriers ($n = 58$), respectively.

Mutations in genes that are implicated in metabolic processes have recently been identified and amplification of genes encoding for metabolic enzymes has been found in breast cancers. An example is the gene encoding phosphoglycerate dehydrogenase, which is frequently amplified in TN breast cancers and increases flux through the metabolic pathway of serine/glycine synthesis thereby providing advantages for bone metastatic breast cancer cells because cell proliferation is stimulated and osteoclastogenesis enhanced [122, 123]. Moreover, the proto-oncogene Neu product (ERBB2) stimulates glycolysis by AKT1-dependent and AKT1-independent pathways. Interestingly, in many breast cancer cell lines, overexpression of ERBB2, a hallmark of HER2$^+$ tumors, leads to increased glucose uptake and lactate production and decreased oxygen consumption [124]. Whether this contributes to the increased propensity of HER2$^+$ tumors to metastasize to the brain remains to be explored. It remains also to be seen how metabolic changes are related to metastasis and which are the exact molecular mechanisms that give advantages to the cancer cells to access vessels and survive in the bloodstream and establish metastases.

5.4.2 Noncoding RNAs (ncRNAs)

Over the past years, ncRNAs have emerged as important mediators in the crosstalk between breast cancer cells and their microenvironment [125]. During breast cancer progression, expression of particular small, (miRNAs) is deregulated. When human breast cancer cell lines were injected into the tail vein of immunocompromised mice, seven miRNAs, miR-335, miR-126, miR-34a, miR-31, let-7, miR-200 s, and miR-29b, suppressed—whereas miR-10b, miR-373/520c, miR-200 s, miR-21, miR-9, and miR-103/107 promoted—several steps of the metastatic process [125, 126]. In particular, loss of expression of tumor suppressor miRNAs through epigenetic silencing lead to increased brain and lung metastases [126, 127]. Mechanistically, silencing and/or overexpression of specific miRNAs affects the expression of numerous genes, including genes involved in EMT, endothelial recruitment, anoikis resistance, invasion, and colonization. For example, silencing of miR-200 s triggers EMT via ZEB1/2-dependent repression of E-cadherin upregulation or miR-21 upregulation which is correlated with active mTOR and STAT3 signaling and increased invasion, tumor growth, and survival. miR-29, which inhibits breast cancer metastasis, for example, targets genes with established roles in collagen remodeling and angiogenesis such as VEGFA, LOX, MMP2, ANGPTL4, and PDGF. Interestingly, micro-vesicles secreted by tumor cells are enriched for miR-9 and have a direct impact on stromal cells through the regulation of the endothelial cell migration.

5.5 Conclusions and Future Perspectives

In vitro and in vivo studies have significantly advanced our understanding of the metastatic process and identified numerous pathways and molecular mechanisms that control it (Fig. 5.1). However, some limitations of the models need

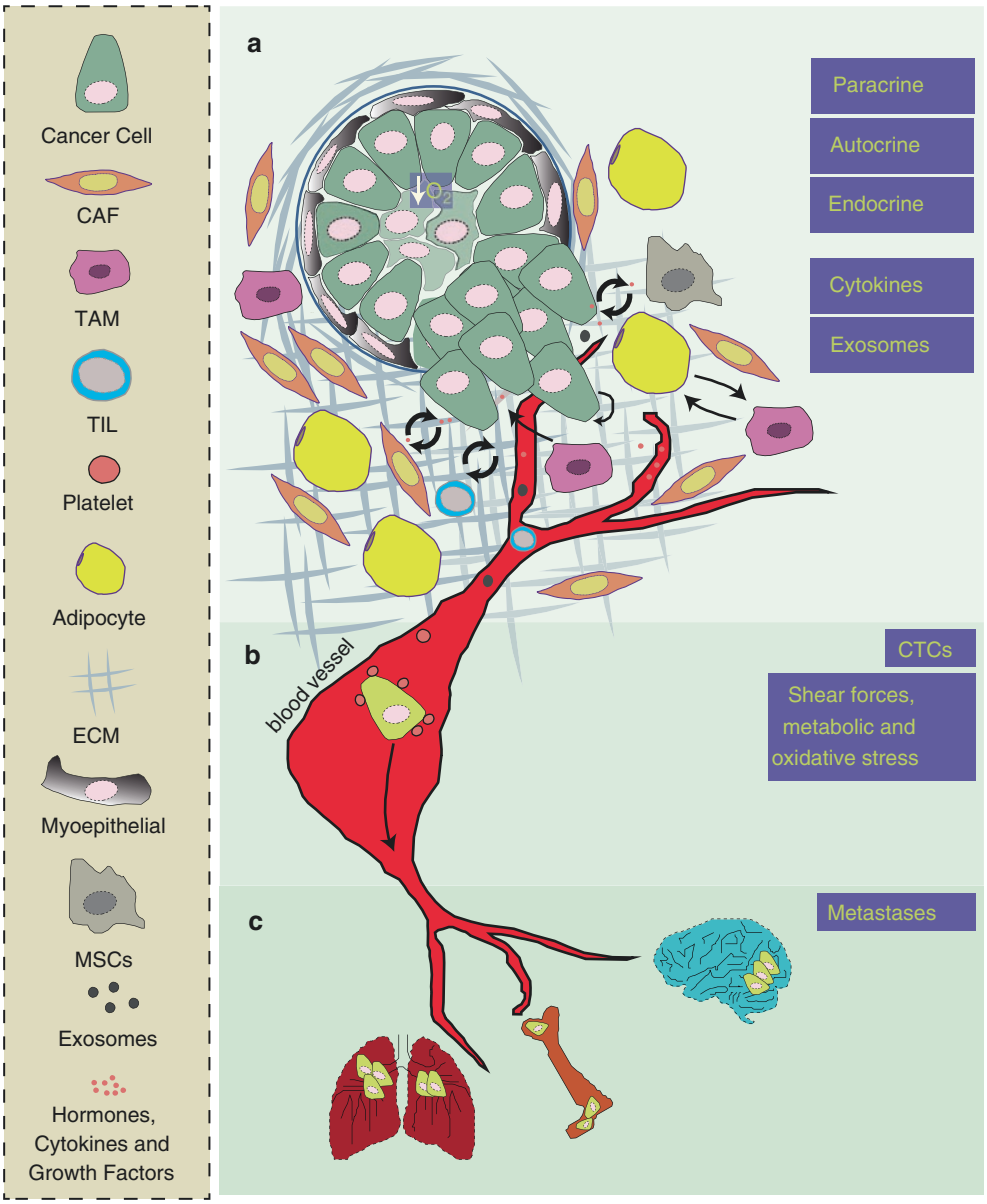

Fig. 5.1 Interactions of breast cancer cells with stromal cells and molecular factors of the tumor microenvironment: **a** Cells and molecular factors found at the primary breast tumor microenvironment and their heterotypic interactions, **b** Circulating tumor cells (CTCs) that have detached from the primary tumor travel in the bloodstream and constitute potential "seeds" for metastases, **c** Breast cancer cells that escape from the primary tumor and survive in the bloodstream frequently colonize and potentially can form metastases to distant organs

to be considered as we try to extrapolate the experimental findings to the clinical situation. The widely used animal models fail to fully reflect the heterogeneity of breast cancer with its many different histopathological and molecular subtypes. It cannot be excluded that some of the factors implicated in xenograft models and GEMMs of a particular subtype may have different roles in different breast cancer subtypes. In particular, a lot may remain to be learned about the hormone-dependent tumors because there are few preclinical models for the ER$^+$ subtypes [128]. GEMMs are mostly ER negative, and few ER$^+$ breast cancer cell lines grow as xenografts. We also need to consider that widely used xenograft models, in which large numbers of cells are injected either subcutaneously, directly into the bloodstream, or to a distal organ, create artifacts that affect the interpretation of the results, and they fail to recapitulate the complete metastatic process. The few ER$^+$ cell lines that grow in vivo need to be provided with exogenous E2 [129]. This creates a nonphysiological systemic environment, which in turn impinges on the local microenvironments. A study with mice that had been xenotransplanted with MCF7 cells and were first hormone depleted by ovariectomy and subsequently hormonally stimulated suggests that ER$^+$ micrometastases are exquisitely sensitive to E2 and progesterone [130]. We have recently demonstrated that the microenvironment is a determinant of the luminal phenotype; ER+ tumor cells grow well in the absence of exogenous hormones when they are engrafted into the milk ducts. Interestingly, in this model MCF-7 cells metastasize to the bones as well as lungs and brain [131]. As such it will be interestign to study the metastatic process in this new model.

Hence more complex models are necessary to improve our knowledge on heterotypic interactions and paracrine signaling and elucidate the role of numerous significant factors such as ECM stiffness and mechanical forces in the TME. 2D coculture, 3D coculture, organotypic slice culture, and in vivo findings need to ultimately be validated in patients.

Mouse Models of Breast Cancer: Deceptions that Reveal the Truth

6

Joana Pinto Couto and Mohamed Bentires-Alj

6.1 Introduction

Breast cancer is the most frequently diagnosed malignancy and results in the highest cancer mortality in women aged 20–59 years worldwide [1]. The disease usually progresses from hyperplasia to ductal carcinoma in situ (DCIS), and subsequently invasive carcinoma and metastasis, the latter accounting for almost all deaths among these patients [2].

Breast cancer is not a single homogeneous disease but rather a collection of distinct phenotypes that can be distinguished using clinicopathological parameters such as receptor status [estrogen receptor (ER), progesterone receptor (PR), and/or ErbB2/HER2] [3]. These parameters have a prognostic value and guide the selection of therapies. For example, most triple negative breast tumors (ER, PR, and ErbB2/HER2-negative), which occur in around 20% of breast cancer patients, present the worst prognosis. Unlike patients with ER-, PR-, and ErbB2/HER2-positive tumors, who receive antihormone or anti-HER2 therapies, targeted therapy for triple negative breast cancer is still lacking. While some patients with metastatic disease initially respond to therapy, curative strategies for the majority are not available.

In early 2000, seminal studies using molecular profiling segregated breast cancers into normal-like, luminal A, luminal B, HER2-enriched, claudin-low, and basal-like [4–6]. These subtypes are associated with clinical prognosis [4, 7–10] and possibly response to therapy [11]. Such studies were complemented later by integrated genomic and transcriptomic analyses that revealed additional subgroups with distinct clinical outcomes and also increased awareness of tumor heterogeneity [12–17]. Heterogeneity is found among tumors from distinct patients (interpatient heterogeneity), within primary tumors (intratumoral heterogeneity) or metastatic lesions (intrametastatic heterogeneity), and among different metastases of the same patient (intermetastatic heterogeneity) [18]. These taxonomic studies paved the way to ongoing research that attempts to rationalize the genomic alterations found in cancer cells and to leverage this knowledge for improved therapy of patients with breast cancer.

"A model is a lie that helps you see the truth," according to American oncologist Howard Skipper. Indeed, mouse models have been crucial to our understanding of the etiology of cancer and its dependencies, as well as to the validation and advancement of drug candidates in the clinic [19]. In this chapter, we discuss mouse models used in breast cancer research, in particular those that have shed light on the mechanisms of the disease and have assisted in the identification and/or validation of therapeutic targets. We will elaborate on the earliest models and then discuss transplantation-based models and finally transgenic mice.

6.2 The Earliest Models: Spontaneous and Carcinogen-Induced Mammary Cancer

Detailed narratives of mouse models of breast cancer from the mid-nineteenth century up to recent years have been elegantly provided by R. Cardiff and D. Medina [20, 21]. The first studies of mouse mammary cancer were performed on spontaneous tumors, mostly those involving the mouse mammary tumor virus (MMTV) or other oncogenic viruses that trigger mammary cancers in certain inbred mouse models [22]. In 1982, R. Nusse and H. Varmus discovered that MMTV is an insertional mutagen that activates transcription of proto-oncogenes located near its integration sites [23]. Several of these insertion sites were later found to include members of the *Wnt*, *Fgf*, and *Rspo* gene families, as well as *eIF3e* and *Notch4* and others [24–26]. Following the development of transgene technology, the MMTV-LTR

(long terminal repeat) has been used up to this day to drive gene expression in the mammary gland of over 50 transgenic mouse models of breast cancer [22].

Besides viruses, mammary tumors can also be induced by treatment with various chemicals (reviewed in [20]). The most frequently used chemical carcinogens have been 3-methylcholanthrene, 7,12-dimethylbenzanthracene (DMBA), and urethane, of which DMBA is the most potent, although its effect on mice is strain dependent. Since most of these chemical carcinogens are not significant etiological agents for human breast cancer, their use in research has declined over the years. In fact, radiation is the only well-documented environmental carcinogen in the mammary gland, and irradiated mouse mammary glands are considered to be a relevant model for carcinogen-induced human breast cancer [27, 28].

Hormones also contribute to mammary cancer. One of the earliest indications of the importance of hormones for mammary tumorigenesis dates back to an observation in 1896 that removal of the ovaries from a woman with breast cancer caused tumor regression [29]. Further experiments showed that ovarian estrogens contribute to breast cancer initiation and progression [30], paving the way for the development of agents that block estrogen signaling (e.g., tamoxifen). Further evidence of the importance of hormones in mammary tumorigenesis is that continuous exposure to prolactin induces mammary tumors in mice [31].

6.3 Transplantation Models of Breast Cancer and Metastasis

Tumorigenesis and metastasis are multistep processes involving profound interactions between transformed cells and the surrounding environment, for example, immune cells. Cancer immunoediting has been proposed as a mechanism of such interactions in which the immune system eliminates abnormal antigen-expressing cells during tumorigenesis (a process termed elimination). This may result in an equilibrium state in which tumor cells that escaped elimination remain under the influence of the host immune system. However, cells may eventually escape this immune surveillance and lead to overt tumor development and metastatic dissemination [32].

The fatal hallmark of breast cancer is its ability to metastasize [33, 34]. During metastasis, cancer cells penetrate the basement membrane and reach blood or lymph vessels (intravasation) (1) survive in the circulation (2) extravasate into secondary organs (3) where they may remain dormant (4) or proliferate and colonize the organ [35]. Clearly, no single approach can model all aspects of this complex process, and several transplantation-based models and techniques have been developed to study the metastatic cascade. The pros and cons of each approach can be examined, and those appropriate to the question of interest can be applied. The operation of a functional immune system in the recipient mouse model (syngeneic model) or its deficiency (xenograft model), the use of ectopic or orthotopic transplantation, and the transplantation of a tumor fragment or cancer cells or a primary tumor-derived xenograft will all have paramount consequences for mammary tumor development, progression, metastatic tropism, and growth.

6.3.1 Transplantation in Immunocompetent Versus Immunodeficient Animals

The microenvironment contributes significantly to breast tumorigenesis. Given that some secreted factors lack cross-species mouse-human reactivity [36], the transplantation into syngeneic hosts of mammary cancer fragments or cells from carcinogen-induced tumors or from genetically engineered mice is crucial to the study of tumor-host interactions. Syngeneic models are very important for dissecting cross talk between cancer cells and the immune system, particularly given the importance of the latter in tumor progression and metastasis. They are equally important for the study of antitumor immunotherapy.

Inbred mice, however, do not recapitulate the complexity and diversity of human genomes and may display mouse-specific oncogenic idiosyncrasies. To avoid these potential limitations, human cancer cells can be transplanted into immunodeficient mice; a method referred to as xenograft transplantation. The most common mouse strains used for the implantation of human cells are *nu/nu* (nude), *Rag1/2* knockout (KO), SCID, SCID-beige, NOD-SCID, NOG, and NSG. These differ in the severity of their immune defects [37], angiogenesis, and metastasis susceptibility [38]. As discussed above, tumor-host interactions may be limited by species boundaries, and the absence of the immune system precludes the investigation of this major contributor to tumor surveillance and progression to metastasis when human cells are transplanted into immunodeficient mice. The development of humanized models may circumvent this potential drawback [37].

6.3.2 Sites of Transplantation: Ectopic Versus Orthotopic

With the generation of the first inbred mouse strain (DBA) in 1910 by C.C. Little and the development of subsequent inbred strains [39], transfer of cells from one organism to another and the growth of explants in a precise and reproducible manner were finally possible [20]. Mammary cells and tumors are transplanted in two ways: orthotopic and ectopic.

In *orthotopic* transplantation, cells are implanted at the site of the initial tumor. This technique has been used extensively in breast cancer research, given the easy accessibility of the mouse mammary gland. In 1959, DeOme and his student Faulkin developed cleared fat pad transplantation, the signature technique of the mammary gland field [40]. This consists of removing the rudimentary mammary ductal tree of a 3-week-old recipient female mouse. Normal or neoplastic mammary gland fragments or cells from a donor mouse are then implanted into the resulting epithelium-free fat pad. This assay has proved valuable for studying the biology of the normal and neoplastic mammary gland, e.g., of stem cell potential, tumor initiation, and the contributions of stromal and epithelial cells to these processes [20]. Orthotopic transplantation is particularly useful when applied to transgenic mice that develop other neoplasias prior to the onset of mammary tumors, for example, in the case of p53-null mice [41]. Transplantation of p53-null preneoplastic cells into syngeneic mice was found to be sufficient to promote mammary tumorigenesis [41, 42], and this was further enhanced by hormonal stimulation [41]. Orthotopic transplantation can also be performed without removal of the mammary ductal tree, especially when the sources of the explants are tumor cells or fragments. This method may result in more metastases than ectopic transplantation [38] and is referred to as the "spontaneous metastasis model." Recently, the team led by D. Medina has developed a variation of the orthotopic method by injecting breast cancer cells intraductally. This method is effective for studying the progression from DCIS to invasive carcinoma [43, 44].

One problem that can arise when transplanting cancer cells is that before the animals develop metastases, the tumors grow to such an extent that the experiment must be terminated for ethical reasons. This is common with fast-growing cancer cell lines. To overcome this obstacle, tumors can be resected, allowing more time for metastases to develop. This approach can be particularly useful in overall survival studies, which should be the main readout of the success of treatments in preclinical models. In fact, it has been shown that primary tumor metrics do not necessarily predict metastatic behavior and disease progression in mice [45, 46] (Amante R, Leroy C, and M.B-A., unpublished data).

Cancer cells can also be injected ectopically into the highly vascularized renal capsule or subcutaneously, although these sites do not mimic the original microenvironment of breast tumors. Injection of cancer cells directly into the circulation system or at a given metastatic site is often referred to as the "experimental metastases method." Injection into the systemic circulation can be performed via the lateral tail vein (the preferential colonization site is the lung), the intraportal and intrasplenic veins (liver), intracarotid (brain), intraperitoneal (local invasion), intracardiac (bone, brain, adrenal glands, liver, and ovaries), or intra-tibial (bone) [47]. Once in circulation, cancer cells may be trapped in capillaries of the organ, extravasate, and eventually colonize the foreign site. The method is fast and allows control of the number of cells that reach the circulation. Moreover, given that breast tumor relapse in patients often occurs at metastatic sites, experimental metastasis is a very useful preclinical approach for rapidly assessing the effects of therapies. However, the method is less informative about the early steps of metastasis, when breast cancer cells undergo stringent selection. Moreover, when single cells are injected, the contribution of emboli and tumor clusters to metastasis cannot be evaluated [48]. Nevertheless, these models have been instrumental in the discovery of important aspects related to organ tropism of breast cancer cells. Good examples come from the work of J. Massague and team, who generated and studied organ-tropic (brain, bone, and lung) metastatic breast cancer cells by systematic reinjection of cells into the systemic circulation after their isolation from the metastatic organ [49–54].

6.3.3 Cancer Cells, Tumor Fragments, and Primary Derived Xenografts

Human and mouse mammary cancer cell lines have proved useful for investigating several aspects of mammary tumorigenesis. However, as most of these cell lines were derived from pleural effusions and were highly passaged in vitro, clones may have been selected that do not necessarily recapitulate fundamental features of the parental tumor, including tumor heterogeneity [55–58]. To avoid this issue, cell suspensions or fragments derived directly from human breast tumor biopsies can be transplanted subcutaneously or into the mammary fat pad of immunodeficient mice; these models are referred to as "patient tumor-derived xenografts" (PDXs) [59–61]. PDXs are thought to be stable and to resemble the characteristics of the original tumor, such as heterogeneity, histopathology, molecular subtype, metastatic potential, and/or drug sensitivity [59, 62–64]. However, they are subjected to selection pressure when grown in mice, and it seems that only the more aggressive, less-differentiated clones of the tumor grow as PDX [65, 66]. A further study found that PDXs resemble the genetic landscape of the metastases more closely than that of the primary tumor [67]. PDXs have also been described that result in lung metastases in mice although they originated from patients with no signs of lung metastases [63]. In the era of personalized medicine, PDXs could be very useful for testing the efficacy of therapies and predicting mechanisms of resistance. But it is not yet certain that they are more reliable in predicting patient response to therapy than standard cell line xenografts.

Most breast cancer PDXs grow at low efficiency in mice, and it is estimated that only 0–20% can actually engraft,

depending on the mouse model used, the tumor subtype, and whether the patient received therapy or not. The success rate in establishing PDX from hormonal receptor-positive tumors is particularly low. Given that a low success rate of engraftment requires the use of high numbers of immune-compromised mice, the application of PDX is both laborious and costly. Estrogen supplementation, the use of highly immunosuppressed mice (NSG), as well as co-injection of mesenchymal stem cells and/or Matrigel [68, 69] have increased the rates of engraftment, but they are still far below the 100% that would be needed for personalized medicine.

A possible explanation of such low engraftment rates is that not all murine growth factors and cytokines interact with their human cognate receptors [36]. Several strategies used to bypass this problem still only produce moderately low efficacies. These include co-injection of human breast cancer cells and partly irradiated human fibroblasts [70] or implantation of human breast cancer cells into mice carrying human bone grafts [71]. Perhaps one of the most promising strategies is to humanize mice by introducing human immune or hormonal components.

The three main mouse strains used for humanization studies are NSG, NOG, and the BRG (reviewed in [72]), which were generated by crossing the IL-2Rγ−/− and the SCID (NSG, NOG) or RAG2−/− (BRG) strains. These mice are defective in T, B, and NK cells, and their reduced macrophage and dendritic cell functions makes them suitable for humanization. In one of the first studies, human peripheral blood mononuclear cells (PBMCs) and tumor cells were co-transplanted into NSG mice. However, the tumor cells and PBMCs were derived from different donors; MHC mismatching led to an antitumor response or graft versus host disease [73]. Bypassing the rejection, human breast cancer cells were successfully implanted into mice injected with HLA-matched $CD34^+$ hematopoietic stem cells (HSC), which allowed an effective immune response [74, 75]. HSC transfer allows the development of most types of hematopoietic cells, including B and T lymphocytes, NK cells, monocytes, DC, erythrocytes, and platelets; their maturation and function can be further improved by engineering mice to express human cytokines such as hIL-2 [76], hIL-4, hIL-6 [37], HCSF/IL-3 [77], hIL-7 [78], or hTPO [79]. In the two recently generated mouse strains, MITRG and MISTRG, human versions of four genes encoding cytokines important for innate immune cell development were knocked into their respective mouse loci. The human cytokines support the development and function of monocytes, macrophages, and NK cells derived from human fetal liver or adult $CD34^+$ progenitor cells injected into the mice [80]. Overall, although there is still room for improvement; humanized mouse models are a promising strategy for efficient engraftment of patient-derived tumor biopsies and the study of their interaction with immune cell and hormonal components.

Although most of the steps in the metastatic cascade can be modeled, transplantation of breast cancer cells does not recapitulate the natural history of breast tumors, where loss of tumor suppressor genes and the expression of oncogenes transform normal cells. Furthermore, they do not allow study of cancer immune editing. Some of these deficiencies can be potentially recapitulated using genetically engineered mouse models (GEMMs), with mice fully engineered to express genetic lesions that result in autochthonous development of mammary cancer.

6.4 Genetically Engineered Mouse Models (GEMMs) of Breast Cancer

Early GEMMs of breast cancer were constructed by introducing mutations of interest into the mouse genome under the control of a mammary active promoter (e.g., MMTV). This method has several limitations, including the randomness of the insertion site and lack of control of gene copy number. Transgenes have also been integrated by specifically targeting the Rosa26 and H11 loci, where homozygous transgene expression does not disrupt endogenous coding sequences. Transgenes can also be inserted downstream of their endogenous promoters (knock-in), thus allowing physiological control of expression. Many of these early models expressed a particular oncogene or were deprived of a tumor suppressor in multiple cell types of the mammary gland.

6.4.1 Spatiotemporal Control of Transgene Expression

The mammary gland epithelium is composed of luminal cells that produce milk during lactation, together with surrounding myoepithelial/basal cells that have contractile activity and eject the milk [81]. Conditional mice have been developed that include the bacteriophage CRE-lox and the FLP/FRT system from *Saccharomyces cerevisiae*. Genetic lesions can be targeted to mammary cell types via expression of the Cre recombinase or flipase under the control of a specific promoter [82, 83]. Because several promoters are active during embryogenesis or at early phases of mammary gland development, constitutive genetic expression or deletion may impair normal development and preclude studies of the adult gland. Inducible systems such as tamoxifen-inducible Cre-ER [84] and tetracycline-controlled Cre expression [tTA (Tet-off) and rtTA (Tet-on) systems] [85, 86] have been used to induce mutations of interest at specific time points [87–90]. Because of their reversibility, tetracycline-inducible systems can be used to interrupt gene/oncogene expression after overt tumor development. This may reveal whether the tumor is addicted to the studied pathway [91, 92].

Commonly used promoters in GEMMs of breast cancer include the MMTV-LTR and the whey acidic protein (WAP) promoter, both highly active in mammary epithelial cells and responsive to hormonal stimulation. These promoters have been used extensively to drive mammary expression of several oncogenes, including neu/ErbB2, cyclin D1, cyclin E, *PIK3CA*, Ras, and Myc [22]. The MMTV-LTR is active in ductal and alveolar cells throughout mammary development (as early as 6 days postpartum) in a mosaic fashion, and its transcriptional activity increases during pregnancy [93]. A caveat of this model is the leakiness of MMTV-LTR in several organs, including hair follicles and salivary glands [22]. In contrast, the WAP promoter is restricted to the mammary gland, being active in 2–5% of cells during estrus and especially in most alveolar cells in midpregnant and lactating mammary glands [94, 95]. The WAP promoter has been used, for example, for targeted inactivation of tumor suppressors (e.g., pRb) [96] or expression of SV40 T-antigen [97] and *PIK3CA* mutants [89, 98].

Transgene expression can also be targeted preferentially to mammary basal or luminal cells. The results of in situ genetic lineage tracing studies suggest that cytokeratin 14 (K14) is expressed in mammary multipotent embryonic progenitors that give rise to basal and luminal lineages [88]. From birth onward, K14-positive cells become unipotent and give rise exclusively to basal cells [88]. This observation was later challenged by another lineage tracing study that identified bipotent K14-positive cells in pubertal and adult mammary glands [99]. K14-Cre or K14-CreER systems have been used to generate GEMMs, for example, to delete *Brca1* [100] *Tp53* [100] or express mutant *PIK3CA* [89]. The K5 promoter has also been used to target the basal population of the mammary gland [90]. Others have reported rare K5-positive cells that can be multipotent and that are present during puberty and pregnancy [99]. A model of stabilized β-catenin-induced mammary hyperplasia and carcinomas has been generated using K5 [101]. Expression of Lgr5, a downstream target of Wnt identified as a marker of adult stem cell populations in the small intestine, colon [102], stomach [103], and hair follicle [104], is expressed mostly in a subset of mammary basal cells in the nipple area [89, 105]. Expression of mutant *PIK3CA* in this subset of cells evoked mostly benign mammary tumors [89].

Lineage tracing results suggest that the K8 promoter is only active in the luminal compartment of the mammary gland, including luminal progenitor cells, and is involved in the maintenance of this compartment during puberty, adult life, and pregnancy [88]. Expression of the *PIK3CA*^{H1047R} mutant under K8 control led primarily to the formation of mammary tumors [89, 90].

Further promoters used to drive transgene expression in mouse mammary cells include the C3(1) [106], H19 [107], bovine β-lactoglobulin [108–110], and metallothionein promoters [111–114].

6.4.2 Modeling Genomic Alterations in GEMMs

GEMMs of breast cancer can be induced by the expression of an oncogene or the deletion of a tumor suppressor gene, mimicking either germline or somatic genetic defects.

6.4.2.1 Models of Human Germline Breast Tumor Mutations

The *BRCA1* [115, 116] and *BRCA2* [117, 118] germline heterozygous mutations were identified in the 1990s and have been defined as the highest risk factor for the development of familial breast and ovarian cancers [119]. Surprisingly, in contrast to the human situation, *Brca* heterozygous mice do not develop tumors, and homozygous deletion is embryonic lethal [95]. Several BRCA1 conditional models have been developed that exhibit mammary tumor formation in a subset of animals, albeit with a long latency [120]. Concomitant loss of *Tp53* considerably reduces tumor latency [121]. Brca1 tumors are typically ER and HER2/neu negative and resemble sporadic triple-negative basal-like breast cancers at the histopathological and molecular levels [8]. For a long time, this was taken as evidence for a basal origin of these cancers, but this was later challenged by data showing the accumulation of clonogenic aberrant *c-KIT*-positive luminal cells (luminal progenitors) in the breast tissue of mutant *BRCA1* carriers [122]. Moreover, inactivating *Brca1/Tp53* in luminal progenitors but not in basal cells of mice resulted in tumors closely resembling human BRCA1 mutant basal-like breast tumors [109], suggesting a luminal progenitor origin for basal breast cancer.

Brca2 inactivation driven by either WAP-Cre [123] or MMTV-Cre [124] was found to result in mammary carcinomas with a long latency. K14-Cre-mediated deletion produced no mammary tumors, except when combined with deletion of *Tp53* [87].

6.4.2.2 Modeling Somatic Alterations in Human Breast Cancer

Gene Amplification

The poster child model of gene amplification and overexpression and one of the earliest GEMMs of breast cancer is that of the gene encoding the receptor tyrosine kinase ErbB2 (neu/HER2); this member of the EGFR family is amplified in ~25% of human breast cancers [125–127]. HER2 overexpression defines a distinct histological and molecular subtype and is the target of the humanized monoclonal antibody trastuzumab [3, 4, 12]. Recently, cancer genome sequencing data have identified patients with breast tumors lacking *HER2* gene amplification but harboring somatic mutations in extracellular or kinase domains [13, 15, 128–130]. Some of these mutations have oncogenic potential in vitro and their

effect on sensitivity to anti-HER2 therapy [131] is being tested in clinical trials.

Mouse models of ErbB2-driven mammary tumorigenesis include, for example, the ErbB2/Neu-V664E (NeuNT: for Neu transforming) mutant driven by the MMTV-LTR [132, 133] and the endogenous *ErbB2* promoter [134]. While this particular mutation has never been found in human breast tumors, these models have been very useful for investigating several aspects of HER2-evoked tumorigenesis and signaling properties. In contrast to MMTV-LTR-driven expression, the expression of NeuNT under its endogenous promoter is in general not sufficient for the initiation of mammary carcinogenesis [134], highlighting a requirement for gene amplification and concomitant elevated protein expression. Expression of wild-type *ErbB2* under the control of MMTV-LTR also resulted in mammary tumors, albeit with a longer latency than NeuNT [135]. This suggests that additional genetic events are needed to transform the mammary epithelium. Notably, most tumors in these transgenic mice harbored in-frame small deletions in the transgene, and some have transforming capacity [136]. Mammary epithelium-specific expression of neu receptors harboring two of these in-frame neu deletions (NDL) (MMTV-neu-NDL mice) led to rapid induction of mammary tumors that frequently metastasized to the lungs [137]. Interestingly, the NDL mutant resembles an alternative splice form of the human *HER2* gene, Δ16HER2 [138]. The human spliced variant also induces the development of multifocal mammary tumors with a rapid onset [139] and confers tumorigenic and metastatic capacity to nonneoplastic MCF10A cells [140].

Further breast cancer mouse models of amplified genes include overexpression of cyclin D1 [141], cyclin E [142], Ras [143], Myc [143], and Wnt1 [144], mostly under the control of the MMTV promoter [22].

Gain of Function Mutations

The PI3K pathway is hyperactivated in over 70% of human breast cancers, due either to gain of function mutations in *PIK3CA* or *AKT1* or to loss of/reduced expression of PTEN, SHIP, or INPP4B; all these phosphatases dampen the activation of the pathway. *PIK3CA* mutations are present in 25–40% of all breast cancers, followed by about 8% with *AKT* mutations; each of these alterations occurs most frequently in ER-positive tumors [14, 130, 145, 146].

PIK3CA mutations or *AKT1* mutations seem to be an early event in breast tumorigenesis, as shown by the co-occurrence of these mutations in DCIS and invasive counterparts [147]. Several mouse models have been generated driven by inducible expression of the oncogene $PIK3CA^{H1047R\ or\ E545K}$ in different cells [148]. Using lineage tracing [149], recent studies have shed light on the source of tumor heterogeneity found in mutant $PIK3CA^{H1047R}$-induced mouse mammary tumors. Koren et al. [150] and Van Keymeulen et al. [90] showed that $PIK3CA^{H1047R}$ overcomes lineage restriction in adult mammary epithelial cells. Expression in luminal (K8 promoter) or basal (LGR5 or K5 promoters) cells resulted in their dedifferentiation into a multipotent stemlike state that gave rise to heterogeneous tumors expressing both basal and luminal lineage markers. Interestingly, the cell of origin dictated the phenotype of these tumors; tumors arising from basal cells usually displayed more benign histopathological characteristics, while those arising from luminal cells were more frequently malignant [89, 90].

With the publication of a comprehensive molecular characterization of breast cancer in 2012 [151], more than 30,000 genomic mutations were unraveled, and 35 of these were found to be frequently mutated. *PIK3CA*, *TP53*, and *GATA3* somatic mutations occurred at a frequency higher than 10% across all breast cancer subtypes; the next most frequent mutations were in *MAP3K1*, *PTEN*, *CDH1*, and *MAP2K4*. Some of these mutants have been used to produce GEMMs of breast cancer.

Other Models of Activated Pathways

The polyoma middle T (PyMT) antigen has also been expressed under the control of MMTV-LTR. Although PyMT is not a bona fide human oncogene, it induces several pathways that are hyperactive in human tumors, including ERK/MAPK, PI3K/AKT, and SRC. The PyMT is an extremely potent oncogene; within 4 weeks after birth, the mice develop mammary adenocarcinomas resembling human DCIS, both histologically and cytologically. Nonetheless, unlike human DCIS, most of these tumors lack ER expression. MMTV-PyMT mice develop metastases in the lungs as early as 6 weeks, which allows study of this multistep metastatic process [152].

Somatic Alterations in Tumor Suppressor Genes

In knockout/mutant models of tumor suppressor genes, mammary tumors often develop later than those caused by activation of oncogenes, and the mice usually manifest other cancers, especially of lymphatic and conjunctive tissues. Furthermore, these mammary tumors usually depend upon the activation of an oncogenic pathway; thus, a single tumor suppressor gene alteration can lead to different tumors depending on the collaborating oncogenic pathway.

The most commonly altered tumor suppressor gene in human breast cancer and the most commonly disrupted gene in GEMMs is *TP53*, which is mutated in about 30–40% of breast tumors, even higher in ER-negative subtypes [16, 153]. *Tp53* whole-body KO mice rarely develop mammary tumors (1–2% of all cancers), as most of the time, they succumb primarily to lymphomas [154]. This can be circumvented by transplantation of *Tp53* KO mammary glands into the cleared fat pad of *Tp53* WT syngeneic hosts [41] or the use of conditional knockouts [87]. The incidence of mammary tumors in p53-null animals is significantly higher in the

BALB/c murine background than in C57Bl/6×129, especially in p53 heterozygous mice [42]. Models of *Tp53* mutants R172H and R270H, the murine counterparts of human R175H and R273H hotspot mutants, have also been generated [155–157]. The spectrum of the developing tumors differs in these mice, and metastasis frequency is higher than for p53 KO or heterozygous animals [158]. A further model involving *Tp53* disruption is SV40 T-Ag [106], which induces transformation through inactivation of p53 and Rb family members. Remarkably, all of these models develop tumors with similar phenotypes, i.e., they are all heterogeneous with different grades, aneuploid, and genetically instable [158].

CDH1/E-cadherin is a tumor suppressor gene frequently downregulated in human lobular breast cancers [159]. Conditional loss of E-cadherin and p53 in mammary epithelial cells [160] accelerates the development of invasive and metastatic mammary carcinomas, presumably through induction of anoikis resistance and angiogenesis. The tumors closely resemble the human invasive lobular carcinoma (ILC); however, contrary to human ILC, the murine tumors are ER negative.

Germline *PTEN* mutation in Cowden disease predisposes to breast cancer [161]. Furthermore, sporadic breast cancers exhibit frequent loss of heterozygosity at the *PTEN* locus and reduced PTEN protein levels [151]. *Pten* deficiency accelerated mammary tumorigenesis and metastasis in an ErbB-2-driven mouse model [162] and mammary oncogenesis in MMTV-Wnt1 transgenic mice [163]. Full-body *Pten* KO leads to embryonic lethality, while heterozygous animals develop a broad range of tumors, including breast cancer [164]. Mammary epithelium-targeted deletion of *Pten* also led to the development of early-onset mammary tumors [165].

6.4.3 New Technologies for Generating GEMMs

Increasingly sophisticated techniques for manipulating the mouse genome and mouse embryos allow the generation of GEMMs with several mutations and offer unprecedented possibilities for validating and modeling the bona fide human drivers of tumorigenesis and metastasis identified by the sequencing of tumors [166]. An extensive review of the generation of GEMMs has been published elsewhere [167]. Until very recently, the interaction of different mutations in cancer was very difficult to test using mouse models, the crossing of different lines with specific mutations being laborious, costly, and time-consuming. With CRISPR-Cas9 technology, several different mutations can be introduced simultaneously into a given mouse in a relatively short time. This approach has been used successfully to generate GEMMs of lung cancer [168, 169], and its application to breast tumors is awaited.

6.4.4 Advantages and Disadvantages of GEMMs

In 1999, a group of experts in the mammary gland field, comprising medical and veterinary pathologists, gathered in Annapolis, Maryland, to systematize the classification of breast lesions arising from GEMMs in the framework of human disease. They evaluated 39 mouse models and proposed both a consensual nomenclature and guidelines for the classification of future models [170]. One of the main conclusions of this conference was that in general, genetically engineered mice give rise to tumors that do not resemble histologically the common types of human breast cancer (i.e., ER pathway-dependent tumors). A further limitation is the scarcity of breast cancer GEMMs that form metastases; when they do, the lung is the preferential organ of metastatic growth, while in humans, the bone, liver, lung, and brain are common metastatic sites. In humans, tumors spread initially via the lymphatic system and not via the blood, as in mice. Moreover, the mouse mammary stroma is rich in fat, while collagen and fibrous stroma are predominant in human breast. The latter may explain why mouse tumors exhibit much less fibrosis and inflammation than human breast tumors. Finally, although spatiotemporally controlled gene manipulation in mice is advantageous compared with initial GEMMs, the number of cells per gland targeted by the mutation largely overrides that found in sporadic human cancers. However, the benefits of GEMMs do outweigh their potential limitations. Many of the molecular lesions causing breast cancer in humans also lead to mammary tumors in mice. Furthermore, mammary tumorigenesis in mice is consistent with the multi-hit kinetics of human tumors. Another remarkable aspect is that certain GEMMs can recapitulate the level of heterogeneity that is found in human tumors. Accordingly, a recent genomic analysis of tumors from GEMMs of breast cancer revealed that individual mouse models could recapitulate the heterogeneity found among human breast cancer samples [171]. In addition, every subtype of human breast cancer was found to have its murine counterpart in terms of profile of signaling pathways activated. Notwithstanding important differences between the mouse and human immune systems [36], the presence of an intact immune system in GEMMs allows investigation of its involvement in autochthonous mammary cancer growth and progression, as well as the preclinical testing of immunotherapies. From a technical point of view, the mouse genome is fully sequenced and is easy to manipulate. Furthermore, mice have short generation times and ten mammary glands that provide material for ex vivo cell biological and biochemical studies.

Conclusions

Mouse models have made and will continue to make decisive contributions to our understanding of biological mechanisms of breast cancer initiation and progression,

to the preclinical validation of drug candidates, as well as to the discovery of new mechanisms of drug resistance and of predictive biomarkers. Technological advancements in genome editing, such as CRISPR-Cas9, the establishment of large PDX banks, and the development of humanized mouse models will continue to increase the number and diversity of available models.

The proper selection of a preclinical model is critical to drug discovery and should take into account the biological context of the target and the proposed mechanism of action of the drug [19]. Clearly, no one model will fit all drug discovery programs or recapitulate all aspects of the disease. As stated by B. Cardiff, a useful mouse model should be testable, predictive, and usable to falsify a hypothesis (Cardiff B, personal communication) [172, 173]. The model should provide a reproducible answer to a question that accurately verifies or rejects a hypothesis, whether it involves oncogene dependency, metastatic capacity, the validation of drug targets, or the identification of mechanisms of resistance. Careful attention must be paid to the attributes of the disease (molecular, biological, and structural) that are recapitulated in a specific model. The model should recapitulate a particular aspect of breast cancer biology and thus have relevant predictive power in human breast cancer.

Acknowledgments We thank Robert D. Cardiff and Daniel Medina for critical reading of the manuscript.

Box 1 General Considerations when Generating GEMMs (M. Barbacid, Keystone Symposium on Inflammation, Microenvironment and Cancer, 2008, Personal Communication)—Adapted from [174]

1. The genetic alteration studied should be found in human breast tumors.
2. The expression of the gene of interest should be targeted preferentially to the endogenous locus and not expressed as a transgene.
3. The genetic alteration should be introduced in a specific mammary cell subpopulation or lineage.
4. Expression or deletion should be inducible to allow activation/deletion in the adult gland or following tumor development.
5. The resulting tumors should recapitulate some features of human disease in terms of morphology, heterogeneity, pathways activated, and gene expression profile. In particular, more hormone-dependent (ER- and/or PR-positive) models should be developed.

7.1 Global Patterns in Breast Cancer Incidence and Mortality

Estimated numbers of new breast cancer cases, cancer deaths, incidence, and mortality age-standardized rates by world regions and country for 2012 were compiled by the International Agency for Research on Cancer (IARC) and obtained from the GLOBOCAN platform. Detailed information about the source of data and the methods used for countries lacking incidence or mortality data are available in an article by Ferlay et al. [1].

Breast cancer is the most frequent cancer in the world among women with an estimated 1.7 million new cancer cases diagnosed in 2012, representing 25% of all cancers [2]. It is the most common cancer both in more developed and less developed regions of the world with slightly more cases in less developed (883,000 cases) than in more developed (789,000) regions. Incidence rates vary more than threefold across the world regions, with rates standardized according to the world population (ASR) ranging from 27 per 100,000 in Middle Africa and Eastern Asia to more than 90 in North America and Western Europe (Table 7.1). High incidence rates of breast cancer are also recorded in Australia and Southern Europe; intermediate rates in South America, in the Caribbean, and in Central and Eastern Europe; and low rates in most parts of Africa and Asia (Fig. 7.1).

Breast cancer is also the most frequent cause of death from cancer in women being responsible for 522,000 deaths, representing 15% of all cancers deaths in the world in 2012. It is the most frequent cause of cancer death in less developed regions (324,000 deaths, 14.3% of total), but it now ranks as the second cause of cancer death after lung cancer in more developed regions (198,000 deaths, 15.4%). Again, we observe a more than threefold range in age-standardized mortality rates across the world regions. Despite paucity of data from many of the less developed countries, highest mortality rates were estimated in Western Africa (20 per 100,000), while low mortality rates were estimated in Eastern Asia (6 per 100,000) (Table 7.1). Elevated mortality rates (>16 per 100,000) are observed in all European regions, intermediate rates (14–15 per 100,000) in North America and in Australia, and low rates (<14 per 100,000) in Central and South America (Fig. 7.1).

Because of the multifactorial aspects related to breast cancer incidence (see later section on lifestyle and hormonal risk factors) and breast cancer mortality (lowered by accessibility to mammographic screening and advanced treatment protocols) and of the wide variation of these factors between less developed and more developed countries, the ratio of mortality to incidence provides distinct information on the burden of breast cancer. In fact, we observe a wide variation in the mortality-to-incidence rates ratio worldwide mainly due to differences in survival between less developed and more developed regions. In most developed countries, the mortality-to-incidence rates ratio is lower than 0.20 (or one death for every five new cases), with lowest rates ratio observed in North America (0.16), in Australia and New Zealand (0.17), in Western and Northern Europe (0.18), and in Southern Europe (0.20). In contrast, highest mortality-to-incidence rates ratio are observed in Middle Africa (0.55), Western Africa (0.52), and Eastern Africa (0.51) with approximately one death for every two new breast cancer cases. Intermediate rates ratios are observed in South America (0.27) and Central and Eastern Europe (0.35) (Table 7.1).

Country-specific mortality data were also retrieved from the WHO mortality database for the most recent year for which they were available. The single country with the highest mortality rate from breast cancer is Armenia with 545 deaths reported in 2012, corresponding to an ASR of 24.6

per 100,000, followed by Barbados (24.0 per 100,000), Uruguay (18.9 per 100,000), Croatia (18.0 per 100,000), or Hungary (17.7 per 100,000). Many of the other countries with high mortality rates are situated in Northern, Central, and Eastern Europe and in South America. High rates are also reported for Israel (17.4 per 100,000). Many of the countries with the lowest mortality rates (<7 per 100,000) are situated in Central America (El Salvador, Guatemala, Nicaragua, Ecuador) and the west border of South America (Peru). Other countries with low mortality rates include the

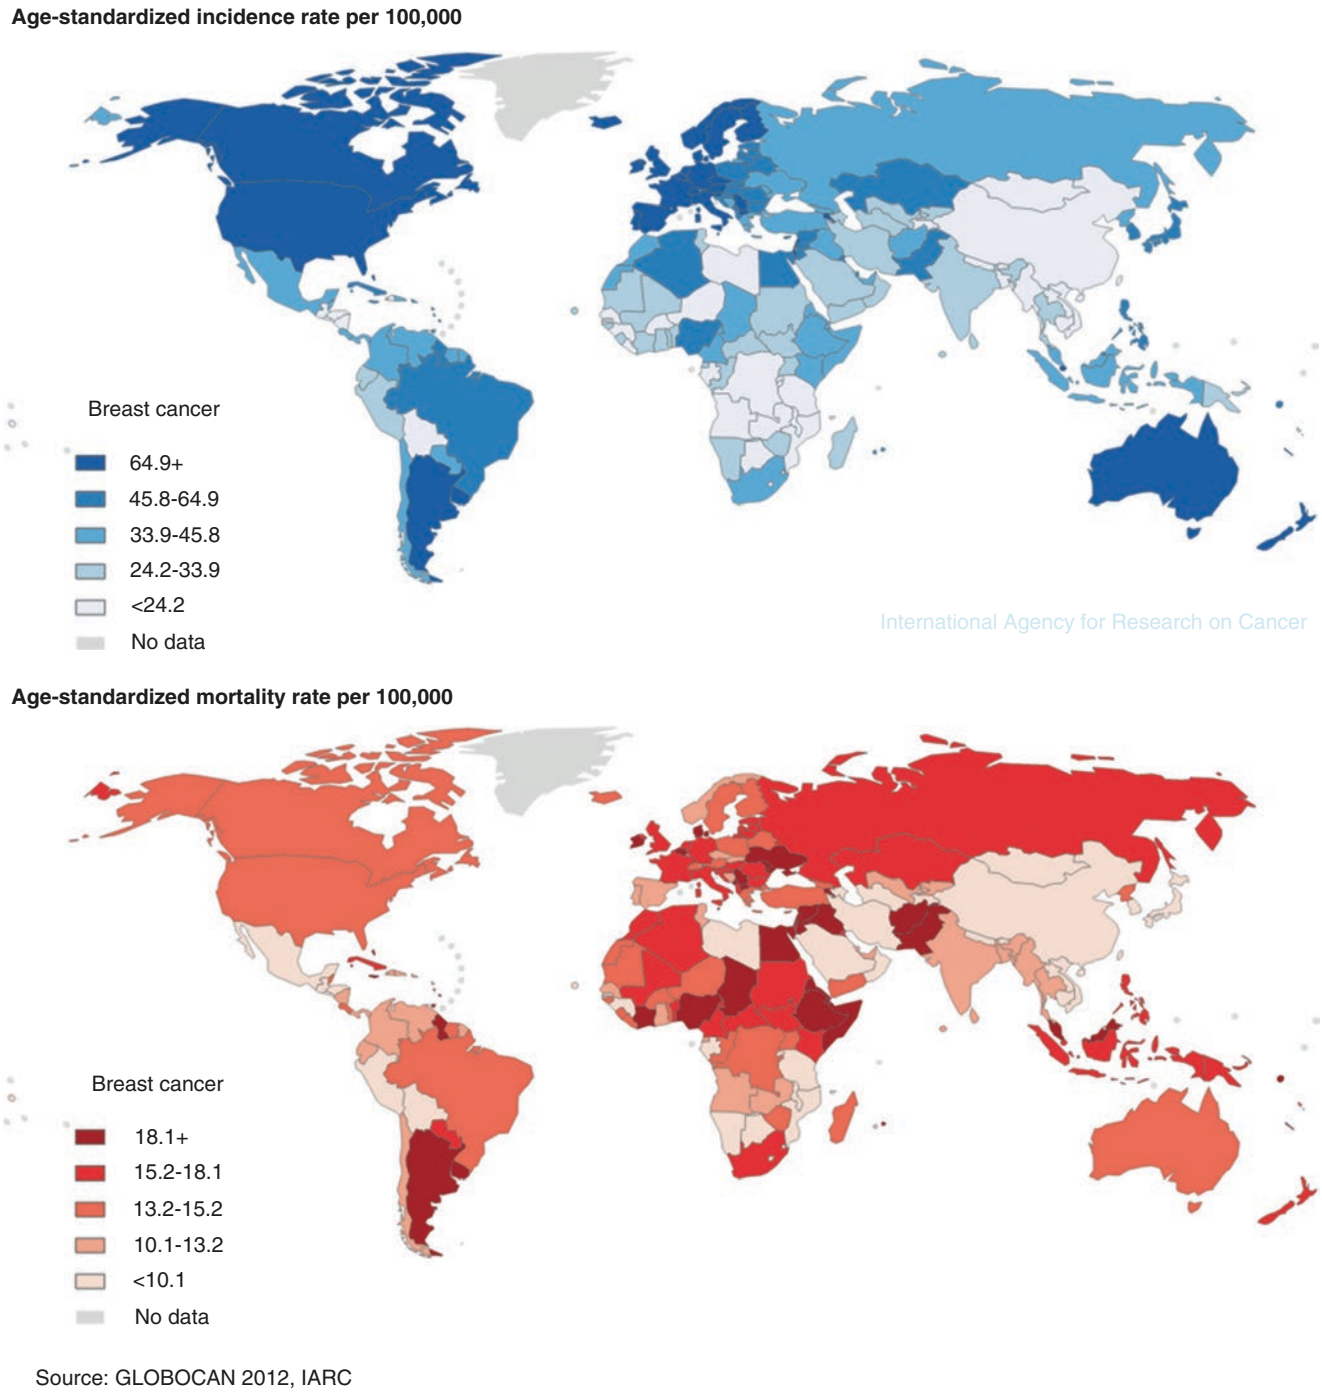

Fig. 7.1 Estimated age-standardized incidence and mortality rates from breast cancer, 2012. *Source* GLOBOCAN 2012, IARC

Republic of Korea (5.6 per 100,000) and Japan (9.0 per 100,000) (Table 7.2).

Trends in incidence of and mortality from female breast cancer are presented in Fig. 7.2 for selected countries with available long-term data. Between 1975 and 2010, breast cancer incidence rates rose by 20–50% in developed countries. This increase could largely be ascribed to change in reproductive patterns, the use of exogenous hormones, and

intensification of breast cancer screening. This increase was particularly marked in Northern European countries, such as Denmark or Finland, and in England. Similar but somewhat slower increase in incidence was observed in Asian countries (China, Thailand, Japan, Singapore). Only modest increase in breast cancer incidence was observed in India or in the Philippines. In several countries including the USA, Canada, Australia, and New Zealand, the increase halted around year 2000, followed by a decline in incidence. This stabilization or decline in incidence could be due to the leveling of breast cancer screening in these countries [3].

In contrast to incidence trends, age-standardized death rates were stable in most countries until the mid-1980s to early 1990s and subsequently significantly decreased in the following period. However, in few countries from Asia (Japan, Republic of Korea, Singapore) or from Central America (Colombia, Costa Rica), breast cancer mortality rates are still increasing, but the absolute mortality rates in these countries remain among the lowest worldwide (around 10 per 100,000). More details about international variation in female breast cancer incidence and mortality are available in a recent article by DeSantis et al. [4].

7.2 Demographic, Lifestyle, and Environmental Factors

7.2.1 Age- and Race-Specific Incidence Rate

As for most forms of cancer, breast cancer incidence increases with age. It represents a very rare form of cancer before 25 years of age to become a substantial form of cancer in women after age 50. Its incidence is strongly increasing until age 70 and declines at older age (Fig. 7.3). Overall, less than 5% of all breast cancer cases are diagnosed before age 40 and more than 60% after age 60. Breast cancer incidence also varies according to racial and ethnic groups. In the USA, incidence from breast cancer is higher among white than among black women. It is also lower among women of Hispanic or Asian origin and among Pacific Islanders.

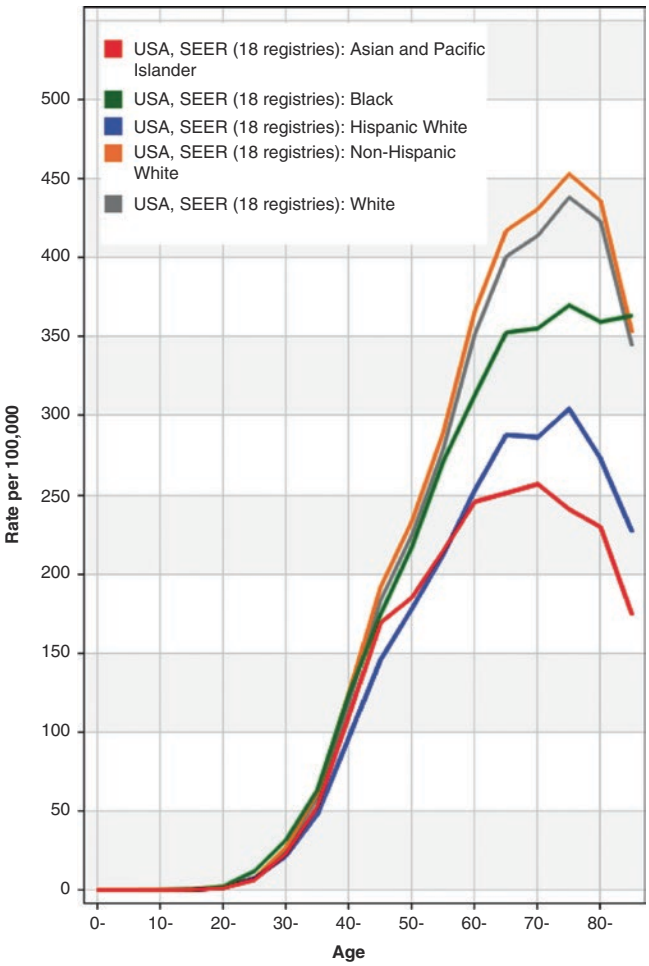

Fig. 7.3 Age- and race-specific incidence rates from female breast cancer in the USA (SEER 18 registries)

7.3 Reproductive and Hormonal Factors

Studies have shown that a woman's risk of developing breast cancer is related to her exposure to hormones that are produced by her ovaries (endogenous estrogen and progesterone). Reproductive factors that increase the duration and/or levels of exposure to ovarian hormones, which stimulate cell growth, have been associated with an increase in breast cancer risk. These factors include early age at menarche, late onset of menopause, later age at first pregnancy, and never having given birth.

In addition to direct effects on breast cells, pregnancy and breastfeeding both reduce a woman's lifetime number of menstrual cycles and thus her cumulative exposure to endogenous hormones.

7.3.1 Age at Menarche and Age at Menopause

Menarche and menopause are indicators of the onset and cessation of ovarian and related endocrine activity during women reproductive years. Early age at menarche and late age at menopause are known to increase women's risk of developing breast cancer.

A pooled analysis of individual data from 117 epidemiological studies shows that the risk of breast cancer decreases by 5% (95% CI 4.4–5.7%) for every 1-year delay in onset of menses [5], confirming results from an early study [6]. The same study shows that women breast cancer risk increases by 2.9% (95% CI 2.5–3.2%), for every year older at menopause. In addition, premenopausal women had a 43% excess risk (RR 1.43, 95% 1.33–1.52) of developing breast cancer than postmenopausal women of an identical age [5].

Breast cancer risk increased by a significantly greater factor for every year younger at menarche than for every year older at menopause, indicating that menarche and menopause may not affect breast cancer risk merely by extending women's total reproductive years [5].

7.3.2 Oophorectomy

Bilateral oophorectomy reduces breast cancer risk, likely because of reductions in levels of circulating ovarian hormones. In the Women's Contraceptive and Reproductive Experiences Study, bilateral oophorectomy was associated with reduced breast cancer risk overall (OR 0.59, 95% CI 0.50–0.69). In particular, women who had both ovaries removed before age 45 had about half the risk (ORs ranging from 0.31 to 0.52) of developing breast cancer compared to women who had a natural menopause, but not those who were older at surgery [7].

7.3.3 Pregnancy

There is well-established evidence that parity and early age at first full-term pregnancy are associated with reduction of breast cancer risk [8, 9]. The older a woman is when she has her first full-term pregnancy, the higher her risk of breast cancer. For example, women who have a first full-term pregnancy before age 20 have half the risk of developing breast cancer than that of women whose first full-term pregnancy occurs after the age of 30 [10]. The risk of breast cancer further declines with the number of full-term pregnancies even after adjustment for age at first birth [11]. However, a first childbirth

after age 30–35 no longer confers protection against breast cancer. Breast cancer risk is also transiently increased after a full-term pregnancy. Pregnancies that end as a spontaneous or induced abortion do not increase risk of breast cancer [12].

7.3.4 Breastfeeding

Breastfeeding is associated with a modest decrease risk of developing breast cancer, above and beyond that associated with multiple pregnancies. The longer women breastfeed, the more they are protected against breast cancer: the relative risk of breast cancer decreased by 4.3% (2.9–5.8) for every 12 months of breastfeeding in addition to a decrease of 7.0% (5.0–9.0) for each birth [13].

7.3.5 Oral Contraceptives

Oral contraceptive use is associated with a slight and transient increased risk of breast cancer. Authors of a meta-analysis based on individual data from 54 studies estimated a relative risk of 1.24 (95% CI 1.15–1.33) for current users. This increased risk declines to 1.16, 1–4 years after stopping oral contraceptive use, and to 1.07, 5–9 years after, while no risk was seen after 10 years from cessation [14].

Several hypotheses have been made about the influence of oral contraceptives on breast cancer risk. It was thought to be more important before cellular differentiation occurring with a full-term pregnancy and possibly to vary according to the type or formulation used. A large nested case–control study suggested that recent use of contemporary oral contraceptives was associated with an increased breast cancer risk, which may however vary by formulation [15]. In this study, the authors did not find an association with low-dose estrogen oral contraceptives. In another recent study from South Africa, a significant increased risk of breast cancer was found for women using injectable progestin-only contraceptives, but again the risk decreased to normal few years after cessation [16].

7.3.6 Hormone Replacement Therapy

There is a large body of evidence that long-term use of combined hormone replacement therapy (HRT) containing estrogen plus progestogen given to relieve the climacteric symptoms of menopause is associated with an increased risk of breast cancer [17, 18]. The increased risk is greater for women starting HRT soon after the onset of menopause [19] with linear diminishing influence as time from menopause increased [20]. The risk also dissipates within 2–5 years of discontinuation of HRT use, regardless of the duration of treatment. In a meta-analysis, use of combined estrogen–progestogen therapy was associated with a 7.6% increase in breast cancer risk per year of use [21].

Contrasting results observed for women receiving estrogen-only therapy in the Women's Health Initiative (WHI) trials in the USA [22] and the Million Women Study in the UK [23] could be largely ascribed to differences in age distribution and anthropometric measures [24].

7.4 Other Demographic and Lifestyle Factors

7.4.1 Height

Increasing height, which is influenced by childhood nutrition, genetic predisposition, prenatal exposures, and IGF levels, has been associated with an increase of breast cancer, particularly in postmenopausal women. In a pooled analysis of individual data from prospective cohort studies, van den Brandt et al. estimated that the risk of breast cancer increases by 7 percent for 5 cm of height increment (RR 1.07; 95% CI 1.03–1.12) in postmenopausal women [25].

Length at birth and during childhood have also been positively associated with breast cancer risk suggesting that factors influencing fetal, childhood, and adolescent growth are important independent risk factors for breast cancer in adulthood. In a cohort of 16,016 women in Norway, birth length was positively associated with risk. Women who were ≥53 cm had a relative risk of 1.8 (95% CI 1.2–2.6) compared with women who were shorter than 50 cm, after adjustment for multiple confounding factors [26]. A 5 cm increase in height at age 8 was associated with an 11% increased risk of breast cancer (RR 1.11; 95% CI 1.07–1.15). A 5 cm height increase between age 8 and 14 was associated with a 17% increased risk of breast cancer (RR 1.17; 95% CI 1.09–1.25). Compared to girls measuring around 151 cm at age 14, those measuring 168 cm had a 50% increased risk of developing breast cancer during adulthood (RR 1.51, 95% CI 1.36–1.68) [27].

7.4.2 Obesity

There is strong evidence that adiposity is associated with breast cancer risk, but this association varies by menopausal status. Elevated body mass index (BMI) is associated with an

increased risk of breast cancer in postmenopausal women, and there is growing evidence that obesity is associated with poor prognosis in women diagnosed with early-stage breast cancer. In a meta-analysis of 31 observational studies comprising 23,909 breast cancer cases, an increase of BMI of 5 kg/m^2 has been associated with a 12% increased risk of cancer (RR 1.12; 95% CI 1.08–1.16) in postmenopausal women [28].

On the contrary, BMI increase was inversely associated with the risk of premenopausal breast cancer (RR 0.95 for 5 kg/m^2 increase; 95% CI 0.94, 0.97), but this association varies by ethnicity, remaining significant only among Africans and Caucasian women [29].

In an analysis of individual data from eight prospective studies, the Endogenous Hormones and Breast Cancer Collaborative Group concluded that the increase in breast cancer risk with increasing BMI among postmenopausal women is largely the result of the associated increase in estrogens, particularly bioavailable estradiol [30].

7.4.3 Diet

There was almost universal agreement that diet or nutritional practices in some form must play a role in establishing breast cancer risk. This was a credible assumption to explain the remarkable changes that occur in breast cancer risk following migration from low-risk to high-risk areas of the world. However, no specific component of the adult diet and no particular nutrient have been consistently associated with breast cancer risk [31].

The results of a large meta-analysis of 26 published studies from 1982 to 1997 [32] and of a pooled analysis of 8 cohort studies [33] suggest that fruit and vegetable consumption during adulthood is not significantly associated with reduced breast cancer risk.

A pooled analysis of individual data from seven prospective studies in four countries comprising 337,819 women and 4980 breast cancers also suggested a lack of association between total fat, saturated fat, mono- and polyunsaturated fat intake and breast cancer risk [34].

Based on an extensive review of the literature, an experts panel for the World Cancer Research Fund classified as "Limited evidence—no conclusion" the association with dietary fiber, vegetables and fruits, soya and soya products, meat, fish, milk and dairy products, folate, vitamin D, calcium, selenium glycemic index, dietary patterns, and breast cancer. The expert panel found "Limited—suggestive" association for total fat and postmenopausal but not premenopausal breast cancer [31].

7.4.4 Physical Activity

There is more convincing information for an inverse association between physical activity and breast cancer risk [35]. The evidence is stronger for postmenopausal breast cancer, with risk reductions ranging from 20 to 80%, than for premenopausal breast cancer. Moderate physical activity during adolescence or young adulthood has also been associated with a lowered risk of developing breast cancer. Lagerros et al. reported that each hour increase of recreational physical activity/week during adolescence (in 12–24-year-old females) was associated with a 3% (95% CI 0–6%) risk reduction of breast cancer [36].

According to the World Cancer Research Fund, physical activity probably protects against breast cancer postmenopause, and there is limited evidence suggesting that it protects against this cancer diagnosed premenopause [31].

7.4.5 Alcohol and Tobacco

There is substantial evidence that alcohol consumption increases breast cancer risk. A collaborative reanalysis of data from 53 epidemiological studies [37] demonstrated that compared to women who abstained to drink alcohol, those who consumed 35–44 g of alcohol daily (corresponding to 3–4 alcoholic drinks per day) had a 30% increased risk of developing breast cancer (RR 1.32; 95% CI 1.19–1.45). The risk increases by nearly 50% for women who drink an equivalent of 45 g of alcohol per day (RR 1.46; 95% CI 1.33–1.61). It is estimated that the relative risk of breast cancer increased by 7.1% (5.5–8.7) for each additional 10 g per day intake of alcohol, i.e., for each extra unit or drink of alcohol consumed on a daily basis.

In the same report, the authors found no evidence of an association between smoking and breast cancer risk, after adjustment for alcohol drinking. Despite mixed result in earlier studies, there is growing evidence that smoking may slightly increase the risk of breast cancer. In a recent meta-analysis, current (HR 1.12; 95% CI 1.08–1.16) and former smoking (HR 1.09; 95% CI 1.04–1.15) were weakly associated with breast cancer risk; a stronger association (HR 1.21; 95% CI 1.14–1.28) was observed in women who initiated smoking before first birth [38].

7.4.6 Radiations

Observations in Hiroshima and Nagasaki atomic bomb survivors [39] and in women who have received therapeutic radiation treatment to the chest [40] document increased

breast cancer risk. It is postulated that exposure during adolescence, a period of active breast development, enhances the effect of radiation exposure [41].

7.4.7 Occupational Exposure

A recent an exhaustive review of environmental and occupational causes of cancer, considered "Suspected" evidence of a causal link when results of epidemiological studies are mixed, yet positive findings from well-designed and conducted studies warrant precautionary action and additional scientific investigation, while "Strong" causal evidence of a causal link was based primarily on a Group 1 designation by the International Agency for Research on Cancer. For all occupational exposures evaluated (pesticides, polycyclic aromatic hydrocarbons (PAHs), ethylene oxide, and polychlorinated biphenyls (PCBs)), there was only a suspected association with breast cancer. Of interest, a pooled analysis of data from five large studies in the USA does not support an association of breast cancer risk with plasma/serum concentrations of 1,1-dichloro-2,2-bis(p-chlorophenyl) ethylene (DDE) or PCBs [42].

7.5 Genetic Factors

Up to 10% of breast cancer cases in westernized countries are due to genetic predisposition. Having a first-degree relative with breast cancer approximately doubles the risk of developing breast cancer. The risk varies with the age at which the affected relative was diagnosed and with the number of affected relatives. A first-degree relative with ovarian cancer also confers a modest risk of breast cancer. This will be extensively detailed in the next chapter.

Conclusion

Breast cancer is the most frequent form of cancer and the leading cause of cancer death among women worldwide. High age-standardized rates are observed in North America, in Australia and New Zealand, and in Northern and Western Europe; intermediate in Central and Eastern Europe, South America, and the Caribbean; and low in most of Africa and Asia. International variations in breast cancer incidence and mortality rates reflect differences in risk factors, in access and dissemination of breast cancer screening and modern treatment protocols.

Nongenetic breast cancer risk factors include consuming alcohol; not having children or having children at late age; not breastfeeding; using or having recently used oral contraceptives or hormone replacement therapy after menopause; being tall, overweight, or obese; not being physically active; or having been irradiated to the chest.

8.1 Introduction

Breast cancer is the most common form of cancer and the second most common cause of cancer death among women in the developed world. It has been estimated that women in the USA have a 12% lifetime risk of developing breast cancer beginning in their 20s, with a risk of developing cancer in the next 10 years for a woman in her 30s of approximately one in 250, and 1 in 50 by age 50 [1]. In the modern era, the goal is to identify women at increased risk to try to prevent their breast cancers. Currently, it is well known that individual risk for breast cancer is increased in individuals carrying a mutation in a predisposing gene and in others with a number of affected relatives with early age of disease onset in whom no specific mutation has been identified [2]. Approximately 5–10% of the total breast cancer cases follow a Mendelian inheritance pattern (autosomal dominant) and are characterized as hereditary. An additional 15–20% of breast cancer cases are named familial, referring to women who have two or more first- or second-degree relatives with the disease, without an identified gene. Among hereditary breast cancer cases, at least 30% are caused by germline mutations in the high-penetrance genes *BRCA1* and *BRCA2* [2], and the risk associated with less prevalent and more moderately penetrant genes is the subject of intense research effort.

Knowledge of somatic genetics and genomics has increasingly broad implications in oncology, not only in the identification of new treatments such as trastuzumab for HER2-positive breast cancer [3] but also as the basis for assays evaluating recurrence risk and treatment guidance, such as Oncotype DX, MammaPrint, and PAM50 [4, 5]. The germline or heritable genome provides important implications for the identification of high-risk individuals, ultimately for the development of effective cancer prevention strategies across the tumor types for which the genes confer increased cancer risk. However, there have been implications for therapeutic interventions as well. Prominent examples of the latter include the data for cis- and carboplatins in *BRCA1/2*-associated breast and ovarian cancers [6, 7] and PARP inhibitors in *BRCA1/2*-associated breast, ovarian, pancreatic, and prostate cancers. For this chapter, the ultimate goal of germline information is to identify individuals and families not yet affected, but at high risk of developing tumors who might be interested in preventive interventions that might effectively reduce their cancer mortality, at least for those cancers for which they have greatest risk.

The evolution of next-generation sequencing technologies has enabled parallel simultaneous testing of multiple genes beyond *BRCA1/2*, leading to concurrent analysis of breast cancer predisposition genes with a range of associated cancer risks, including high- and intermediate-/moderate-penetrance genes. The efficiency of next-generation sequencing has also increased the speed of the analysis, thereby reducing turnaround time, and has significantly reduced the costs. The effect of the widespread introduction of NGS technologies, therefore, has been to increase access to more comprehensive genetic analyses. However, access to this technology has also brought new challenges: the identification of the ideal candidates for utilization of panels, the

appropriate management of patients with mutations in genes whose penetrance still is not clear, the increase in the number of variants of uncertain significance (VUS) found, and the incidental finding of mutations in genes in families that do not have a clear phenotype of that syndrome.

8.2 Genetic Testing

Patients with breast cancer should be offered genetic testing, according to consensus guidelines. The guidelines may differ in some specifics depending on the country, but most would concur that individuals with breast cancer should be tested if they are diagnosed at a young age (< age 50 is a frequent criterion), when they present with triple-negative histology, or with ovarian cancer, and recently castrate-resistant prostate cancer or pancreatic cancer. Individuals without cancer are often eligible for genetic testing based on family cancer history that includes the above tumors in various configurations.

The ESMO guidelines comprise widely accepted clinical criteria for referral for genetic evaluation of unaffected individuals with family histories as follows: three or more breast and/or ovarian cancer cases, at least one <50 years, two breast cancer cases <40 years, male breast cancer and ovarian cancer or early-onset female breast cancer, Ashkenazi Jewish individuals with breast cancer of <60 years, young onset bilateral breast cancer, and breast and ovarian cancer in the same patient. In some countries, the criterion for testing is based on an a priori 10–20% probability of finding a mutation based on predictive models such as BRCAPRO, BOADICEA, or Manchester score [8]. However, others believe these criteria are too strict [9].

Much of the early data came from studies of *BRCA1* and *BRCA2*, and still the most substantial and stable data come from the study of individuals with mutations in these genes. They were the first identified, and data come from large cohorts, including the CIMBA consortium, which is custodian for tens of thousands of *BRCA1/2* mutation carriers that have been systematically studied for more than 10 years [10]. For these patients the most well-established genes to be evaluated are *BRCA1/2*, especially because those are the most common genes involved in breast cancer susceptibility and also because those are the ones for which we have the best data regarding penetrance and management.

At this time, however, the availability of multigene panel testing has raised new issues regarding eligibility for gene testing beyond BRCA and new challenges about interpretation and management of the results. According to the National Comprehensive Cancer Network (NCCN) in the USA, patients who have a personal and family history suggestive of a specific syndrome may be best evaluated by a target gene analysis. For those whose history can be explained by more than one gene—which is the majority of patients—evaluation by panel can be more efficient and/or cost-effective. For those patients with *BRCA1/2*-negative tests and with a strong family history, panels can be a good option in increasing the chance of finding a mutation in another predisposing gene by about 4% [11].

In this chapter we will first present the most important genes related to breast cancer risk, detailing their prevalence, associations with different cancers, and any pathologic characterizations and/or molecular features of those cancers. We will then discuss the clinical management of individuals carrying significant alterations in each gene as regards surveillance, risk-reducing surgery, and other available treatment regimes.

8.3 High-Penetrance Genes

8.3.1 *BRCA1* and *BRCA2*: Hereditary Breast and Ovarian Cancer (HBOC) Syndrome

The first gene associated with hereditary breast cancer is *BRCA1*, located on chromosome 17q. This gene was identified in 1990 using linkage analysis in families with suggestive pedigrees [12]. In 1994, *BRCA2* was mapped to chromosome 13q, and together they became the most important and studied genes related to hereditary breast and ovarian cancers [13].

Female carriers of pathogenic variants (mutations) in *BRCA1* or *BRCA2* have a lifetime risk of breast cancer of 50–85% [14–16]. In addition, there is a substantially increased risk of ovarian cancer, with an estimated lifetime risk of 20–60% for *BRCA1* carriers and 10–20% for *BRCA2* carriers [14, 17]. There are other tumors associated with mutations in BRCA2 in particular, and cases of melanoma, prostate, and pancreatic cancer [18] should be taken into account when considering family history.

When considering histopathological features, it is well established that *BRCA1*-related breast tumors, as a group, differ from non-*BRCA1* tumors in terms of histological phenotype. Malignant primary breast tumors of *BRCA1* mutation carriers are more likely to be high grade with medullary subtype features, including greatly increased mitotic count, pushing margins, lymphocytic infiltrate, trabecular growth pattern, and necrosis. Most importantly, about 70% do not express estrogen or progesterone receptor or HER2 (triple-negative breast cancer—TNBC) [19], but perhaps 20% are positive for ER and PR, and the remaining 5–10% are HER2 positive [20, 21]. This distribution has led to recognition that a significant subset of TNBC will occur in women who carry a germline *BRCA1* mutation, even in the absence of family cancer history, and has made TNBC in women younger than age 60 at diagnosis, a criterion for BRCA testing.

The majority of *BRCA2*-associated tumors are invasive ductal, high-grade, estrogen and progesterone receptor positive and negative for HER2. They are less likely than controls to express the basal cytokeratin CK5 or to overexpress HER2/neu protein. In fact *BRCA2* tumors are predominantly high-grade invasive ductal carcinomas of no special type, and they demonstrate a luminal phenotype despite their high histologic grade [20, 22, 23].

Among hereditary breast cancer cases, at least 30% are attributed to germline mutations in the high-penetration genes *BRCA1* and *BRCA2*, but these numbers can vary across different populations due to founder effects [2, 24].

Evidence shows that, in addition to the presence of a mutation on *BRCA1/2*, other factors such as environment, lifestyle factors, mutation locations, and the presence of some SNPs might be important to precisely estimate the quantitative cancer risks associated with specific BRCA mutations in carriers [25] and may affect the clinical management of these patients in the future. Direct evidence for genetic modifiers of risk has been provided through studies that investigated the effects of common breast and ovarian cancer susceptibility variants on cancer risk for *BRCA1* and *BRCA2* mutation carriers, identified through genome-wide association studies (GWAS) or candidate gene studies in the general population [26–30]. The GWAS data required independent validation but could provide helpful stratification of risk to assist women with the planning of risk-reducing measures, childbirth, and other aspects of life. Another important issue, addressed in a large analysis of genotype/phenotype data published by Rebbeck et al. on behalf of the CIMBA consortium, is that breast and ovarian cancer risks vary with the precise location of the mutation in *BRCA1* or *BRCA2*. The clustering of mutations in the large exon comprising the "ovarian cancer cluster region" (OCCR) and other associations with breast cancer cluster regions (BCCR), for both *BRCA1* and *2,* speak to the challenge of genetic heterogeneity [31].

8.3.2 *TP53*: Li–Fraumeni Syndrome

The *TP53* germline mutations give rise to Li–Fraumeni syndrome (LFS), a rare inherited cancer predisposition syndrome associated with approximately 1% of breast cancer cases. Germline mutations in this gene predispose to a wide spectrum of malignancies, including sarcomas, brain tumors, adrenocortical carcinomas, and leukemias, occurring at any point in an individual's lifetime, with a median age at diagnosis of first malignancy of 25 [32]. Otherwise, somatic *TP53* mutations are the most common mutations in adult adenocarcinomas.

TP53 is a tumor suppressor gene located on chromosome 17p13.1 that plays a major role in the regulation of cell growth [33]. Approximately 70% of patients with classic LFS criteria have a detectable TP53 germline mutation [34]. Mutations are most commonly missense, but deletions of the coding or promoter region of p53 can also occur [35].

TP53 mutation carriers face a lifetime risk of cancer that exceeds 90% [36]. Breast cancer is the most frequent malignancy among female *TP53* mutation carriers and represents up to one third of all cancers in LFS families [37]. Overall, although LFS is responsible for a small fraction of breast cancer cases, a woman with LFS has a breast cancer risk of 56% by the age of 45 and greater than 90% by the age of 60, which accounts for a 60-fold increased risk for early-onset breast cancer when compared to the general population [38, 39]. Women with LFS-related breast cancer have a tendency to present at a very young age (20s or 30s) with a more advanced disease (tumor > 5 cm, positive axillary nodes) [40–42]. Furthermore, recent studies have shown that two thirds of LFS-associated breast cancer tumors are positive for epidermal growth factor receptor 2 (HER2/neu) and/or estrogen and progesterone receptor [41, 42]. It is possible that the outcome of LFS patients identified in the modern era will be better because of the introduction of therapies that effectively target HER2.

Recently, with clinical availability of NGS-based multigene panel tests that analyze dozens of hereditary cancer genes in parallel usually including TP53, new challenges arise due to many patients without criteria for LFS being tested [43]. This less strict approach to genetic evaluation has resulted in the identification of mutations in various established hereditary cancer genes in patients who lack the expected phenotype, raising important questions about prevalence, penetrance, and phenotypic spectrum [44–46]. This technology has also enabled the identification of low-level DNA variation consistent with germline mosaicism or somatic interference, which can be particularly challenging in clinical practice [47].

8.3.3 *CDH1*: Hereditary Diffuse Gastric Cancer Syndrome

E-Cadherin germline mutations are responsible for the development of hereditary diffuse gastric cancer (HDGC), an autosomal inherited syndrome [48]. These constitutional alterations were first identified in a Maori population with a remarkable clustering of diffuse gastric cancer in a single large kindred [49]. This large pedigree was characterized by the presence of multiple gastric tumors as well as lobular breast cancers (LBCs) among female family members. A germline mutation in *CDH1* was identified among affected relatives. The *CDH1* gene is located on chromosome 16q22.1 and encodes the E-cadherin protein [50], which is critical for establishing and maintaining polarized and differentiated

epithelia through intercellular adhesion complexes, functioning as a cell invasion suppressor. Aberrant E-cadherin activity leads to loss of cell adhesion, increased cell motility, and metastatic ability of the tumor [51, 52].

The penetrance of gastric cancer in people with *CDH1* mutations is reported to be 70% for men and 56% for women by age 80. Furthermore, the cumulative risk of LBC for women with a *CDH1* mutation is estimated to be 42% by age 80. There is currently no evidence that the risk of other cancer types in individuals with a *CDH1* mutation is significantly increased [53].

Apart from the well-documented association between LBC and HDGC syndrome, novel E-cadherin germline mutations have recently been detected in individuals without history of HDGC. Recent studies have provided evidence that early-onset LBC might be the first manifestation of HDGC. Benusiglio et al. [54] identified E-cadherin germline deleterious mutations in three bilateral LBC cases (age at onset >50 years) not fulfilling the International Gastric Cancer Consortium criteria, negative at the beginning for HDGC in first- and second-degree relatives and without *BRCA1* and *BRCA2* alterations. Interestingly enough, E-cadherin mutations have been identified in four bilateral early-onset LBCs (age at onset >50 years) with no family history of HDGC [55].

Recently the International Gastric Cancer Consortium has added a novel criterion, recommending genetic testing also in bilateral LBC patients or women with a family history of two or more cases of LBC (>50 years at onset) [53]. However, *CDH1* germline mutations have also been identified in isolated cases with age at onset >45 years [56].

In a recent study, penetrance data for *CDH1* mutation carriers has been updated based on affected individuals who presented clinically with HDGC or LBC, from 75 families with pathogenic *CDH1* mutations. The cumulative risk of HDGC for *CDH1* mutation carriers by age 80 is reported to be 70% for men (95% CI 59–80%) and 56% for women (95% CI 44–69%). The cumulative risk of LBC for women with a *CDH1* mutation is estimated to be 42% (95% CI 23–68%) by age 80. There is currently no evidence that the risk of other cancer types in individuals with a *CDH1* mutation is significantly increased [57].

8.3.4 *PTEN*: Cowden Syndrome

Germline mutations in *PTEN* are the cause of Cowden syndrome (CS) or *PTEN* hamartoma tumor syndrome (PHTS). Hamartoma is a benign, focal malformation that resembles a neoplasm in the tissue of its origin. This is not a malignant tumor, and it grows at the same rate as the surrounding tissues. It is composed of tissue elements normally found at that site, but growing in a disorganized mass.

CS is an autosomal dominant multisystem disorder characterized by increased risks of malignant and benign tumors of the breast, thyroid, endometrium, and other organs, as well as a combination of mucocutaneous findings such as trichilemmomas, oral papillomas, and acral keratoses [58]. PHTS can be differentiated from other hereditary cancer syndromes based on personal as well as family history. However, many of the benign features of CS are common in the general population, making the diagnosis of CS challenging [59].

More than 90% of CS individuals with germline (heritable) *PTEN* mutations are believed to manifest some feature of the syndrome, although rarely cancer, by age 20, and by age 30, nearly 100% of mutation carriers are believed to have developed at least some of the mucocutaneous signs. CS remains underdiagnosed because of its variable expression (often with only subtle skin signs); consequently, the current prevalence estimate of one in 200,000 is still likely to be an underestimate [60].

PTEN is a phosphatase and tensin homolog located on chromosome 10q23.3 with phosphatidylinositol-3-kinase (PI3K) phosphatase activity. *PTEN*'s precise function is not clear; however, dysfunctional *PTEN* leads to the inability to activate cell cycle arrest and apoptosis, leading to abnormal cell survival [61]. Approximately 80% of affected individuals will have a detectable *PTEN* mutation that may include a missense, point, deletion, insertion, frame shift, or nonsense mutation [62]. Among the 20% of patients with no identifiable *PTEN* mutation, half may bear a mutation in *PTEN* promoter [63].

What is histologically unique in patients with CS is ductal adenocarcinoma surrounded by hyalinized collagen, and this suggests a diagnosis of CS. Women with CS also have a high risk (67%) of benign breast disease, such as fibroadenomas, microcysts, adenosis, and apocrine metaplasia. Mammary hamartomas are characteristic of this group of patients and might be multiple and bilateral. Colocalization with breast cancer is frequent [64]. In patients with germline *PTEN* mutations and thus PHTS, three studies to date have examined risks for malignancy [65–67]. The largest, by Tan et al., identified greatly increased lifetime risks for breast, thyroid, renal, and endometrial cancers and slightly elevated risks for colorectal cancers and melanoma [65].

Early estimates of breast cancer risk for females with *PTEN* mutations were traditionally reported to be around 25–50% [68, 69]. More recent studies have reexamined the lifetime risks for malignancy in patients with germline *PTEN* mutations and have found that early risk figures may have been underestimates [65–67, 70]. The largest of the three studies by Tan et al. identified increased risks for several types of cancer, with the highest risk estimate increase for female breast cancer. Tan et al. [68] identified an 85%

lifetime risk, beginning around age 30, for female breast cancer with 50% penetrance by age 50. This risk figure is comparable to that quoted for patients with HBOC syndrome [67] but has been controversial.

According to NCCN guidelines, the presence of a known *PTEN* mutation in an individual's family is a clear indication for genetic testing for CS. Genetic testing for CS is also warranted when several diagnostic criteria are met (Table 8.1) [71], which are mainly based on clinical phenotype and the development of neoplasia. The *PTEN* risk calculator was developed by the team at the Cleveland Clinic to evaluate patients with suspected CS and is available on their website. This tool was developed from a multicenter prospective study in which 3042 probands satisfying relaxed CS clinical criteria were accrued, and it can help to distinguish patients more likely have clinical CS and test positive for PTEN mutations [68]. This tool was also proven to be cost-effective and provided a well-calibrated estimation of pretest probability of *PTEN* status [60].

Table 8.1 National comprehensive cancer network 2015 Cowden syndrome criteria [71]

Major criteria
Breast cancer
Endometrial cancer (epithelial)
Thyroid cancer (follicular)
Gastrointestinal hamartomas (including ganglioneuromas but excluding hyperplastic polyps)
Lhermitte–Duclos disease (adult)
Macrocephaly (97th percentile: 58 cm for adult women, 60 cm for adult men)
Macular pigmentation of the glans penis
Multiple mucocutaneous lesions (any of the following):
Multiple trihilemmomas (3, at least 1 proven by biopsy)
Acral keratoses (3 palmoplantar keratotic pits and/or acral hyperkeratotic papules)
Mucocutaneous neuromas (3)
Oral papillomas (particularly on the tongue and gingival), multiple OR biopsy-proven OR dermatologist diagnosed
Minor criteria
Autism spectrum disorder
Colon cancer
Esophageal glycogenic acanthosis
Lipomas
Intellectual disability (i.e., intelligence quotient/75)
Renal cell carcinoma
Testicular lipomatosis
Thyroid cancer (papillary or follicular variant of papillary)
Thyroid structural lesions (e.g., adenoma, multinodular goiter)
Vascular anomalies (including multiple intracranial developmental venous anomalies)
Three or more major criteria, but one most include Lhermitte–Duclos disease, macrocephaly or GI hamartoma
Two major criteria plus three minor criteria

8.3.5 *STK11*: Peutz–Jeghers Syndrome

Germline mutations in the *STK-11* gene are the cause of Peutz–Jeghers syndrome (PJS). PJS is a rare autosomal dominant disorder characterized by multiple gastrointestinal hamartomatous polyps and mucocutaneous pigmentations of the lips, buccal mucosa, and digits. These lesions fade during puberty, with the exception of those in buccal mucosa. Polyps can occur anywhere in the gastrointestinal tract and can increase in size enough to cause bowel obstruction, most commonly in the small bowel [72].

The *STK-11* gene is located on chromosome 19p13.3 and encodes for serine–threonine protein kinase 11. It is designated as a tumor suppressor gene, participating in membrane bonding and apoptosis [73]. Furthermore, it is a negative regulator of the mTOR pathway [74]. Although PJS has been described since 1949 [75], *STK-11* mutations were identified as its cause in 1998 [76]. Mutations of *STK-11* are detected in approximately 70–80% of patients with PJS, with 15% of them being deletions [77].

Affected individuals are at increased risk for colorectal, breast, small bowel, pancreatic, gastric, and ovarian cancer. Women with PJS present with an increased risk for breast cancer that reaches 50% lifetime. Breast cancer can occur early, but at a lower incidence compared to LFS and CS. In a case series that included 240 patients with PJS, breast cancer incidence has been shown to rise up to 32% by the age of 60, whereas it was only 8% by the age of 40 [78]. Similar to the general population, breast cancer in individuals with PJS is usually ductal in histology. Interestingly, women with PJS also have a 20% risk for ovarian cancer, mainly sex cord tumors [79].

8.4 Moderate-Penetrance Genes

Following the discoveries of *BRCA1* and *BRCA2*, many additional genes have been identified as breast cancer susceptibility genes. A prominent group of these are referred to as moderate-risk susceptibility genes because protein-truncating variants and severely dysfunctional missense substitutions in them appear to confer, on average, two- to fivefold increased risk of breast cancer. This magnitude of increased risk is less dramatic than risks conferred by most pathogenic alleles in the high-risk genes *BRCA1*, *BRCA2*, and *PALB2*, but potentially high enough to influence the medical management of carriers [80]. However, unlike *BRCA1* and *BRCA2*, the risk these genes pose is less certain, although data are accumulating more rapidly because more testing is being done. The most important genes in this group, involved in breast cancer risk, are *CHEK2*, *ATM*, *PALB2*, *NF1*, *BARD1*, *BRIP1*, *MRE11A*, *NBN*, *RAD50*, *RAD51C*, and *RAD51D*.

8.4.1 CHEK2

CHEK2 gene encodes for a serine–threonine kinase, which is activated in response to DNA double-strand breaks. It has also been found to phosphorylate *BRCA1*, facilitating its roles in DNA repair [81]. Certain pathogenic *CHEK2* mutations have been associated with breast cancer. Mutation 110delC has been shown to increase breast cancer risk two- to threefold, while missense mutations have conferred lesser risk [82]. Histologically, 70–80% of *CHEK2*-associated breast cancers are ER-positive [83].

The *CHEK2* 1100delC mutation is particularly frequent in Northern European populations, where it confers a lifetime risk of breast cancer as high as 37% [84]. Homozygotes have a sixfold increased risk of breast cancer [58]. Additionally, some data suggest that *CHEK2* mutation carriers who develop breast cancer have a higher risk of recurrent breast cancers and a poorer disease outcome than noncarriers [85]. Although responsible for less than 1% of familial breast cancer syndromes, *CHEK2* mutations have been identified in approximately 5% of breast cancer patients who are not from BRCA breast cancer families. Furthermore, four other mutations of the *CHEK2* gene have been identified and appear to also confer a moderate breast cancer risk; however only limited data for these four variants are available [86].

8.4.2 ATM

Homozygous *ATM* mutation carriers suffer from ataxia-telangiectasia (AT), a disorder characterized by cerebral ataxia, immunodeficiency, and increased risk of certain malignancies, including breast cancer [87]. Heterozygous carriers of *ATM* mutations have a twofold increased breast cancer risk compared to general population. Women under age 50 with specific *ATM* mutations may have as high as a fivefold increased risk [88]. The risks are particularly difficult to assess because of the high frequency of ATM mutations in the general population.

ATM is a multifunctional gene that plays a pivotal role in double-strand break repair and in cell cycle progression. Genetic testing of *ATM* should be performed in members of families with a known mutation or a history of a clinical diagnosis of ataxia-telangiectasia. ATM is present on most multigene breast cancer susceptibility panels, so will typically be examined in patients with a history of hereditary breast cancer. However, clinical utility of *ATM* genetic testing in heterozygotes is difficult to assess and there are no specific guidelines at this time. Small studies have not demonstrated increased risk of radiation-induced second primary breast cancers, but definitive data on radiation sensitivity are not yet available. Of note, decreased expression of *ATM* protein has been associated with aggressive features in sporadic breast cancer [89].

8.4.3 PALB2

PALB2 has emerged a new breast cancer susceptibility gene that is in transition from moderate to high risk. It was named as a "binding partner and localizer of *BRCA2*," contributing to the DNA repair mechanism homologous recombination and tumor suppression [90]. Classification of *PALB2* as a breast cancer susceptibility gene was based on data showing that about 1% of individuals with hereditary breast cancer negative for *BRCA1/2* harbor a monoallelic mutation in *PALB2* [91]. In a recent study with data from approximately 1500 patients with familial breast cancer, the prevalence of *PALB2* mutations was 0.8%, with the majority occurring in high-risk patients [92]. Although the above studies characterize *PALB2* as a rare, intermediate-risk gene with regard to inherited genetic susceptibility to breast cancer, a recent study that included 154 families with *PALB2* mutations demonstrated a breast cancer risk of approximately 35% [93]. This estimated risk is higher than the one associated with other genes such as *CHEK2* and *ATM* and is classified as high, which may warrant the addition of *PALB2* genetic testing to *BRCA1/2* as a high-penetrance gene for breast cancer, particularly triple-negative disease.

8.4.4 NF1

Neurofibromatosis type 1 is an autosomal dominant tumor predisposition gene with a prevalence as high as one in 2000 births. The pleiomorphic condition is caused by mutations of the *NF1* gene on chromosome 17.3 [94]. *NF1* is a multisystem disease with varying combinations of benign and malignant tumors, developmental dysplasias, and functional deficits, including cognitive impairment. Almost all adult patients with *NF1* have cutaneous neurofibromas, which are benign tumors that do not become malignant. More than one half of patients with *NF1* also have plexiform neurofibromas, which may become malignant [95, 96]. The most common malignancies associated with *NF1* are intracranial gliomas and malignant peripheral nerve sheath tumors (MPNSTs) [97]. In addition to malignancies originating from the nervous system, other cancers associated with *NF1* include breast cancer, gastrointestinal stromal tumor (GIST), and pheochromocytoma [98–100]. Multiple population-based studies have demonstrated a three- to fivefold increase in lifetime breast cancer risk for women with *NF1*, with the highest risks for those <50 years of age. In a study with data from England, the age-specific excess risk of breast cancer comparing the *NF1* cohort with the control cohort was elevated 6.5-fold (95% confidence interval 2.6–13.5) in women aged 30–39, and there was a 4.4 (2.5–7.0) times higher risk among women aged 40–49 [101].

8.4.5 *NBN*, *RAD51C*, *RAD51D*, *BRIP1*, *RAD50*, and MRE11

Genes involved in the Fanconi anemia (FA)-BRCA pathway, critical for DNA repair by homologous recombination, interact in vivo with *BRCA1* and/or *BRCA2* [102]. Some of these genes are mainly associated with ovarian cancer rather than breast cancer, and data are still emerging.

In *NBN*, one protein-truncating variant, c.657del5, is sufficiently common in some Eastern European populations to allow its evaluation in a case–control study. A meta-analysis of ten studies reported strong evidence of an association with breast cancer risk for this variant (summary relative risk, 2.7; 90% CI, 1.9–3.7; $P = 5 \times 10^{-7}$) [103].

For two other DNA repair genes, *MRE11A* and *RAD50*, which encode proteins that form an evolutionarily conserved complex with *NBN*, the data is more conflicting [102, 104, 105]. Currently, there are insufficient data to consider them as breast cancer risk genes [106].

8.5 Multigene Panel Testing

Some considerations must be done when doing multigene panels:

Multipanel can include moderate-penetrance genes for which there are no clear guidelines on risk management for carriers of pathogenic mutations. Until data are clearer, identification of these mutations may not alter the management plan compared to what might be recommended based on family history alone, so their immediate clinical utility could be questioned.

The use of NGS panel testing will lead to a considerable increase in the finding of variants of uncertain significance (VUS), sequence alterations that may or may not affect the function of the gene, or its resultant protein. The frequency of VUS in a large series of clinical specimens examined with NGS breast cancer susceptibility panel reached about 40%, with up to five variants found in individual patients, depending on the series evaluated [11]. An uncertain result—a VUS can ultimately be reclassified as pathogenic or benign—can be very stressful for the patient and family. VUS are clinically troubling for several reasons, including the temptation to assume that a particular VUS is responsible for disease risk in a family, when most will ultimately be considered benign. They are inherited like any other sequence alteration, so it should be shared among family members, but few families are of sufficient size to allow for definitive classification of pathogenicity based on the association with disease status [107]. However, a fraction of VUS will be reclassified to disease causing, highlighting the need for providers to track VUS reclassification and inform patients, which requires time and resources often for many years. Multiple expert groups use functional laboratory assays and computational approaches to classify sequence alterations, which are maintained in publicly supported databases like ClinVar, ClinGen, and the new BRCA Challenge of the Global Alliance for Genomics and Health.

There is a chance of finding a gene that does not match with personal and family history. In some series this finding varies from 0.3 to 0.8% of the tests [11]. Here, the difficulty occurs when mutations are discovered in genes that are predicted to be unrelated to the clinical presentation (e.g., a 40-year-old woman with ductal carcinoma of the breast with no family history of gastric cancer and a mutation in *CDH1*). The appropriateness of counseling this young woman to consider risk-reducing gastrectomy or testing family members for the CDH1 mutation in the setting of concern for gastric cancer risk remains difficult to determine [44].

8.6 Management of Carriers of Mutations in High-Penetrance Genes

8.6.1 BRCA1 and BRCA2

The main goal in management of BRCA mutation carriers is to reduce the risk of developing cancer or at least to promote an early opportune diagnosis and increase the chances of cure.

8.6.1.1 Screening

Breast Cancer

Surveillance of breast cancer in BRCA carriers includes monthly self-examinations, clinical breast examinations twice a year, and yearly magnetic resonance imaging (MRI) of breasts starting at age 25–30 with the addition of annual mammograms thereafter. Earlier screening can be discussed in a family with history of breast cancer prior to age 30. Between ages 25 and 30, MRI is preferred over mammography as false-negative mammogram has been associated with dense breast tissue, and multiple prospective trials have demonstrated far inferior sensitivity of mammogram compared to MRI in BRCA1/2 mutation carriers. In *BRCA1*, the development of "interval cancers" between imaging studies led to the practice of alternating mammograms and MRI's 6 months apart and the recommendation for breast self-exam in *BRCA1* mutation carriers [108]. Between ages 30 and 75, at this time, both breast annual MRI and mammogram are recommended, and after age 75, screening must be individualized [71].

Although earlier studies have not shown an association between radiation exposure and an increased risk of breast cancer in *BRCA* carriers, a recent study did find an increased risk of breast cancer when patients are exposed

to radiation (including mammogram) before age 30. This study further highlights the possible advantage of using MRI alone in this group [109].

Ovarian Cancer

Unfortunately, there is no effective screening for ovarian cancer at this time. The use of transvaginal ultrasound plus CA 125 has not proven to be sufficiently sensitive and specific to substitute for surgery in women at increased genetic risk of ovarian and related cancers.

The NCCN does not consider screening for ovarian cancer to be a reasonable substitute for salpingo-oophorectomy in women with HBOC syndrome [34]. A woman who declines salpingo-oophorectomy can undergo screening with the use of serum measurement of CA 125 and transvaginal ultrasonography every 6–12 months starting at ages 30–35 or 5–10 years before the earliest diagnosis of ovarian cancer in the family, but the patient must be advised about the lack of evidence about this strategy [8]. Ongoing clinical trials are examining bilateral salpingectomies for ovarian cancer risk reduction, with plans for oophorectomies at natural menopause to avoid the very significant side effects of early surgical menopause. Long-term data on efficacy are not yet available.

Other Tumors

Patients with *BRCA1/2* mutations should undergo annually skin examinations as suggested in NCCN and ESMO guidelines because of increased risk of melanoma. There are no official guidelines about pancreatic screening, but the CAPS trials are available for individuals who carry a pathogenic *BRCA1/2* mutation and have a family history of pancreatic cancer in close relatives [8, 71].

8.6.1.2 Risk-Reduction Surgeries

Bilateral Mastectomy

Bilateral mastectomy is largely accepted as an option for women carrying a mutation in either *BRCA1* or *BRCA2*. From 1999 through 2004, the results of four retrospective and prospective observational studies were published. These studies compared breast cancer outcomes in women who underwent prophylactic mastectomy with women of similar risk who did not undergo surgery [110–114]. Four studies showed a **reduction of 90%** or more in the risk of subsequent breast cancer among women who underwent prophylactic mastectomy; updated reports and additional studies have confirmed these initial results.

Although bilateral mastectomies have shown to reduce breast cancer incidence, this procedure is not associated with reduction in breast cancer mortality. This information must be discussed with patients in order to help them decide between surgery and surveillance [113].

Recently, a new technique called nipple-sparing or total skin-sparing mastectomy is becoming more and more common. During this procedure, the surgeon preserves the overlying skin of the nipple areola complex and removes the underlying glandular tissue at risk. Reconstruction can be performed immediately with a variety of techniques. In this procedure, cosmesis is enhanced by preserving the nipple skin, leading to less psychosocial impact, but still loss of sensation and erectile function. More about these surgical options will be addressed in Chap. 10 [115].

Risk-Reducing Salpingo-Oophorectomies

Due to the lack of effective screening for ovarian cancer, *BRCA1/2* mutation carriers are advised to undergo a risk-reducing salpingo-oophorectomy (RRSO) between ages 35 and 40, after women have completed childbearing. This surgery reduces the risk of developing ovarian cancer by as much as 85–96% and breast cancer by approximately 50% [116–119] and reduces both ovarian and breast cancer mortalities [119]. For women with *BRCA2* mutations, who have previously undergone mastectomy, the delay of RRSO until ages 40–45 can be considered since the ovarian cancer onset tends to be late in *BRCA2* carriers [120]. Uptake of RRSO, however, varies widely among individuals and across countries, with lower uptake among European than American women in most data.

Premature surgically induced menopause can lead to an increased risk of cardiovascular disease, osteoporosis, vasomotor symptoms, sleep disturbances, mood swings, and sexual dysfunction and thus adversely affect quality of life. Hormone replacement therapy (HRT) has been shown to at least partially alleviate vasomotor symptoms in *BRCA1/2* mutation carriers and decrease fracture risk in the general population [121–123]. Data have shown that short-term use of HRT in *BRCA1/2* mutation carriers does not negate the breast cancer risk reduction gained by RRSO [124]. The use of HRT may therefore mitigate the adverse effects of surgery on quality of life.

Given the adverse effects of premature menopause and data that ovarian cancer most often originates in the fallopian tube fimbria rather than ovarian surface epithelium, there has been growing interest in salpingectomy with or without delayed oophorectomy as a risk-reducing strategy. It is important to recognize that even with a better profile of impact in quality of life, this approach is not the standard of care of risk-reducing surgery. Fortunately, clinical trials are under way [125, 126]. In addition, oophorectomy in premenopausal women has been shown to reduce the risk of developing breast cancer by 50% in BRCA carriers, depending on the patient age at the time of the procedure, and salpingectomy probably will not have the same effect. These data have recently been questioned.

Chemoprevention

Oral contraceptives, which reduce ovarian cancer risk in the general population, also reduce ovarian cancer risk in *BRCA1/2* mutation carriers, but aspects of the data have been controversial. Observational studies have shown associations between the use of oral contraceptives and a reduced risk of ovarian cancer among *BRCA1* and *BRCA2* carriers, with odds ratios suggesting a 40–50% reduction in risk [127, 128]. However, there are data showing a 2.5-fold increase in breast cancer risk in *BRCA2* carriers in particular, for whom the ovarian cancer lifetime risk is lower (10–20%). The risk reduction with oral contraceptives is generally not considered sufficient to render risk-reducing salpingo-oophorectomies unnecessary, though some women may feel more comfortable delaying surgery if they have used oral contraceptives for many years.

Currently, data on the use of tamoxifen for primary prevention of breast cancer in *BRCA1* and *BRCA2* carriers are very limited. The only prospective data derive from the National Surgical Adjuvant Breast and Bowel Project P1 trial where investigators identified mutation status in 288 women who developed breast cancer, among whom only eight *BRCA1* carriers and 11 *BRCA2* carriers were identified. The hazard ratios for the development of breast cancer among women who received tamoxifen were 1.67 (95% CI, 0.32–10.7) among *BRCA1* carriers and 0.38 (95% CI, 0.06–1.56) among *BRCA2* carriers. Although these results are limited by small sample sizes, they are consistent with an effect in *BRCA2* carriers; approximately 77% of breast cancers in *BRCA2* carriers are ER-positive. Because of small sample sizes, these results are uninformative for *BRCA1* carriers. And the major question of whether or not tamoxifen can provide primary prevention of breast cancer in *BRCA1* carriers, of whom 75–80% of breast cancers are ER-negative, remains. The case–control studies involving *BRCA1* and *BRCA2* carriers reported that tamoxifen protects against contralateral breast cancer with odds ratio of 0.50 (95% CI, 0.30–0.85) to 0.38 (95% CI 0.19–0.74) for *BRCA1* carriers and 0.42 (95% CI, 0.17–1.02) to 0.63 (95% CI 0.20–1.50) for *BRCA2* carriers [129, 130]. Data are more consistent for tamoxifen in the setting of secondary prevention.

There are some preclinical studies suggesting that the use of PARP inhibitors can delay tumor development and extend the life span of *BRCA1*-deficient mice [131], but there are no current trials in humans as these drugs have only limited approval in the therapeutic setting at this time.

8.7 Li–Fraumeni Syndrome

Current practice guidelines established by the NCCN recommend yearly physical examinations including skin and neurologic examinations for all individuals with LFS, with special attention to the possibility of rare malignancies, secondary malignancies, and/or pediatric cancers, depending on the at-risk population. The NCCN also advise some specific considerations as outlined in detail below.

8.7.1 Breast Cancer

Breast cancer is one of the most common cancers occurring among women with germline TP53 mutations. Breast cancer surveillance programs for women with LFS are based on data that established the value of breast MRI in women with *BRCA* mutations.

The complete screening program includes a clinical breast examination once or twice yearly beginning at the age of 20–25. This can be performed earlier depending on the earliest age of onset of breast cancer in the family. Imaging should be used as a screening modality annually starting at the age of 20–25, or earlier, depending on family history. The NCCN recommend that between ages 20 and 29, patients should receive annual MRIs; after age 29, patients should begin mammograms and continue with MRI [71]. European guidelines generally do not include mammography because of concerns about radiation exposure in this population.

There are no data on this specific group regarding risk-reducing surgery, but depending on the prevalence of breast cancer in LFS patients, mastectomy may be considered based on BRCA patient data [71, 132].

8.7.2 Whole-Body MRI

Regarding the large spectrum of tumor in patients with LFS, other strategies have been discussed in order to improve surveillance in this group. A recent study incorporated whole-body MRI into a comprehensive screening protocol that also included clinical examinations and laboratory measures [133]. Participants who elected to enroll in this enhanced screening protocol were compared with those who decided not to undergo screening. The group without screening presented with tumors when they became symptomatic. The striking finding was the difference in outcome between the two groups: individuals in the group who underwent screening had a significant survival advantage with 100% survival at 3 years compared to 21% in the non-surveillance group (95% CI 4–48%) [133]. Separate breast MRI is still required in females because whole-body MRI does not visualize the breasts in sufficient detail.

The use of MRI in this setting has the distinct advantage of avoiding ionizing radiation, and as technology improves, faster whole-body screens have become possible. The existing data, while impressive and hopeful, are neither randomized nor complete; thus whole-body MRI is not yet a standard

of care worldwide. However, multiple research centers are currently working toward the design and implementation of prospective whole-body MRI protocols for LFS families that will contribute to further our understanding regarding the risks and benefits of such screening. Currently, two trials in particular must be considered: the SIGNIFY study in the UK and the LIFESCREEN study in France. Carriers of germline *TP53* mutations should be encouraged to participate in such clinical trials as they are critical for identifying the best care and management strategies for individuals with LFS [132].

8.7.3 Other Tumors

The NCCN also advise consideration of colonoscopy every 2–5 years beginning at age 25 for LFS patients. Annual dermatologic exams are also recommended. Biochemical screening per the Toronto protocol for screening has been less widely adopted [133].

8.8 Cowden Syndrome

8.8.1 Screening

8.8.1.1 Breast Cancer

Women should start MMG and consider MRI, especially in the presence of dense breast tissue, by age 35 or 10 years before the earliest case in the family [71, 134, 135].

8.8.1.2 Other Tumors

As mentioned previously, all these screening procedures are based on expert opinion and have become incorporated into guidelines [71, 134] (Table 8.2). In particular, thyroid surveillance is noninvasive and has been widely adopted.

8.8.2 Risk-Reduction Surgery

8.8.2.1 Mastectomy

Given the high lifetime cancer risks of breast cancer to be 85% [65], prophylactic mastectomy can be discussed on an individual basis, particularly if breast imaging and clinical surveillance are challenging due to extensive benign breast involvement [71, 134].

Table 8.2 Screening procedures for other tumors related to Cowden syndrome

Cancer type	Recommended screening guidelines
Thyroid	Annual ultrasound
Endometrial	Starting at age 30: annual endometrial biopsy or transvaginal ultrasound
Renal cell	Starting at age 40: renal imaging every 2 years
Colon	Starting at age 35: colonoscopy every 2 years
Melanoma	Annual dermatologic examination

8.8.2.2 Hysterectomy

Hysterectomy should be discussed after childbearing, due to the risk of endometrial cancer [71, 135].

8.9 Peutz–Jeghers

8.9.1 Screening

The new guideline from the American College of Gastroenterology suggests that surveillance in affected or at-risk PJS patients should include monitoring for colon, stomach, small bowel, pancreas, breast, ovary, uterus, cervix, and testes cancers, but the guideline does not specify the frequency or the exams that should be performed [136]. Regarding breast cancer risk development, MRI should be considered, but mastectomy is not usually recommended [71].

8.10 Management of Carriers of Mutations in Moderate-Penetrance Genes

There is a lack of evidence regarding management of moderate-penetrance genes. Although these genes are more frequently evaluated by multipanel testing, for the great majority of them, there are no prospective good data about penetrance, management, and clinical utility [71, 137]. The cancer risks associated with mutations in these genes are lower and different than those reported for high-penetrance genes, and the extrapolation of guidelines for the management of individuals with high-penetrance variants of cancer susceptibility genes to the clinical care of patients with moderate-penetrance gene mutations could result in substantial harm [106].

The NCCN guidelines suggest to do breast MRI and/or mammogram. Breast MRI is recommended when lifetime breast cancer risk exceeds 20%, as in patients harboring mutations in *ATM*, CHECK2, and *PALB2*; there are insufficient data for the intervention for *BRIP1*. The guidelines suggest offering RRSO for patients with mutations in *BRIP1*, *RAD51C*, and *RAD51D*; there are insufficient data for *PALB2*. Mastectomy should be offered just to *PALB2*, and the evidence is still insufficient for *ATM* and CHECK2. Table 8.3 summarizes this discussion [71].

Another important consideration is when to start breast cancer screening for these patients. In a recent publication in *Nature Reviews Oncology*, Tung et al. discussed this issue and concluded that screening should begin in this population when the average 5-year lifetime risk exceeds population

Table 8.3 Clinical management guidelines of high-penetrance genes

Gene syndrome	Lifetime risk of breast cancer	Other tumors	Breast cancer screening	Risk-reducing surgery	Other screening
BRCA1/2 HBOC syndrome	50–85%	Ovarian, pancreatic, melanoma, prostate	25–29 MRI 30–75 MMG + MRI	Mastectomy RRSO	–
TP53 Li–Fraumeni syndrome	65–90%	Sarcoma, leukemia, adrenocortical brain tumors, other	20–29 MRI 30–75 MMG + MRI	Mastectomy	Whole-body MRI
CDHI HDGC syndrome	45%	Gastric	30–75 MMG + MRI	Mastectomy Gastrectomy	–
PTEN Cowden syndrome	85%	Endometrial thyroid, colorectal, renal	30–75 MMG + MRI	Mastectomy Hysterectomy	Colonoscopy Thyroid USG TVUS + Endo BX Renal Ultrasound
STK11 Peutz–Jeghers	32%	Colorectal, small bowel, pancreatic, gastric, and ovarian	30–75 MMG + MRI	–	–

Table 8.4 Screening guidelines for moderate-penetrance genes (after Tung et al. [106])

Gene	Mammography (clinical breast examination and/or MRI)	RRSO
ATM	Annual starting at 40 y	Based on family history
CHECK2 truncating	Annual starting at 40 y	Based on family history
NBN	Annual starting at 40 y	Based on family history
PALB2	Annual starting at 30 y	Based on family history
BRIP1	Based on family history	50–55 y
RAD51C	Based on family history	50–55 y
RAD51D	Based on family history	50–55 y

risk at ages 45–50, the age at which mammographic screening is recommended in women in the USA [106]. Women with pathogenic mutations in *PALB2*, *ATM*, *NBN*, and *CHEK2* (other than p.I157T) have a cumulative life risk (CLTR) of breast cancer that exceeds 20% and thus meet existing guidelines for MRI surveillance, at least in the USA. For practical reasons it would be reasonable to initiate MRI surveillance at the same time as mammography [106].

The suggested age to start screening annually with mammogram and/or MRI is 40 years for *ATM*, CHECK2, and *NBN* and 35 years for *PALB2*. The RRSO procedure should be considered only for *BRIP1*, *RAD51C*, and *RAD51D* between ages 50 and 55 [106] (Table 8.4).

Chemoprevention

9

Andrea De Censi, Bernardo Bonanni,
and Massimiliano Cazzaniga

9.1 Introduction

In 1976, Sporn defined the term "chemoprevention" as the use of natural, synthetic, or biologic chemical agents to reverse, suppress, or prevent carcinogenic progression to invasive cancer [1].

Although the precise mechanisms promoting the development/progression of breast cancer are not completely established, the success of several clinical trials in preventive settings, mainly in selected high-risk populations, suggests that chemoprevention is a rational and an appealing strategy (Fig. 9.1).

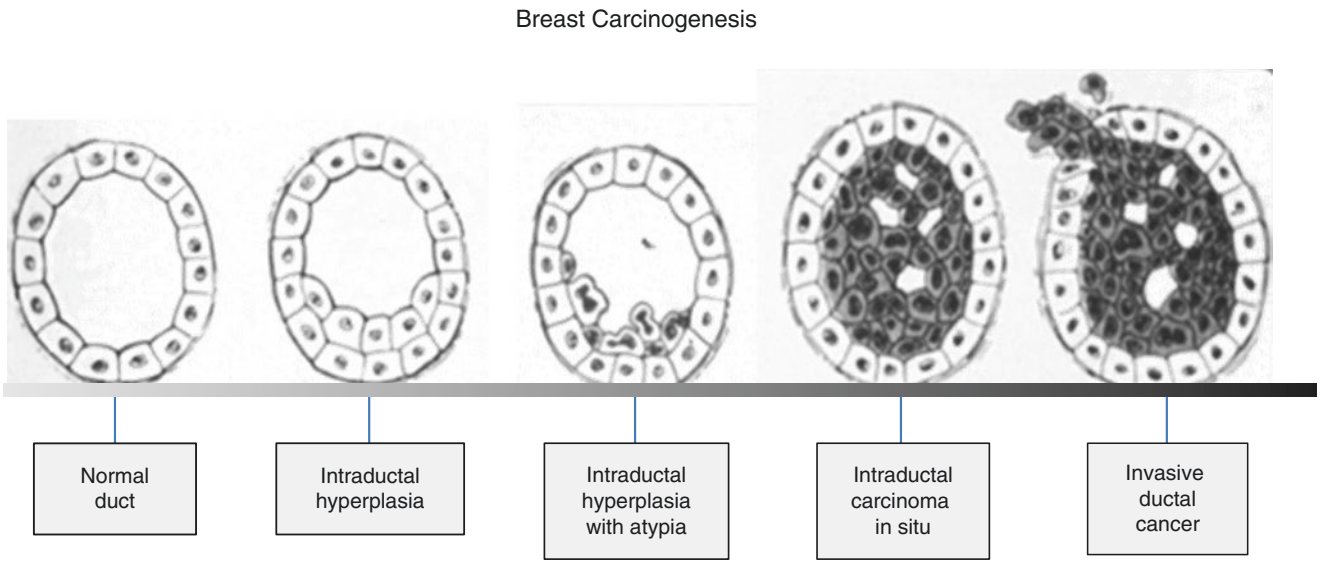

Fig. 9.2 Breast cancer carcinogenesis

Breast carcinogenesis is a multistep, multipath, and multiyear disease of progressive genetic and associated tissue damage. It spans the continuum from simple hyperplasia without atypical cells to intraepithelial neoplasia (IEN) and finally to invasive cancer (Fig. 9.2) [2].

In detail, the carcinogenetic process starts with unspecified accumulations of genetic events leading to a progressive dysplastic cellular appearance with genotypic and phenotypic alterations, deregulated cell growth, and finally cancer. Chemoprevention is just part of these mechanisms and works with the aim to arrest or modify them, thus resulting in a decrease in the incidence of the disease.

In the last few decades, following the therapeutic paradigm for the treatment of cardiovascular diseases that began to include a chemopreventive risk reduction approach [3], preventive therapy for several kinds of cancers, including breast cancer, is currently oriented toward the reduction of modifiable risk factors. The first task, of course, is to identify modifiable factors that would influence the development and progression of the disease in order to tailor prevention strategies on the basis of the individual risk. However, it is now accepted that therapeutic cancer prevention is an effective and essential tool in the fight against cancer, although the use of preventive therapy is sadly still inadequate.

Many subjects at increased risk for breast cancer could benefit from preventive therapy. Defining breast cancer risk incorporates knowledge of individual risk factors known to be associated with increased risk. These risk factors are included in various available risk calculation models, mainly Tyrer-Cuzick and Gail model, to provide a numeric risk that can be used to help quantify the level of individual risk. Other individual risk factors for the selection of candidates for preventive therapy are substantially the presence of premalignant disease (LCIS, ADH, ALH), the presence of mammographic density, and/or the use of HRT, the high-risk penetrant genes (BRCA mutation carriers) or the less penetrant but higher frequency polygenic risk score SNPs [4, 5].

9.2 Breast Cancer Chemoprevention

9.2.1 Prevention of ER-Positive BC

Although the precise mechanism causing breast cancer is not fully established, it is well known that hormones play a significant role in almost 70% of cases [6] and current chemopreventive strategies have targeted hormonally responsive breast cancers. The two major classes of antiestrogenic drugs, selective estrogen receptor modulators (SERMs) and aromatase inhibitors (AIs), have been recently used for their activity in breast cancer prevention.

The SERM tamoxifen was proven extremely effective on recurrent and new contralateral tumors, hence showing a good toxicity profile in the treatment of hormone receptor-positive breast cancer [7]. Tamoxifen has therefore been an obvious candidate for assessment as a preventive agent.

Four historical large trials [8–11] on tamoxifen effectiveness were undertaken, and long-term follow-up data are available. An overview of these trials has shown a 43% reduction in estrogen receptor (ER)-positive invasive breast cancer, but no effect on ER-negative disease [12]. The data from these studies and, in particular, from NSABP P-1 trial led to the 1998 US Food and Drug Administration (FDA) approval of tamoxifen for reduction of breast cancer incidence in high-risk women.

Furthermore, the direct comparison of tamoxifen with raloxifene (a second-generation SERM) in the STAR trial showed that raloxifene is less effective than tamoxifen (mainly on in situ breast cancer), but with fewer side effects. The initial report from 2006 found raloxifene to be as effective as tamoxifen in preventing invasive breast cancer, but with fewer associated toxicities. In the recent update [13], raloxifene has retained approximately 81% of the effectiveness of tamoxifen in preventing invasive breast cancer and continued to grow closer to tamoxifen in preventing noninvasive breast cancer. Raloxifene has also maintained a better profile with respect to uterine disease, thromboembolic events, and death.

Data from the STAR trial and the other raloxifene/placebo trial (MORE-CORE and RUTH) resulted in the approval of this drug by the US FDA for a reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis as well as a reduction in the risk of invasive breast cancer in postmenopausal women at high risk of invasive breast cancer. Finally, another recent meta-analysis by Cuzick [14] of nine randomized double-blind trials comparing various SERMs with placebo or another drug on women without breast cancer showed a 38% reduction in breast cancer incidence overall, including ductal carcinoma in situ (Fig. 9.3). The reduction appears larger in the first 5 years of follow-up than in years 5–10. Authors reported a reduction in both year groups, though with a minor effect in the 5–10-year group. No evidence of heterogeneity was found between trials. Moreover, the analysis recorded a significant 34% reduction in vertebral fractures.

While all SERMs increased venous thromboembolic events, only tamoxifen showed a clear increase in endometrial cancers. The large amount of extended follow-up available for this analysis has provided a clear overview of the benefits and harms of these drugs.

The fear of incurring some adverse effects of this drug has hampered its uptake by women at increased risk, and a relative recent route of administration of tamoxifen seems to have solved the question. A simple and economic approach to retain tamoxifen efficacy while reducing the risks was to diminish its dose. The effects of these different doses on proliferation were analyzed using the Ki-67 expression, as the

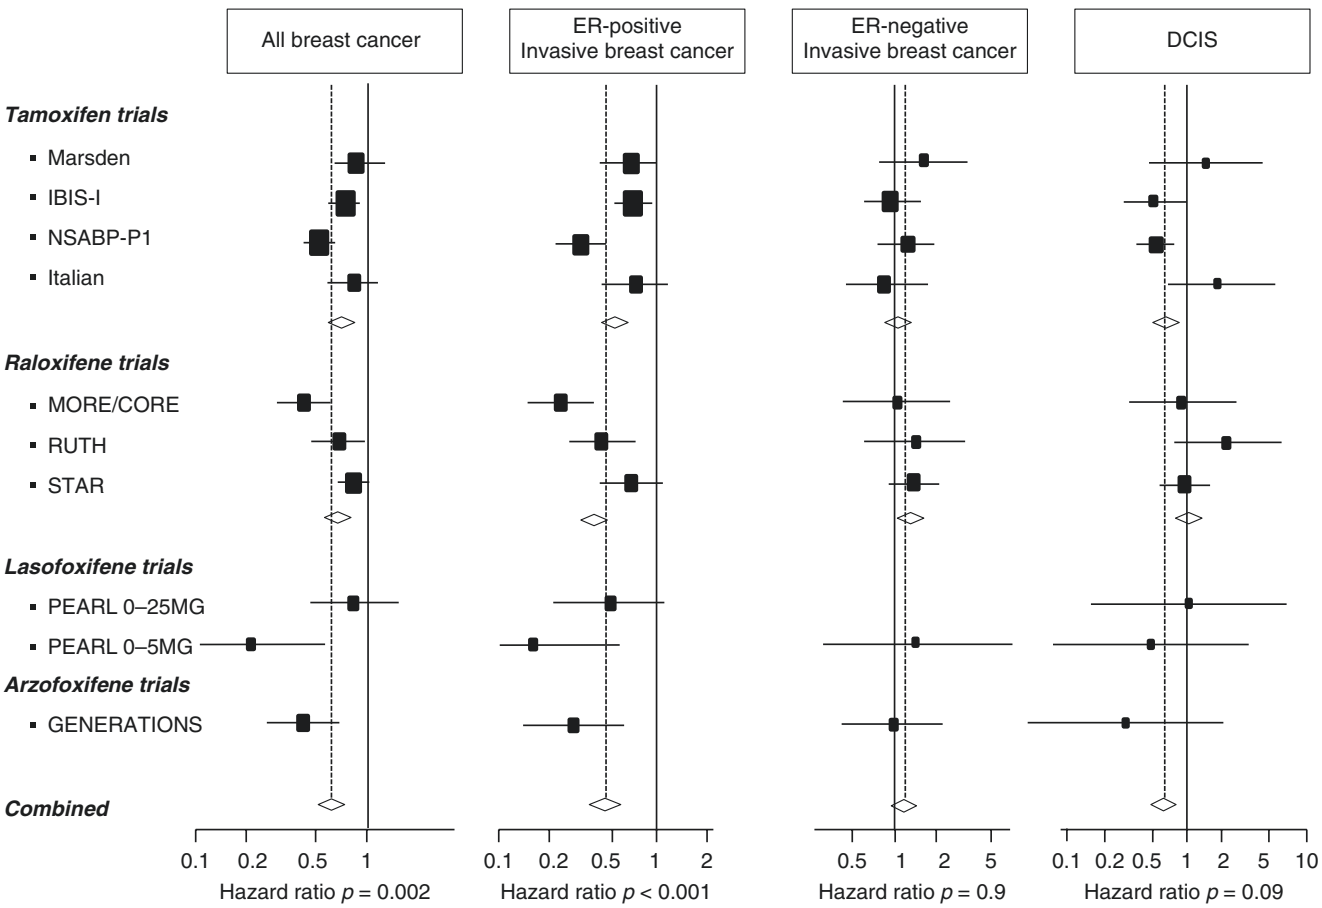

Fig. 9.3 SERMs efficacy in all breast cancer (invasive and in situ) in 10-year follow-up

main surrogate end point marker in several studies [15–18]. The change of the marker expression induced by lower doses of tamoxifen was confirmed to be comparable to that obtained with the standard dose.

Each of the three third-generation AIs used in adjuvant BC trials is effective in suppressing aromatase activity by 97–99% [19], thus achieving near-complete inhibition of aromatase in vivo as well as near-complete suppression of plasma estrogen levels. The significant reduction in contralateral BCs found in adjuvant AI clinical trials [20] has raised interest in these agents for primary prevention, in particular because they may be associated with a less adverse effect profile, specifically in thrombophilic events and endometrial cancer, compared with SERMs. There have been two landmark studies of AIs for BC primary prevention.

The National Cancer Institute of Canada Clinical Trials Group Mammary Prevention 3 (MAP.3) trial was an international prospective, randomized, placebo-controlled, double-blind study, designed to detect a 65% relative reduction in IBC with 25 mg of exemestane compared with placebo [21] In addition, the combined incidence of IBC and DCIS was reduced by 53% in the exemestane group compared with placebo. The IBIS-II [22] was a double-blind, randomized, placebo-controlled study that aimed to assess the efficacy and safety of anastrozole for BC prevention in high-risk postmenopausal women. A total of 3864 postmenopausal women were randomized to either 1 mg of anastrozole daily or placebo. This study showed that anastrozole significantly reduced IBC (mainly high-grade tumors) and DCIS diagnoses.

The MAP.3 and IBIS-II results demonstrate that exemestane and anastrozole were associated with a greater magnitude of BC risk reduction compared to SERMs. However, we should also consider their less adverse effect (especially in thrombophilic and gynecological events) and their simultaneous associated reduced bone mineral density leading to an increased fracture risk, an increase in musculoskeletal side effects, and also, most likely, an increase in cardiovascular events [23, 24]. Relevant issues for both types of chemoprevention, i.e., appropriate duration of therapy, dose optimization, target population, and, ultimately, effects of primary prevention on mortality, still remain unanswered. Finally, because of the absence of head-to-head comparisons and inter-study differences in patient characteristics, it remains unclear whether SERMs or AIs are the preferred agents for BC chemopreventive risk reduction.

9.3 Prevention of ER-Negative BC

Estrogen receptor-negative and triple-negative breast cancers are types of aggressive tumors that account for approximately 30 and 15% of total breast cancers, respectively [25]. Selective estrogen receptor modulators and aromatase inhibitors are unable to treat and prevent these subtypes of mammary tumors, and other approaches are, therefore, needed. Notably, around 90% of breast cancers arising in BRCA-1 mutation carriers are triple negative or estrogen receptor negative [26]. For these reasons, available preventive strategies are urgently needed in BRCA mutation carriers and, in general, in young high-risk population.

It is therefore worth identifying new pathways, biomarkers, and agents that are effective in the treatment and prevention of these subtypes. With the accumulating knowledge in understanding the biology of cancer development, several classes of a new generation of chemopreventive agents modulating the non-endocrine biochemical pathways have been developed, and many of these are still currently under investigation (Table 9.1).

These agents include retinoids, poly(ADP-ribose) polymerase (PARP) inhibitors, EGFR tyrosine kinase inhibitors (for HER2-positive tumors), metformin, cyclooxygenase-2 (COX-2) inhibitors, bisphosphonates, and peroxisome proliferator-activated receptor (PPAR) inhibitors. Due to their lack of proven efficacy or to an unacceptable risk-benefit ratio for healthy subjects, several of these agents are currently on standby. Only the following most apparently promising agents are described.

Table 9.1 Class, specific pathways, and agents actually involved in the treatment and prevention of ER-negative breast cancer

Class	Targets	Drugs or agent
Nuclear receptors	Retinoid acid receptor RXR	Fenretinide (4-HPR) 9 cis-retinoic acid (Targretin)
	VDR	VIT D3 analogues
	$PPAR_Y$	Troglitazone, rosiglitazone, pioglitazone
Membrane receptors and signal transduction	HMG-CoA	Statins
	Tyrosine kinase	Gefitinib (Iressa)
	HER-1, HER-2	Trastuzumab (Herceptin), lapatinib, genfitinib, neratinib
	IGF-R, IGF-1, IGFBP3	Metformin
Anti-inflammatory and antioxidant	COX-2	Celecoxib,rofecoxib, NSAIDs
Angiogenesis	VEGF	Bevacizumab
DNA modulation	BRCA1-BRCA2\	PARP-inhibitors

4-HPR N-(4-hydroxyphenyl) retinamide, *COX* cyclooxygenase, *ER* oestrogen receptor, *HMG-CoA* 3 hydroxy-3 methylglutaryl coenzyme A, *NSAIDs* nonsteroidal anti-inflammatory drugs, *PARP* poly (ADP-ripose) polymerases, *PPAR* peroxisome-activated receptor, *RXr* retinoid X receptor, *VDR* Vitamin D receptor

9.4 Retinoids

Retinoids (either natural or synthetic compounds structurally related to vitamin A) have long been studied for their chemotherapeutic effect and for their chemopreventive potential in breast cancer setting. They are able to regulate cell growth, differentiation, and apoptosis [27] in ER-positive and ER-negative breast cancer cells. The most promising retinoid in chemoprevention setting is fenretinide, N-4-hydroxyphenyl retinamide (4-HPR). The first important study where 4-HPR was administered as a single agent was an Italian multicentric phase III randomized trial, started in 1987. Stage I breast cancer patients were randomly assigned to receive either no treatment or fenretinide given orally at a dose of 200 mg/day for 5 years. The main outcome measure was the occurrence of contralateral breast cancer as first malignant event. Also, a different effect was noticed when the analysis was stratified by menopausal status, with a beneficial trend in premenopausal women on both contralateral and ipsilateral breast cancer (38%) and a reversed trend on contralateral breast cancer in postmenopausal women. Importantly, the protective effect persisted for up to 15 years (i.e., 10 years after retinoid cessation) [28]. Such benefit was associated with a remarkable 50% risk reduction in women aged 40 years or younger. This phase III trial suggested a possible role of fenretinide as a preventive agent acting at different levels of breast carcinogenesis. This protective effect was suggested also in women with a high probability of carrying a BRCA mutation.

9.5 Metformin

Epidemiological studies have strongly suggested that metformin can reduce cancer risk and mortality in diabetic subjects. A recent meta-analysis [29] on 47 independent studies and 65,540 cancer cases in diabetic patients showed that metformin reduced the overall cancer incidence by 31%, while mortality was reduced by 34%. Several preclinical studies have confirmed the effect of metformin in vitro and in vivo and showed a significant reduction of both breast epithelial cell proliferation and protein synthesis [30, 31].

Because of these promising epidemiologic and preclinical data, several phase I and II trials were conducted to investigate its breast cancer preventive effects [32–34]. Most of these were neoadjuvant "window of opportunity" studies among women with operable breast cancer and investigated a variety of biomarker changes after metformin administration. Metformin reduced proliferation (KI67) and increased apoptosis (TUNEL staining) in invasive tumor tissue, in particular in patients with a metabolic unbalanced condition [32, 35]. Phase II and III clinical trials are currently in progress to further elucidate the cancer preventive effect of metformin [36–39]. The most important one is a currently ongoing phase III study (the NCIC-MA.32 trial), testing 5 years of metformin versus placebo among women with early-stage breast cancer [36].

Metformin's antineoplastic mechanisms of action involve several pathways through which the drug acts in direct or indirect mode. In particular, metformin regulates the AMPK/mTOR pathway implicated in the control of protein synthesis and cell proliferation [40]. It has been confirmed that metformin produces a significant repression of cell proliferation and this effect was found to be different in human breast cancer cell lines if related to either positive or negative ERs. A complete cell growth repression was detected in ER-positive cell lines, although only a partial inhibition was detected in ER-negative phenotypes [41]. These data suggest that although ER-negative cells are not as sensitive as ER-positive ones, both of them show a reduction in cell growth under metformin treatment.

9.6 Bisphosphonates

Bisphosphonates are commonly used in patients with breast cancer to reduce skeletal-related events in metastatic disease and to mitigate bone loss associated with cancer therapy in early-stage disease. Antiresorptive agents, including bisphosphonates such as ibandronate, risedronate, and zoledronic acid and the receptor activator of nuclear factor kappa B ligand (RANKL) inhibitor denosumab, have been shown to mitigate aromatase inhibitor-associated bone loss in a series of trials [42]. In addition, adjuvant breast cancer trials evaluating the oral bisphosphonate clodronate suggested a reduction in cancer recurrence and prevention with a direct antitumor effects involving anti-angiogenic, antiproliferative, and proapoptotic mechanisms [43]. Recent adjuvant trials suggest that bisphosphonates may also delay disease recurrence in some populations of estrogen-depleted women in early breast cancer setting supporting a potential anticancer effect. Two large cohort studies reported reductions in breast cancer incidence of around 30% in bisphosphonate users [44, 45]. Both studies reported similar benefits for ER-negative breast cancers.

9.7 EGFR Tyrosine Kinase Inhibitors (TKIs)

Researchers have recently focused their attention on EGFR-HER-1 and EGFR-HER-2 pathways and consequently on TK inhibitors, because the mechanism of resistance to antiestrogen therapy is usually associated with an increased expression of HER-1 and HER-2 receptors.

EGFR is one of a family of four closely related receptors (EGFR or erbB-1, HER-2/neu or erbB-2, HER-3 or erbB-3, and HER-4 or erbB-4) that uses tyrosine kinase activity and contributes to a large number of processes involved in tumor survival and growth, including cell proliferation and inhibition of apoptosis and angiogenesis [46], thus making it an attractive target for cancer prevention. There are two different and concomitant strategies able to inhibit erbB activity. One involves blockade of this activity with monoclonal antibodies (trastuzumab), whereas the second involves the TKIs. TKIs have several advantages over monoclonal antibodies, such as oral bioavailability and potentially less toxicity, and these make them attractive preventive agents [47]. There are two agents tested in this setting, lapatinib and gefitinib.

Lapatinib has been evaluated in several phase II and III trials in various types of breast cancer [48, 49]. Moreover, in prevention setting, it showed a significant delay in the development of ER-negative mammary tumors [50]. This preventive action was seen in premalignant mammary lesions, and this suggests its effectiveness also in the initiation and progression of breast carcinogenesis. Gefitinib showed the ability to suppress ER-negative mammary tumor formation in MMTV-ErbB2 transgenic mice [46], and, despite the results of preclinical and clinical studies, gefitinib recognized ability to inhibit proliferation in early-stage breast cancers and in normal adjacent epithelium remains controversial. This could be the rationale for the use of this compound in prevention trial.

Finally, a mention must be done to neratinib, another irreversible tyrosine kinase inhibitor of HER1, HER2, and HER4, which has recently shown [51] clinical activity in patients with HER2-positive metastatic breast cancer. Neratinib for 12 months significantly improved 2-year invasive disease-free survival when given after chemotherapy and trastuzumab-based adjuvant therapy to women with HER2-positive breast cancer. Disease-free survival including ductal carcinoma in situ was also significantly improved with neratinib compared with placebo after 2 years, and this action about early phases of cancinogenesis should be promising in the preventive settings too.

9.8 Limited Uptake of BC Chemoprevention

Despite the availability of several efficacious agents, the utilization of preventive therapy has been poor due to various barriers, such as the lack of physician and patient awareness, fear of side effects, and licensing and indemnity issues. For preventive therapy, we cannot identify those individuals whose cancer was prevented or risk was substantially reduced because of the lack of measurable biomarkers of efficacy, which currently exist for other diseases, including cardiovascular diseases, prevention of diabetes complications, or osteoporotic bone fractures.

Therefore, from those persons' point of view, they either have taken unnecessary medication or, worse, they have unnecessarily suffered the adverse effects of such therapy. Preventive therapy for cancer is often discounted as overtreatment and used as an example of overmedicalization. Understanding and overcoming such perception differences, along with other barriers, are essential if we are to realize the full potential of this approach for cancer control. New strategies are needed in order to improve this condition, and they include improving physician awareness and countering prejudices by highlighting the important differences between preventive therapy and cancer treatment. Researchers in the last few decades have discussed about the important barriers to therapeutic cancer prevention and the strategies to overcome these barriers and future research needs (Table 9.2).

Several reasons seem to be the causes that complicate the spread of the use of preventive therapies, although the most important often seems to be the fear of side effects. Moreover, future research to improve therapeutic cancer prevention needs to include improvements in the prediction of benefits and harms and improvements in the safety profile for new or existing agents by experimentation with dose.

Table 9.2 Barriers to preventive therapy and strategies to overcome these barriers

Barriers	Strategies to overcome barriers
Underestimation of benefits and/or overestimation of harms	• Acknowledging different needs of risk prediction for different diseases and agents • Refining risk prediction and risk communication • Development of biomarkers than can be frequently monitored by non-invasive means
Adverse effects of agents	Exploring strategies to reduce adverse effects, e.g., dosing modifications
Individual lack of knowledge	Improving physician-patient communication and information sharing; educational interventions
Individual's fear of side effect	Exploring re-purposing of commonly used agents with well-documented safety profile
Physicians' lack of knowledge/prejudices	Increasing physician awareness and countering prejudices
Licensing and off-label use issues	Policy engagement
Lack of well-proven agents for several cancers	Increased focus on preventive research, particularly in academia

9.9 Natural Compounds

Lifestyle changes do offer an important strategy for cancer prevention [52]. They generally include diet and nutrition modifications as well as a regular and suitable physical activity. Moreover, recent attention has been given to the use of natural products in a preventive setting, especially in trying to counteract the concern of drugs' side effects, in addition to making a possible preventive approach intriguing [53]. Some of the most promising compounds include catechins (e.g., epigallocatechin gallate (EGCG), green tea extract), curcumin, carotenoids, omega-3 fatty acids, resveratrol, soy isoflavones, and vitamin D. Unfortunately, none of these dietary agents has been shown to consistently prevent breast cancer. So, in spite of the fact that natural products are a promising alternative strategy for cancer prevention, their potential efficacy in the prevention of ER-negative and, particularly, triple-negative breast cancer will be determined in the near future. In particular, it might be useful to identify those natural products that cannot act directly on carcinogenic mechanisms but on the main risk factors. Since the properties of some carcinogenic pathways, such as inflammation, cholesterol, metabolic syndrome, and hyperinsulinemia, are already known, natural products could successfully be used in the regulation and/or control of these pathways and could also indirectly act on the risk of developing the disease.

One simple strategy is to combine nutraceuticals which are in common use as food ingredients to make a single cancer polypill. This was done with success for antihypertensive agents in the polypill for stroke prevention in the general population [54].

Conclusions

The success of several recent clinical trials in the preventive setting in selected high-risk populations suggests that chemoprevention is an effective strategy. New pathways, biomarkers, and agents are actively searched in this subgroup of cancers and have been recently put under investigation in order to improve the effectiveness and reduce the toxicity. These strategies accompanied by a serious lifestyle and nutrition changes could be a decisive step to breast cancer prevention and treatment.

Surgical Prevention

10

Paolo Veronesi and Nickolas Peradze

The surgical strategies available today for breast cancer prevention are prophylactic bilateral or unilateral mastectomy and prophylactic bilateral salpingo-oophorectomy.

Mastectomy is intended to remove breast tissue and therefore to remove the very substance of cancer growth, while oophorectomy eliminates the major part of the body's source of estrogen, with the additional benefit of decreasing ovarian cancer risk in *BRCA1* and *BRCA2* mutation carriers.

Overall mastectomy rates have increased over the past decades [1–3]. In part, this is due to the introduction of new imaging modalities capable of detecting additional breast lesions, which in turn require more extensive surgery. It is also due to the growing patient choice for preventive surgery as a reflection of the increased awareness of genetic breast cancer, increased genetic testing, and increased knowledge of improvements in mastectomy and reconstruction techniques, together with anxiety and overestimation of the risk of developing breast cancer.

Several studies have demonstrated that the risk as perceived by patients of developing breast cancer is much higher than the objective risk, given the fact that those patients who are the most well informed and involved in decision-making are more likely to choose mastectomy [4, 5].

Mastectomy, especially bilateral, is an extended and elective surgery and may have unfavorable effects in terms of complications and associated costs as well as in terms of body image and sexual function. Therefore a better understanding of its indications, use, and outcomes is crucial to improve cancer care [6–9].

In general, prophylactic mastectomy may occur in two populations of patients: those already affected by unilateral breast cancer who undergo contralateral mastectomy for the prevention of cancer development in the contralateral breast and those without breast cancer, but at high risk, and therefore undergo bilateral risk-reducing mastectomy.

In 2007 Giuliano et al. stated the potential indications for prophylactic mastectomies. In this statement, the indications for prophylactic mastectomies include BRCA mutations or other susceptibility genes, strong family history without genetic mutation, histologic risk factors, difficult surveillance, and reconstructive issues (symmetry/balance) [10].

10.1 Contralateral Prophylactic Mastectomy

Various studies have evaluated trends, implications, and outcomes of contralateral prophylactic mastectomy (CPM).

The Surveillance, Epidemiology, and End Results Program (SEER) from 1998 to 2003 in the USA confirmed increased rates of CPM by 150% [11]. Similar trends were observed in other studies [12–15].

The categories of patient who may benefit from CPM may be varying.

Despite limited evidence in survival improvement after CPM published in 2010 in a large Cochrane analysis [16], several studies which were subsequently published showed minimal benefit in overall survival [17–19].

Yao et al. examined the effect of CPM on survival on 219,983 mastectomy patients using the National Cancer Data Base (the largest study so far to examine survival with CPM). Adjusted hazard ratio (HR) was 0.88 (95% CI 0.83–0.93; $p < 0.001$), and an absolute 5-year benefit of 2% was observed. Differential effect of CPM by stage and age was observed with HR = 0.88 (95% CI 0.82–0.94; $p < 0.001$) in women younger than 70 with stage I/II, and HR = 0.95 (95% CI 0.88–1.04; $p = 0.28$) in women with stage III or older than age 69 with absolute 5-year benefit of 1.3%. This improvement in survival could be attributed to the category of high-risk patients (family history and/or BRCA mutation carriers), who have higher risks of contralateral cancers and therefore may benefit from a CPM. Finally, the authors were unable to establish a cause-and-effect relationship between CPM

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_10

and survival, due to the lack of data regarding family history, BRCA carrier status, hormonal receptor, and HER2 status [20].

In large meta-analysis performed by Fayanju et al., the authors concluded that patients without known high risk (familial/genetic) should not be advised to undergo CPM [21].

In the recent study conducted by Basu et al. [22], the authors developed a series of guidelines to aid clinicians dealing with requests for, and management of, CPM. These included several steps for the process of preoperative assessment and counseling before CPM can be given and may be summarized as follows:

- Taking a history
- Calculating the risk of contralateral breast cancer
- Cooling-off period whenever possible
- Multidisciplinary team (MDT) discussion
- Patient consent

Therefore breast cancer patients should be provided with precise and accurate information on the risk of contralateral breast cancer and on the risks and benefits of CPM.

10.2 Bilateral Prophylactic Mastectomy

As outlined earlier, indications for bilateral prophylactic mastectomies include BRCA1/BRCA2 mutation or other susceptibility genes, strong family history without genetic mutations, and histologic risk factors.

Large prospective analyses report the average cumulative risks for breast cancer by the age of 70 years for BRCA1 carriers of 60% (95% confidence interval [CI] = 44–75%) and 83% (95% CI = 69–94%) for contralateral breast cancer. For BRCA2 carriers, the corresponding risks are 55% (95% CI = 41–70%) and 62% (95% CI = 44–79.5%) for contralateral breast cancer [23, 24].

Retrospective analyses of the results of the study conducted by Hartmann et al. demonstrated risk reduction of about 90% for BRCA1 and BRCA2 mutation carriers after bilateral prophylactic mastectomy (BPM) [25, 26].

In the study conducted by Heemskerk-Gerritsen et al., authors evaluated breast cancer incidence, all-cause mortality, and breast cancer specific mortality in healthy BRCA1 and BRCA2 mutation carriers undergoing bilateral prophylactic mastectomy. These were compared with a surveillance group. No incidence of breast cancer cases was observed during 1379 person-years of observation after BPM. 10-year overall survival was 99% for the BRRM and 96% for the surveillance groups, respectively. The authors concluded that BPM substantially reduces breast cancer occurrence in healthy BRCA1/BRCA2 mutation carriers. However, longer follow-up and larger sample size are needed to confirm statistical significance [27].

Interesting results were presented by the study of Skytte et al., which included 307 women with a pathogenic BRCA1 or BRCA2 mutation, of whom 96 underwent bilateral risk-reducing mastectomy. None of the study participants had a previous history of breast or ovarian cancer or had undergone risk-reducing bilateral salpingo-oophorectomy prior to the time of BRCA testing. The annual incidence of post-mastectomy breast cancer was 0.8% compared with 1.7% in the non-operated group [28].

A more recent meta-analysis performed by De Felice et al. reported risk reduction of developing breast cancer in BRCA1 and BRCA2 mutation carriers after risk-reduction mastectomy by 93% [29].

The risk of breast cancer after mastectomy could be presumably explained by a tumor developing in left-over breast tissue. However this hypothesis is debatable. In fact in the study of Skytte et al., women who developed breast cancer after mastectomy had undergone a simple mastectomy including removal of the nipple–areola complex.

Today the most popular prophylactic mastectomy technique is the so-called conservative mastectomy or nipple-sparing mastectomy/skin-sparing mastectomy or subcutaneous mastectomy with immediate reconstruction. This surgical technique has been shown to be feasible and safe, with outstanding cosmetic results, and allows preservation of the woman's body image [30–33].

This was also supported by a recent review by van Verschuer et al. in which the authors stated that the incidence of primary breast cancers after prophylactic mastectomy is very low after total mastectomy as well as after conservative mastectomy [34]. It is suggested to surgeons that they minimize risk by paying particular attention to ensure that all glandular tissue is dissected, especially in the axillary tail, chest wall, and nipple–areola complex.

Recently Toesca et al. reported the first experience of robotic prophylactic nipple-sparing mastectomy. This seemed to improve outcomes of mastectomy from a cosmetic and patient satisfaction point of view [35].

NCCN guidelines support the use of risk-reducing mastectomies for selected patients at high risk who desire this intervention. Nevertheless histologic factors such as ADH, LCIS are associated with an increased risk of breast cancer, surgical risk reduction is not recommended in most of these patients [36].

There is a lack of data concerning the utility of sentinel lymph node biopsy (SLNB) during risk-reducing surgery. It is recommended that MRI assessment be performed prior to risk-reducing surgery as some patients may be at risk of occult breast cancer, having strong family history or mammographic density, and the use of SLNB should be decided on a case-by-case basis [37].

10.3 Bilateral Prophylactic Salpingo-Oophorectomy

Several studies have reported a breast cancer risk reduction of approximately 50% after risk-reducing salpingo-oophorectomy in BRCA1/BRCA2 mutation carriers [26, 38–43].

Heemskerk-Gerritsen et al. revised the association between risk-reducing salpingo-oophorectomy (RRSO) and breast cancer risk in BRCA1/BRCA2 mutation carriers, proposing a different analytical approach in order to mini-

mize potential biases as much as possible compared with previous studies. Applying the requirement of no history of cancer at the date of DNA diagnosis and the inclusion of person-time preceding risk-reducing salpingo-oophorectomy, the authors found no evidence for first breast cancer risk. Nonetheless, cumulative breast cancer risk curves suggest a slightly protective effect of risk-reducing salpingo-oophorectomy on breast cancer risk when performed at premenopausal age [44].

BRCA1 tumors have been more frequently found to be steroid hormone receptor-negative, rather than BRCA2 tumors [45, 46]. Therefore, the BC risk-reducing effect of RRSO may be expected more in BRCA2 mutation carriers.

In the most recent review conducted, Hartmann et al. summarized and presented current guidelines and statements on indications for preventive surgical procedures [47] (See table provided by Hartmann et al., NEJM).

In conclusion, risk-reducing surgery provides considerable benefits in terms of cancer prevention. Although, being an extended surgery, risk-reducing procedures may be associated with complications and adverse physical and psychosexual effects. Patient education plays an important role in avoiding the overestimation of breast cancer risk. Efforts should be made to provide information regarding sexuality, body image, reconstruction techniques, fertility, and the likelihood of familial predisposition.

The decision to undergo preventive surgical procedures is complex and patients require careful assessment in a multidisciplinary setting comprising clinicians, psychologists, and geneticists.

Box 1. Overview of Key Positions Regarding Risk-Reducing Surgery in Women with Hereditary Breast and Ovarian Cancer Syndrome.

The following position statements pertain to women without prior breast or ovarian cancer. These statements acknowledge that bilateral risk-reducing mastectomy and salpingo-oophorectomy have potential adverse effects, and multidisciplinary consultations before surgery are recommended to ensure informed decision making by the patient.

Bilateral Mastectomy

NCCN (National Comprehensive Cancer Network; www.nccn.org): "Risk-reducing mastectomy . . . provides a high degree of protection against breast cancer in women with a *BRCA1/2* mutation." Discuss risk-reducing mastectomy on a case-by-case basis, with a review of the potential adverse effects of the procedure. Risk-reducing mastectomy is also an option for patients with the Li–Fraumeni syndrome and the Cowden syndrome. Consensus recommendations are not provided for carriers of mutations in other genes.[34]

USPSTF (U.S. Preventive Services Task Force): "Among high-risk women and mutation carriers, risk-reducing mastectomy [as compared with no surgery] decreased breast cancer by 85 to 100% and breast-cancer mortality by 81 to 100%."[35]

Society of Surgical Oncology: Indications for bilateral prophylactic mastectomy include mutations in *BRCA1*, *BRCA2*, or other strongly predisposing breast-cancer susceptibility genes or, in the absence of data on mutations, a hereditary breast-cancer syndrome.[36]

NICE (National Institute for Health and Care Excellence; United Kingdom): "Bilateral risk-reducing mastectomy is appropriate only for a small proportion of women who are from high-risk families and should be managed by a multidisciplinary team . . . . Bilateral mastectomy should be raised as a risk-reducing strategy option with all women at high risk."[37]

Additional international guidelines have been summarized by Easton et al.[10]

Comments on the procedure: No mastectomy can remove all breast tissue, which is widely distributed on the chest wall. Several mastectomy approaches have been used for prophylaxis. A total (simple) mastectomy removes more than 95% of breast tissue, including the overlying skin and nipple–areolar complex. In a classic subcutaneous mastectomy, the skin and nipple–areolar complex are preserved, and varying amounts of glandular tissue may be left below the areola. The use of this procedure for prophylaxis has been criticized because of the possible retention of excess at-risk tissue in the skin flaps and below the areola. Most surgical oncologists recommend a skin-sparing mastectomy for prophylaxis; this preserves the natural skin of the breast. A recent technique called "nipple-sparing" or "total skin-sparing" mastectomy also preserves the overlying skin of the nipple–areola complex. The underlying glandular tissue at risk is removed, and immediate reconstruction is performed. Cosmesis is enhanced by preserving the nipple skin.[38,39] More than 90% of women who undergo bilateral risk-reducing mastectomy elect immediate breast reconstruction, usually with implants. Complications may be immediate or delayed. In a prospective cohort of 112 consecutive women who underwent risk-reducing mastectomy followed by immediate breast reconstruction and were followed for 2.8 years, 10% had bleeding, 9% infection, and 14% capsular contracture. A total of 33% of women required reoperation.[40]

Bilateral Salpingo-Oophorectomy

NCCN: "Recommend risk-reducing salpingo-oophorectomy (ideally in consultation with a gynecologic oncologist) typically between 35 and 40 years, and upon completion of child bearing."[34]

USPSTF: "Risk-reducing salpingo-oophorectomy decreased breast cancer incidence by 37 to 100%, ovarian cancer by 69 to 100%, and all-cause mortality by 55 to 100%."[35]

Society of Gynecologic Oncology: "The most proven method for the prevention of ovarian cancer in women who carry a deleterious *BRCA1* or *BRCA2* mutation is risk-reducing salpingo-oophorectomy. Prospective studies have reported a 70% to 85% reduction in ovarian cancer . . . risk-reducing salpingo-oophorectomy between the ages of 35 and 40 years is recommended for risk reduction in women at increased genetic risk of ovarian cancer. The age [at which risk-reducing salpingo-oophorectomy is performed] may also be individualized according to the earliest age of onset in the family and personal choices."[41]

Comments on the procedure: The procedure, usually performed laparoscopically, should include visual assessment of the abdomen and pelvis, a pelvic washing, and total bilateral salpingo-oophorectomy, including ligation of the ovarian artery and vein approximately 2 cm proximal to the ovary and tube to ensure removal of all tissue. Because of the possibility of occult cancer, including serous tubal in situ carcinoma, meticulous processing of the surgical specimen is necessary according to the SEE-FIM protocol (protocol for sectioning and extensively examining the fimbriated end).[41-43]

Salpingectomy Alone

NCCN: "Salpingectomy [alone] is not the standard of care and is discouraged outside a clinical trial. The concern for risk-reducing salpingectomy alone is that women are still at risk for developing ovarian cancer."[34]

Society of Gynecologic Oncology: "Salpingectomy can be considered at the completion of childbearing in women at increased genetic risk of ovarian cancer who do not agree to salpingo-oophorectomy. However, this is not a substitute for oophorectomy, which should still be performed as soon as the woman is willing to accept menopause, preferably by the age of 40 years."[41]

Pathology: Standard and Molecular Diagnostics

Premalignant and Pre-invasive Lesions of the Breast

11

Elena Guerini-Rocco and Nicola Fusco

11.1 Introduction

Premalignant and pre-invasive lesions of the breast belong to a complex and heterogeneous group of lesions and represent a matter of remarkable interest from both clinical and biological standpoints. These frequent noninvasive alterations are related with an increased probability of breast cancer development. What is more, they show extremely variable risks of progression toward invasive forms of disease. Indeed, while there are many histologically defined premalignant lesions in the breast, only a few of them constitute true neoplastic precursors that will progress to invasive cancer. Disappointingly, it is currently not conceivable to identify a priori, with absolute certainty, which of these precursors will progress and which not. Therefore, classifying risk indicators, precursors, and non-obligate precursors of invasive breast cancer, and ultimately defining robust protocols for their clinical management, is a hot topic in the multidisciplinary approach to breast cancer patients, that involves pathologists, radiologists, surgeons, and oncologists.

The introduction of mammography-based breast cancer screening programs has increased spectacularly the detection of noninvasive lesions [1]. Nowadays, in situ carcinomas account for up to 21% of breast cancer diagnoses [1], while atypical lesions are "incidental" findings in nearly 10% of breast biopsies with non-carcinomatous alterations [2]. Therefore, the correct and early diagnosis of premalignant and pre-invasive lesions of the breast has become one of the most crucial tasks for radiologists and pathologists, given its decisive implications in terms of tailored management schemes implementation. However, the histological identification and classification of this vast collection of entities remains not trivial at all, since the rules for their diagnosis has changed over the time, and even changes over the space with substantial interobserver and inter-institutions variability. Nowadays, breast care providers are living in an era of extraordinary changes in clinical approaches to nonmalignant lesions, and the integration of multiples disciplines as well as cutting-edge diagnostic methods has not yet fully achieved. As a result, guidelines for the screening, treatment, and follow-up of these patients are in constant evolution and reshape, based on the biologic insights that high-throughput technologies are currently providing. At present, to master noninvasive and pre-invasive changes of the breast at both morphologic and molecular levels is key to allow the most appropriate clinical workup for these women.

Over the past few years, many models have been put forward to unravel the complexity of breast cancer tumor progression. To date, it is widely recognized that a strict morphology-based approach is no longer able to capture the innumerable ramifications of this complicated issue. Lately, based on the activation of estrogen receptor (ER) and ER-regulated genes, a multistep model of breast cancer evolution, encompassing most of the precursor and non-obligate precursor lesions, has been proposed [3]. High-throughput sequencing studies are further corroborating this hypothesis [4–6]. However, given the intrinsic limitations of the published studies, including the relatively small sample size and the extremely challenging set up of functional models of breast tumor progression, the biological determiners of the progression from pre-invasive to invasive disease have yet to be fully elucidated. Indeed, we are still not able to predict which lesions will progress to invasive disease. The implementation of novel biomarkers to diagnose and predict the outcome related to noninvasive breast lesions at an individualized level represents the prerequisite for the realization of the potentials of precision medicine.

11.2 Classification of Noninvasive Lesions of the Breast

11.2.1 Multistep History of Breast Cancer Evolution Model

The initial morphology-based classification systems of breast alterations allowed for several speculations on the cell from which breast malignancies originate. In the past, pioneer scientists postulated that breast cancers would arise from distinct sites within the mammary gland. It was a rather dichotomic but extremely charming conception that soon became viral among breast care providers. Basically, some tumors were thought to originate from the ducts, while others would arise from the milk-producing lobules and therefore named invasive ductal carcinomas and invasive lobular carcinomas, respectively. Not surprisingly, lesions that were morphologically confined inside of their "original site," without evidence of spread to surrounding tissues, were named ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). At present, this "vintage" nomenclature remains widely adopted for indicating adenocarcinoma-like (ductal) and discohesive-cell tumors (lobular). Over 30 years ago, this model has been questioned by the outstanding works of Wellings and Jensen [7, 8] that provided the first scientific evidence that most of breast cancers and a proportion of precursors lesions (both of ductal and lobular types) would arise within the same microanatomical site, namely, the terminal duct lobular unit (TDLU). It is interesting to note that only in 2012, the World Health Organization (WHO) in its classification of breast tumors changed the terminology of "invasive ductal carcinoma, not otherwise specified (NOS)" into "invasive carcinoma of no special type (NST)," avoiding outdated assumptions on the ductal origin of the cancer cells [9]. Drs. Wellings and Jensen proposed a linear multistep model of the breast cancer evolution based on epidemiological data and on the histological continuum of the lesions [7, 8, 10]. The key steps of this model included progression from hyperplasia, to atypical hyperplasia (ductal or lobular), carcinoma in situ (DCIS or LCIS), and ultimately invasive ductal or lobular carcinoma.

During the last decades, the accumulation of new molecular data have further complicated this model of tumor evolution. Indeed, comparative genomic hybridization (CGH) and microarray-based expression profiling studies demonstrated that estrogen receptor (ER)-positive, HER2-positive, and triple-negative (i.e. ER-negative, progesterone receptor (PR)-negative and HER2-negative) breast cancers constitute biologically and clinically distinct diseases [11–13]. In recent years, the advent of next-generation sequencing methods showed that these entities are underpinned by distinct repertoires of genetic aberrations [14]. Seminal analyses of bona fide precursors of breast cancer suggest that these lesions are at least as heterogeneous as their invasive counterparts [3]. It is currently accepted the notion that low-grade and high-grade tumors and their respective precursor lesions harbor completely different genomic and transcriptomic features and evolve through distinct pathways [4, 5, 15–17]. Moreover, molecular analyses identified two distinct pathways of breast cancer evolution based on the activation of ER. The concept of low-grade ER-positive breast neoplasia family encompasses pre-invasive and invasive lesions, including flat epithelial atypia (FEA), ER-positive DCIS, lobular neoplasia, and ER-positive low-grade invasive breast cancers that have been demonstrated to coexist at a frequency greater than expected by chance and to share specific genetic aberrations (e.g., deletions of 16q, gains of 1q and 16p) [3, 18, 19]. Deletion of 16q is an uncommon finding in HER2 positive or triple negative tumors; however, this peculiar genetic signature has been described in a subset of high-grade ER-positive lesions, suggesting a progression from low- to high-grade ER-positive cancers [20]. Recently, microglandular adenosis (MGA) emerged as bona fide non-obligate precursors of both low- and high-grade triple-negative breast cancers, which are characterized by recurrent *TP53* mutations and a complex pattern of somatic mutations and copy-number alterations [21–24]. At present, the combination of nuclear grade and ER status seems to delineate the two major pathways of breast cancer evolution. However, quoting Kornelia Polyak quoting Johann Wolfgang Von Goethe: "*progress has not followed a straight ascending line […]*" [25].

11.2.2 Terminology and Classification Systems

The constantly evolving model of breast cancer evolution leads to continuously reshape the taxonomy of noninvasive breast lesions (Table 11.1). At least three systems are used to classify these entities based on prognostic, predictive or pathologic purposes, and considerations.

In the "prognostic system," the multitude of proliferative breast changes can be categorized as risk indicators (i.e., lesions that are associated with increased risk of breast cancer development in the ipsilateral or contralateral breast) and/or precursors (i.e., lesion that can progress to invasive cancer). Atypical hyperplastic lesions and carcinoma in situ have been shown to confer a relative risk of breast cancer development of 4% [26–30] and 8–10% [3, 31], respectively. Although the low relative risk of atypical lesions have been recognized since the seminal study of Dupont and Page [26, 27], new data on cumulative risk of breast cancer among women with atypical hyperplasia (cumulative risk, 30% at

Table 11.1 Taxonomies of premalignant and pre-invasive lesions

Traditional terminology	WHO 2012 classification	Tavassoli classification	European guidelines for quality assurance in breast cancer screening and diagnosis	Clinical implication (prognosis)
Columnar cell change (CCC) Columnar cell hyperplasia (CCH)	Columnar cell lesion (CCL)		B2	Risk indicator and non-obligate precursor
Columnar cell change with atypia (A-CCC) Columnar cell hyperplasia with atypia (A-CCH)	Flat epithelial atypia (FEA)	Ductal intraepithelial neoplasia, grade 1A (DIN 1A)	B3	Risk indicator and non-obligate precursor
Atypical ductal hyperplasia (ADH)	Atypical ductal hyperplasia (ADH)	Ductal intraepithelial neoplasia, grade 1B (DIN 1B)	B3	Risk indicator and non-obligate precursor
Ductal carcinoma in situ, low grade (DCIS grade 1) Ductal carcinoma in situ, intermediate grade (DCIS grade 2) Ductal carcinoma in situ, high grade (DCIS grade 3)	Ductal carcinoma in situ (DCIS), low grade Ductal carcinoma in situ (DCIS), intermediate grade Ductal carcinoma in situ (DCIS), high grade	Ductal intraepithelial neoplasia, grade 1C (DIN 1C) Ductal intraepithelial neoplasia, grade 2 (DIN 2) Ductal intraepithelial neoplasia, grade 3 (DIN 3)	B5	Risk indicator and non-obligate precursor
Atypical lobular hyperplasia (ALH)	Atypical lobular hyperplasia (ALH)	Lobular intraepithelial neoplasia, grade 1 (LIN1)	B3	Risk indicator and non-obligate precursor
Lobular carcinoma in situ, classic type (LCIS) Lobular carcinoma in situ with necrosis or pleomorphic	Lobular carcinoma in situ (LCIS) High-grade LCIS and Pleomorphic lobular carcinoma in situ (PLCIS)	Lobular intraepithelial neoplasia, grade 2 (LIN2) Lobular intraepithelial neoplasia, grade 3 (LIN3)	B3 B5	Risk indicator and non-obligate precursor

25 years' follow-up) have been recently published and are currently changing the management strategies of these conditions [30, 32, 33]. Moreover, some of these risk indicators have been shown to harbor molecular aberrations identical to those of the matched invasive disease and thus, they are considered breast cancer precursors [3, 34–36]. Given that only a still unidentifiable subset of these precursors will effectively progress to invasive breast cancer, they are indeed defined as non-obligate precursors of breast cancer together with in situ carcinoma.

The "predictive" system has been created for clinical management purposes. The current European Guidelines for quality assurance in breast cancer screening and diagnosis required all breast needle core biopsies to be classified according to a five-tier pathologic-based classification scheme: B1, normal; B2, benign; B3, lesion of uncertain malignant potential; B4, suspicious for malignancy; and B5, malignant [37, 38]. These categories are based only on the histological findings of the specimen and clinical management of the detected lesions has to take into account also their clinical and imaging characteristics. Given the limited specimen of a core biopsies, the B-classification does not require pathologists to give a definite diagnosis, simplifying pathological evaluation. An Italian survey on diagnostic concordance of B-classification reported a good overall interobserver agreement (mean kappa score, 0.61), with, however, lower concordance rates for B3 category [39]. Similarly, Elmore et al. reported a good overall concordance (75.3%) between US pathologists and expert consensus diagnoses, with again lower levels of agreement for atypical lesions with uncertain malignant potential [40]. The B3 category encompasses 3–10% of the histologically assessed biopsy of screening detected lesions [41]. This subgroup comprises different histopathological entities that are known to have variable risk of associated concurrent malignancy [41, 42]. Except for DCIS, all noninvasive breast lesions fall into the B3 category, including FEA, atypical ductal hyperplasia (ADH) and lobular neoplasia (LN), together with papillary lesions, radial scar, and phyllodes tumor. An improvement of the diagnostic concordance and definition of this group is warranted in order to avoid over- or undertreatment of the women with a diagnosis of B3 lesion.

The formal and traditional classification of pre-invasive lesions of the breast, re-proposes the old-fashioned concepts of ductal and lobular lesions with columnar cell changes as the third wheel. This classification has been endorsed by the last edition of WHO classification of breast tumors [9]. In particular, based on differences in quantitative and qualitative morphologic characteristics, clinical behaviors and, recently, molecular features, these entities can be categorized as follows:

- Columnar cell changes, including flat epithelia atypia (FEA)
- Lobular neoplasia, including atypical lobular hyperplasia (ALH), lobular carcinoma in situ (LCIS), and pleomorphic lobular carcinoma in situ (PLCIS)
- Atypical ductal hyperplasia (ADH) and ductal carcinoma in situ (DCIS)

Although it is widely adopted, this classification represents one of the most controversial topics in breast pathology. Indeed, the morphologic criteria and the nomenclature used are still debated, resulting in a high rate of diagnostic interobserver variability. In particular, the distinction between atypical hyperplasia (AH, including ALH and ADH) and in situ lesions is rather problematic. The diagnostic criteria for AH are based mainly on exclusion rather than positive features [27]. ADH and ALH are diagnosed when some features of DCIS or LCIS, respectively, are present, but others are lacking. This qualitative definition of AH has been updated to include (arbitrary) quantitative features. ADH is diagnosed when lesion foci occupy less than two separate ducts [43] or measure less than 2 mm [44]. Noninvasive lobular lesion is classified as ALH if abnormal changes involved less than 50% of acini or TDLU [9, 45, 46]. However, how to define atypical proliferations that are qualitatively identical to in situ carcinomas, but quantitatively "too small," or atypical lesions that extend over the quantitative cut-offs but fail to meet the diagnostic criteria of in situ carcinoma? In the setting of controversial boundaries between atypical lesion and in situ carcinoma, it has been suggested to abandon this terminology in favor of a three-tier framework similar to that used for intraepithelial neoplasia of cervix, vagina, and vulva. In this classification, all ductal and lobular lesions are defined as ductal intraepithelial neoplasia (DIN) and lobular intraepithelial neoplasia (LIN), respectively, including both atypical and in situ entities [47–50]. Avoiding the term "carcinoma" for lesions that are not invasive has the advantages to reduce confusion among health professionals and adverse psychological reactions among patients [50, 51]. However, this three-tier classification has not been endorsed by the 2012 edition of WHO classification since it seems to suggest a progression from low- to high-grade lesions that opposes our current, albeit limited, biological knowledge on breast cancer evolution processes [9, 50].

With all the caveats described above, and waiting for new molecular genetic techniques and biomarkers to pinpoint the basis for a revised unanimous classification system, in the next section a systematic treatise of each noninvasive breast lesions will be given following their traditional taxonomy.

11.3 Columnar Cell Lesions and Flat Epithelial Atypia

Some of the most challenging tasks in diagnostic pathology include subclassifying the spectrum of columnar cell lesions (CCLs). These common alterations of the breast that were first described by Stewart and Foote in 1945 [52], have gained renewed attention from both clinical and research standpoints, given their increased detection rates and association with a wide spectrum of malignant and benign breast lesions. High-throughput sequencing studies are currently validating the hypothesis that CCLs might constitute the "missing link" between normal TDLU and the ADH-DCIS *continuum* [53–56].

Although different classifications and names for this group of lesions have been used [57], including but not limited to flat epithelial atypia (FEA), ductal intraepithelial neoplasia (DIN) flat type, columnar cell alterations with apical snouts and secretions with atypia, enlarged lobular units with columnar alteration, atypical cystic lobules, atypical cystic ducts, and clinging carcinoma monomorphic type, the term CCL is most widely adopted. Under the umbrella of CCL stands a wide spectrum of lesions sharing the histologic hallmark of enlarged TDLUs lined by columnar epithelium. Importantly, CCLs are usually classified based on the presence of architectural and/or cytological atypia. In this respect, the classification system proposed by Schnitt and Vincent-Salomon [57], albeit strictly morphology-based, has been shown the lowest rates of interobserver variability. This system clusters CCLs into four broad groups, namely, columnar cell change (CCC), columnar cell hyperplasia (CCH), columnar cell change with atypia (A-CCC), and columnar cell hyperplasia with atypia (A-CCH). However, based on their partially overlapping molecular features, the latter two entities have been grouped by the WHO into the FEA category [9]. This consensus nomenclature has undoubtedly led more uniform identification of atypical CCLs. Regrettably, grading of CCLs remains rather problematic in terms of interobserver reproducibility.

11.3.1 Epidemiology and Clinical Features

Given that CCLs are frequently associated with microcalcifications, with the increasing frequency of mammographic screening an increased detection rate of CCLs has been observed [58]. For breast pathologists, CCC and CCH represent common findings in daily practice, being part of the spectrum of lesions that can be observed in the context of fibrocystic changes. On the other hand, A-CCC and A-CCH seem to be consistently less common. In a recent study

analyzing over 11,000 excisional breast biopsies, it has been shown that FEAs are uncommon lesions, involving less than 2.5% of benign breast biopsies [59].

11.3.2 Histological Features

CCLs are morphologically characterized by dilated acinar structures lined by a single layer of ER-positive, HER2-negative bland columnar cells with apical snouts, showing different degrees of cytological atypia. As described in the Schnitt and Vincent-Salomon classification [57], these lesions are made up by dilated enlarged TDLUs lined by columnar-shaped cells that can be arranged in mono/bi-stratified (CCC and A-CCC) or pluristratified (CCH and A-CCH) epithelia. The columnar cells characteristically show uniform ovoid-to-elongated nuclei with no or inconspicuous nucleoli. In A-CCC and A-CCH, the cytological atypia can be identified by the presence of rounder nuclei that might also show irregular borders, prominent nucleoli, and increased nuclear/cytoplasmic ratio (Fig. 11.1a and b). Not uncommonly, atypical columnar cells are irregularly oriented along the basement membrane of the TDLU. Mitotic figures, although exceptional, can also be observed, while complex architectural patterns are considered characteristic of ADH and low-grade DCIS and should not be present in CCLs. Apical cytoplasmic blebs or snouts are not uncommon at the luminal interface in CCLs. Intraluminal periodic acid–Schiff (PAS)-positive secretions and variable clusters of amorphous-to-pleomorphic tiny specks of calcium (microcalcifications) are frequent, representing the only mammographic signal of the possible presence of CCLs. Of note, CCLs cannot be identified clinically or on macroscopic examination, their diagnosis being currently histopathology-based and, they are often associated with other alterations of the breast in the context of fibrocystic changes (Fig. 11.1a and b).

All categories of columnar cell lesions typically show diffuse and intense ER expression and low proliferative rate (Ki-67) [57].

11.3.3 Molecular Pathology

The genetics that underpins CCLs is not at all fully clarified. However, recent molecular studies have provided evidences that CCLs, in particular FEAs, are clonal and possess neoplastic features, such as the presence of recurrent copy-number alterations, (CNAs), including losses of 16q and chromosome X and gains of 15q, 16p, 17q, and 19q, as defined by CGH [5, 53–56]. Allelic imbalances have been detected in CCLs and most commonly target chromosomes 3p, 9q, 10q, 11q, 16q, 17p, and 17q [55, 56]. Importantly, the degree of genetic instability found in CCLs seems to reflect the degree of atypia found in different types of CCLs [53, 55]. Furthermore, their frequent association with ADH/low-grade DCIS [18, 60, 61], their identical immunoprofiles [19], and the partially overlapping molecular alterations between CCLs and matched ADH [53], allowed some authors to identify CCLs as bona fide non-obligate precursor to invasive breast cancer. At present, CCLs are considered as a part of the so-called low-grade breast neoplasia family, constituting the earliest histologically identifiable breast lesion linked to cancer progression [3, 19, 53]. Intriguingly, specific miRNA signatures (e.g., miR-132 overexpression) have been recently identified in CCHs and

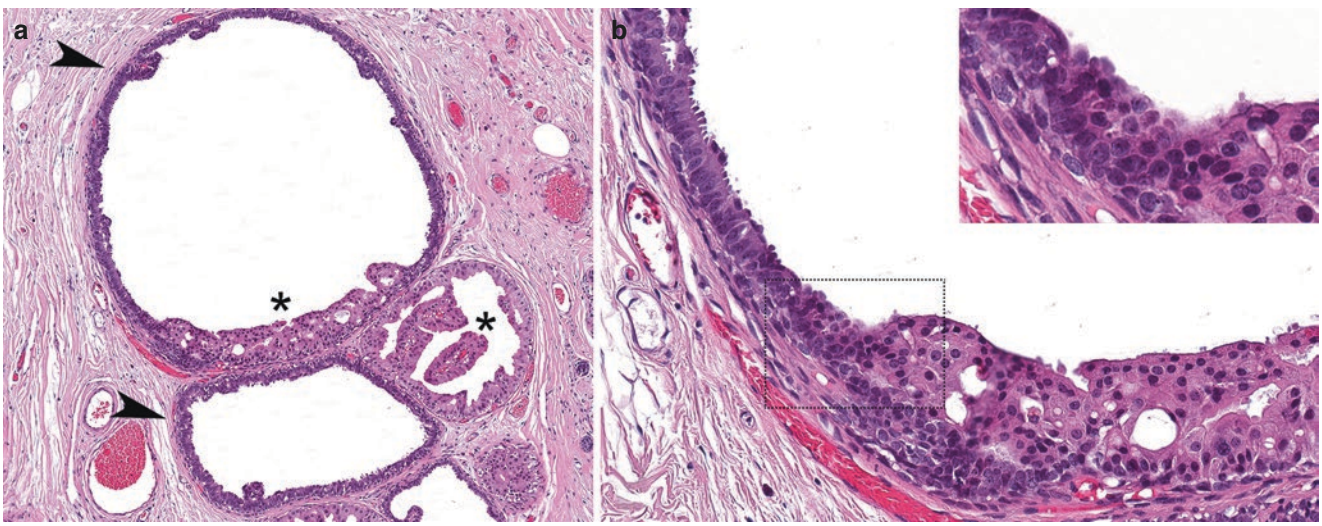

Fig. 11.1 Columnar cell lesion (arrowhead) in the context of fibrocystic changes with foci of apocrine hyperplasia (star). At higher magnification, cells with intermediate cytological features can be observed in the transition areas. ((**a**), hematoxylin and eosin, original magnification 50; (**b**), hematoxylin and eosin, original magnification 200×)

their surrounding stromal compartment, suggesting that epithelial and stromal miRNA changes may represent very early important changes in breast cancer progression [62].

11.3.4 Clinical Implications and Subsequent Risk of Invasive Breast Cancer

Despite the emerging molecular information regarding their neoplastic nature, the association between CCLs and subsequent breast cancer risk remains undefined, with many retrospective studies showing heterogeneous results. The risk of developing breast cancer in patients with a diagnosis of FEA have been estimated at one to two times higher than those without FEA [57, 63–65]. However, the recently published Mayo Cohort Study have shown that a diagnosis of pure FEA seems not convey independent risk of breast cancer [59]. Since some CCLs diagnosed in breast core biopsies are associated with more advanced lesions in the remaining breast, this poses difficulties for the optimal management when found on core needle biopsies. CCC or CCH are regarded as benign (B2 on core biopsy), and there is no need of any additional assessment [37]. Importantly, the presence of FEA foci in a core biopsy is reported to be associated with a high risk of DCIS/invasive carcinoma in subsequent surgical excision specimens (B3 lesion) with an upgrade rate after a vacuum-assisted breast biopsy (VABB) diagnosis of pure FEA that ranges from 0 to 20% [66, 67]. In the recently published First International Consensus Conference on lesions of uncertain malignant potential in the breast (B3 lesions), among 177 cases of FEA that had subsequent therapeutic open surgical excision following VAB diagnosis, the upgrade rate to invasive malignancy was 9% [68]. These data have been provided to support the detection of atypical CCLs in a core biopsy as sensors for monitoring patients with higher risk to develop advanced lesions, therefore justifying their surgical excision [68].

As the natural history of CCLs is not yet well known, this generates difficulties for further clinical management. At present, the optimal management of CCLs patients remains to be determined. However, two major issues have to be acknowledged in setting up diagnostic, treatment, and follow-up strategies while dealing with CCLs. First, clinicians, radiologists, pathologists, and research scientists should avoid any synecdochic approach in the interpretation of breast biopsies with CCLs. Indeed, it is widely recognized that breast core biopsy samples are not necessarily representative of the entire lesion, as CCLs might be a part of an even more complex mosaic of premalignant alterations (e.g. ADH, DCIS, and tubular carcinoma). The second point involves the long-standing topic on the optimal risk-benefit ratio to allow (and recommend) breast surgery in this era of precision medicine. Specifically, despite the recent gains in the diagnosis and treatment of these patients, it is currently extremely difficult to anticipate which of the entities belonging to each CCL category are associated with an increased long-term risk of related invasive cancer. On the other hand, other more aggressive lesions can be present at the periphery of the CCL and might not be straightforward to be sampled based on the intrinsic limitations of mammographic techniques. For CCL without atypia, more studies with a long-term follow-up coupled with high-throughput molecular investigations are warranted, but so far, surgical excision biopsy does not seem to be necessary.

11.4 Atypical Lobular Hyperplasia and Lobular Carcinoma In Situ

Atypical lobular hyperplasia (ALH) and lobular carcinoma in situ (LCIS) are considered part of a spectrum of noninvasive breast lesions often referred to as lobular neoplasia (LN). The term LCIS was first coined in by Foote and Stewart to indicate noninvasive lesions of the breast with cytological resemblance to invasive lobular carcinoma (ILC) [69]. Less well-developed proliferative lesions with morphologic features similar to those of LCIS but associated with a lower risk of breast cancer development were subsequently named ALH [70]. In the late 1970s, Haagensen introduced the umbrella term LN that soon became widely used both in clinical and academic settings [71]. This definition has the undeniable advantage to overcome the problematic distinction between ALH and LCIS but, regrettably, is not able to capture the diverse clinical implications of these lesions. Noninvasive lobular neoplasia is also defined as lobular intraepithelial neoplasia (LIN), with the three-tier grading system proposed by Tavassoli that classified ALH as LIN1, classic LCIS as LIN2, and high-grade and pleomorphic LCIS as LIN3 [48]. ALH and LCIS have been historically considered as risk indicators for subsequent development of IBC, but there are growing observational and molecular evidences to suggest that at least a subset of them are true non-obligate precursors [46, 72–76]. At present, the classification of noninvasive lobular lesions, together with their clinical and biological implications and consequently the appropriate management of women with a diagnosis of ALH or LCIS, are still a multidisciplinary conundrum.

11.4.1 Epidemiology and Clinical Features

Noninvasive lobular lesions are most frequently observed in pre- and perimenopausal women [71, 77]. Since these lesions have no specific clinical and mammographic features, their diagnosis is usually an incidental finding [69, 71]. Therefore, it is difficult to estimate their real prevalence. Large cohort retrospective studies suggest that

LCIS is diagnosed in approximately 0.5–4% of women with otherwise benign breast biopsies [71, 78–80]. It is even more challenging to establish the overall ALH incidence given that this lesion is frequently combined with either LCIS or ADH. In a recent series from the Johns Hopkins Institution, among 10,024 breast core biopsies performed, only 117 (0.1%) cases had a diagnosis of pure ALH [81]. Although remaining a relatively uncommon finding, the incidence of LCIS showed an increased incidence among population-based data of Surveillance, Epidemiology, and End Results (SEER), growing from 2 to 2.75% in 2000 and 2009, respectively [82]. Multifocality and bilaterality are key characteristics lobular neoplasia, as multifocal and multicentric disease is detected in over 50% of cases, while nearly 30% of patients have bilateral lesions at diagnosis [83, 84].

11.4.2 Histological Features

The histological features of ALH and LCIS have long been well established [9, 69, 71]. These lesions are characterized by monomorphic proliferation of small round-to-polygonal discohesive cells that distend the acini with maintenance of the lobular architecture. The neoplastic cells have usually scant clear cytoplasm with high nuclear-cytoplasmic ratio but intracytoplasmic vacuoles composed of darkly staining dots (formerly known as magenta bodies), can often be found (Fig. 11.2a). The abnormal cells frequently show a pagetoid spread, with a characteristic upward diffusion along the ducts, between the normal epithelium and basement membrane.

The distinction between ALH and LCIS is mainly based on quantitative criteria. While the abnormal cells in ALH only partially fills and distends the acini, a diagnosis of LCIS is allowed when the acini are completely filled, with no more visible lumina, and more than 50% of TDLU is involved by the lesion [9, 45]. Regrettably, adopting the above criteria in daily practice is by far problematic, resulting in extraordinarily high rates of inter- and intra-observer variability [85]. Beside the mainstream histological features, additional morphologic details have been used to subclassify LCIS in several variants. The prototypical cells of LCIS with inconspicuous cytoplasm and small bland nuclei with a size similar (1.5×) to that of lymphocytes have been defined as "type A" cells. Conversely, "type B" cells have larger clear cytoplasm compared to that of type A, as well as larger nuclei with mild-to-moderate atypia [86]. Although this distinction has been demonstrated to have only a descriptive meaning, a subset of type B LCIS can display a highly aggressive clinical behavior, as compared to classic variants [87]. Indeed, more than two decades ago, Eusebi, Magalhaes, and Azzopardi described an aggressive variant of LCIS that was named pleomorphic lobular carcinoma (PLCIS) [88], given the eccentric large pleomorphic nuclei (4× bigger than a lymphocyte nucleus), prominent nucleoli and peculiar large eosinophilic granular cytoplasm harbored by the neoplastic cells (Fig. 11.2b). In this LCIS type, necrosis and microcalcifications are frequent. Historically, it has been suggested that PLCIS should be treated following the recommendations of DCIS; however, definitive data regarding their natural history are still missing [85, 89]. Interestingly, recent genomic studies have provided evidences that PLCIS is more closely related to LCIS rather than DCIS [90].

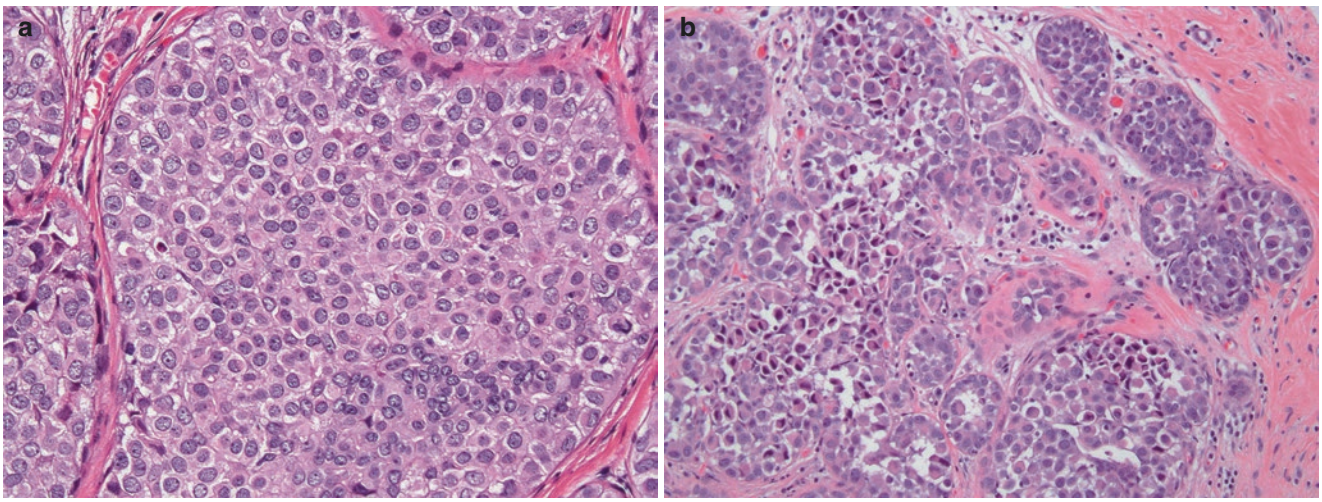

Fig. 11.2 Histological features of lobular carcinoma in situ (LCIS). (**a**) Monomorphic proliferation of polygonal discohesive cells with clear cytoplasm that distends the acini with maintenance of the lobular architecture. (**b**) In situ lesion with lobular phenotype, showing eccentric large pleomorphic nuclei, conspicuous nucleoli and large eosinophilic granular cytoplasm, consistent pleomorphic lobular carcinoma in situ (PLCIS). Hematoxylin and eosin, original magnification 200×

Conventional lobular neoplasia typically shows an immunoprofile similar to that of the luminal A invasive counterpart, such as strong and diffuse expression of ER and progesterone receptor (PR), no HER2 overexpression and low proliferation index (Ki-67) [85]. Importantly, the rule exception is represented by the high-grade LCIS and PLCIS, which are characterized by a higher Ki-67 index, low or absence of ER/PR expression, and possible HER2 overexpression/amplification [85]. Instead, loss of membranous expression of E-cadherin connotes the entire spectrum of lobular neoplasia, and it is considered (and often abused) a cornerstone diagnostic biomarker for both in situ and invasive lobular diseases. E-cadherin is a transmembrane molecule found in cell adherens junctions. Dysfunctional protein leads to loss of cell adhesion, representing the molecular substrate of the characteristic discohesive architecture of the lobular lesions [9, 86, 90–92]. However, aberrant E-cadherin expression may be observed in a proportion of LCIS; therefore, this diagnosis cannot be entirely ruled out in the presence of the clear-cut lobular morphology in E-cadherin positive cases [92]. In case of ambiguous histological appearance, evaluation of p120 catenin expression can be performed in order to confirm the diagnosis. This protein is a membrane-located cell adhesion molecule that accumulate in the cytoplasm of cells with absent or dysfunctional E-cadherin [92].

Given our long-term dealing with LN histologic features, the diagnosis is usually straightforward. However, in a subset of cases showing hybrid histological features, the distinction between classical LCIS and low-grade solid DCIS can be challenging, and it is not always achievable [85]. Furthermore, the cytological features of PLCIS, together with the presence of necrosis and calcification, can lead to the misdiagnosis of high-grade DCIS [85]. In these tricky cases, careful evaluation of morphological characteristic of neoplastic cells, the use of specific biomarkers such as E-cadherin, and asking for second opinion can assist in the correct diagnosis and ultimately lead to the proper clinical management of these patients.

11.4.3 Molecular Pathology

The molecular landscape of LNs is distinctively characterized by loss of expression and/or inactivation of E-cadherin. The inactivation/dysregulation of E-cadherin results from a combination of genetic, epigenetic, and transcriptional alterations [3, 93–96]. Loss of E-cadherin (*CDH1*) gene locus at 16q22 is frequently observed in LCIS as well as inactivating somatic mutations of *CDH1* [76]. Additional recurrent molecular alterations are those that pertain to the so-called low-grade estrogen receptor (ER)-positive breast neoplasia family, including the expression of ER and ER-related genes and the aforementioned deletions of 16q, as well as gains of 1q and 16p [97, 98]. In a recent survey performed on 34 LCIS samples from Memorial Sloan Kettering Cancer Center (MSKCC) using a targeted capture massively parallel sequencing platform, *CDH1* mutations have been detected in 56% of LCIS [76]. Interestingly, then vast majority of *CDH1* alterations were coupled with loss of heterozygosity (LOH) of the gene. Furthermore, *PIK3CA* has been shown to represent second more frequently mutated gene in LCIS. Intriguingly, the authors of this study detected a similar repertoire of somatic mutations in LCIS and paired invasive lobular carcinoma (ILC), providing the molecular evidence that at least some LCIS are non-obligate precursors of IBC. Previous comparative genomic hybridization studies have also shown that LCIS and ILC display similar recurrent copy-number profiles [99]. Formal clonal relationship between LCIS and ILC have been recently demonstrated also by SNP array and whole-exome sequencing analyses [75, 100].

Despite the relatively homogeneous histological and genomic feature of LCIS, heterogeneity has been described at transcriptomic level [101]. In particular, two molecular subtypes of LCIS have been identified based on differentially expressed genes, including proliferation genes and genes of cancer-related pathways (e.g., actin cytoskeleton, apoptosis, p53 signaling, TGF beta signaling, and Wnt signaling). Although the two molecular clusters displayed significantly differences in Ki67 expression levels, no significant correlations have been found between these subtypes and their clinicopathologic features [101].

Finally, the few genomic analyses performed on PLCIS confirmed that these lesions belong to the LN spectrum [90, 102–104]. Indeed, PLCIS have been shown to harbor the hallmark copy-number changes of classic variants of LCIS (i.e., loss of 16q and gain of 1q and 16p) but also display higher rates of genomic instability, with frequent amplification of *MYC* and *HER2*. This molecular scenario may represent the genomic substrate of the clinical aggressiveness frequently observed in PLCIS.

11.4.4 Clinical Implications and Subsequent Risk of Invasive Breast Cancer

LCIS has long been regarded as a risk indicator for subsequent development of IBC. On the other hand, when the term LCIS was coined this group of lesions was dogmatically defined as the pre-invasive step of ILC. Early observational studies [83, 105, 106], however, went against this concept, observing that (1) the risk of IBC conferred by LCIS is lower when compared to the bona fide real precursor, (2) IBC may develop after a diagnosis of LCIS either in ipsilateral and contralateral breast,

and (3) either of lobular and ductal histotypes. Overall, it has been estimated that a diagnosis of LCIS confers a risk of 1–2% per year for subsequent ILC, with a relative risk of 8–10 [32, 71, 78, 105]. Furthermore, the long-term cumulative risk ranges from 11 to 26% at 15 years [32, 71, 77, 105, 107]. On the other hand, women with ALH have a relative risk for later IBC of 4 with a long-term cumulative risk of 27–30% after 25 years [33]. Given these relatively high cumulative risks, application of standardized pathological criteria of ALH is pivotal for reducing the high inter- and intra-observer variability of these diagnoses, especially in small diagnostic specimens. Taken together, the gap between the relative risks of ALH and LCIS underlines the fundamental role of an accurate histopathological distinction between these two entities, discouraging the use of diagnostic ellipsis such as LN. According to the European Guidelines for quality assurance in breast cancer screening and diagnosis [37], LCIS and ALH are both classified as B3 lesions, given the risk of concurrent malignancies with a rates of upgrades after surgical excision that ranges from 0 to 67% [108, 109]. However, if there is concordance between radiologic and pathological findings, the upgrade rate for ALH drops to 0–6% and routine surgical excision is not mandatory in these cases [108, 110].

Back to the initial identification of LCIS and ALH as discrete clinicopathologic lesions, pathologists attempted to detect the morphological abnormalities not only within the lesions themselves but also in their surrounding tissue in order to stratify the risk of the patients for subsequent invasive cancer. In the National Surgical Adjuvant Breast Project (NSABP) Protocol B-17 and the National Surgical Adjuvant Breast and Bowel Project studies, 19 histopathological parameters have been assessed as potential predictors for IBC occurrence [111, 112]. These features included the number of involved lobules, duct extension, type of LCIS (using a grading system similar to that proposed by Tavassoli), intralesional calcification, nuclear grade, cell size, cell variants (e.g., signet ring and histiocytoid), mitotic rate and lymphocytic infiltrate. The results of this study showed that only grade 2 and grade 3 LCIS are significantly associated with increased short- and long-term risks of developing IBC. In the recently published 29-year longitudinal series of MSKCC that include 1032 women with a diagnosis of LCIS undergoing surveillance, among the numerous pathological variables assessed in a case-control analysis, only the disease volume (defined as the ratio of slides with LCIS to total number of slides reviewed), was found to be associated with IBC development [32].

Although ALH and LCIS are indubitably risk indicators of later IBC, current clinico-epidemiological and high-throughput sequencing data support the contention that at least a subset of these lesions are also non-obligate precursors of IBC. ALH and LCIS confer a bilateral risk of IBC that can be either of IDC and ILC; however, the majority of studies reported a higher incidence of ipsilateral ILC [46, 86, 112]. Furthermore, recent molecular studies have demonstrated the presence of identical genetic aberrations in LCIS and matched ILC, confirming that these two lesions are clonally related [75, 76, 99, 100]. 75 years later LCIS was first described, we are back to the original idea about LCIS nature as both risk indicator and non-obligate precursor. Regrettably, we are still no able to identify which of these precursors will evolve to IBC, since the biology of this progression remain poorly understood. For these reasons, the clinical management of ALH and LCIS continues to be a challenge with a plethora of possible management options, ranging from simple observation to radical surgical approaches.

11.5 Atypical Ductal Hyperplasia and Ductal Carcinoma In Situ

Atypical ductal hyperplasia (ADH) and ductal carcinoma in situ (DCIS) are part of a wide group of premalignant and pre-invasive breast lesions that are characterized by proliferation of neoplastic epithelial cells confined within the lumen of TDLUs with preservation of intact basement membrane [9]. DCIS is a well-established non-obligate precursor of invasive breast cancers (IBCs). The observation of spatial (i.e., DCIS adjacent to IBC) and temporal (i.e., IBC developed after a diagnosis of DCIS) proximity between these two entities, the usually concordant nuclear grade and immunophenotype of adjacent DCIS and IBC as their genetic similarity and clonal relationship represent the plethora of evidence of their clinico-biological continuity. However, only a subset of DCIS will progress to IBC (i.e., non-obligate precursor). The identification of the biology underpinning of the DCIS to IBC progression and ultimately the development of biomarkers able to predict which patients will progress are the main clinical, pathological, and molecular challenges (and tasks) posed by DCIS.

ADH is considered both a risk indicator and non-obligate precursor, displaying morphological and genetic features similar to those of low-grade DCIS but a lower risk of breast cancer development. Differentiation of ADH from low-grade DCIS is anything but simple. The histologic criteria for diagnosing of ADH have been known for a long time, but they still represent one of the most controversial issues in breast pathology. The DIN classification is able to highlight the continuum between ADH (DIN1b) and low-grade DCIS (DIN1c). However, this terminology suggests a progression from low-grade to high-grade DCIS (DIN2/3) that oversimplify the "tangle" model of the progression from DCIS to IBC.

11.5.1 Epidemiology and Clinical Features

ADH is a relatively uncommon condition that represent the diagnostic finding in up to 4% of symptomatic benign biopsies [113, 114]. However, the epidemiological data on ADH continue to suffer from the variable interobserver application of diagnostic criteria. Conversely, the incidence of DCIS underwent a precipitous increase following the spreading trend of mammographic screening program that peaked in 2000 and stabilized at lower increase rate after 2005 [1, 115–117]. According to the American Cancer Society, Surveillance Research, 60,290 women were diagnosed with DCIS in 2015, accounting for 17% of all breast cancer diagnosis and of 83% of in situ carcinoma [1, 118]. The majority of DCIS was detected in postmenopausal women with peaks at ages 70–79 [118]. Risk factors for the development of DCIS are similar to those of IBC supporting the evidence of their etiologic relationship [119–121].

Microcalcifications represent the characteristic mammographic sign of DCIS, although masses or areas of architectural distortion can also be found [118, 122].

11.5.2 Histological Features

"*The histologic criteria for diagnosing atypical lesions rests heavily on definitions of histologic features of carcinoma in situ. We demand that all features of carcinoma in situ […] be uniformly present throughout two separate spaces before ductal carcinoma in situ (DCIS) is diagnosed". Anything less will occasion a diagnosis of the corresponding atypical lesion if some of the features of carcinoma* in situ *are present*" (Fig. 11.3). These are the diagnostic criteria for the diagnosis of ADH that were established by David Page and colleagues in 1985 [27]. Indeed, the histopathological features of ADH are essentially those of low-grade DCIS, except for the extent of the lesion. Differentiation of ADH from low-grade DCIS is based on a single criterion that, albeit arbitrary, is rather simple and undeniably pragmatic: if the lesion involves less than two membrane-bound spaces [43] or measures less than 2 mm in greatest dimensions [44], it should be classified as ADH; if not, as DCIS. Importantly, the WHO recommends to perform a diagnosis of ADH only if a diagnosis of low-grade DCIS has been seriously considered [9]. A long-term plethora of studies have reported on the difficulty in achieving acceptable levels of concordance among pathologists in diagnosis of ADH (and other borderline lesions of the breast) [40, 114, 123–127]. Since the correct identification of ADH is an essential step for the proper clinical management of the patients, revision of current criteria with the integration of more reproducible histological and molecular biomarkers should be a future effort for the pathologists.

The term DCIS does not identify a single entity but a spectrum of noninvasive lesions with heterogeneous clinical, morphologic, and molecular features. DCIS are primarily classified in low, intermediate or high-grade based on nuclear features and mitotic activity [128]. Nuclear grade has been demonstrated to be of clinical relevance as predictor of local recurrence [129–131]. The DIN system mirrors this classification considering three categories, DIN1c, DIN2, and DIN3, with increasing nuclear grade [48, 49, 128]. In the routine pathological assessment of DCIS, it is recommended to report also the size of the lesion, the architectural pattern/s, the presence of necrosis, in particular the central confluent necrosis (i.e., comedo

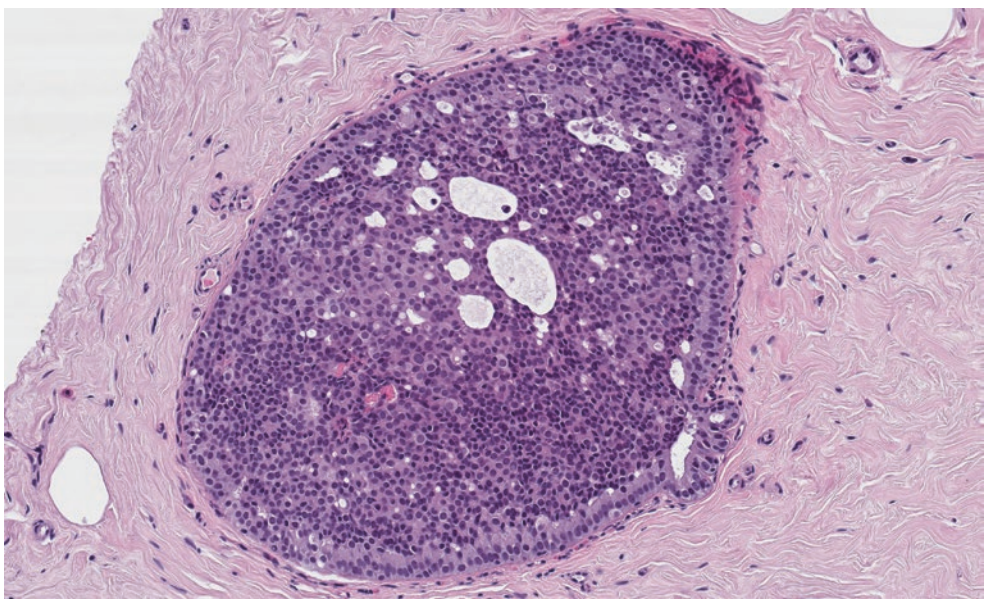

Fig. 11.3 Histological features of atypical ductal hyperplasia (ADH) from a core needle biopsy. In this paradigmatic example of ADH, bland cells are contained within the duct, forming rigid cell "bridges" across the duct space (hematoxylin and eosin, original magnification 100×)

necrosis), the presence of microcalcifications for imaging-pathology correlation, and the distance from excision margins [128, 132, 133].

Low-grade DCIS is characterized by a proliferation of monomorphic cells with slightly enlarge nuclear size, finely dispersed chromatin, inconspicuous nucleoli, and rare mitoses that display variable often intermingled architectural patterns, including cribriform (with neoformed smooth outlined lumina), micropapillary, and solid patterns. Diffuse expression of ER and PR and lack of HER2 overexpression are constantly seen in low-grade DCIS. Apart from differential diagnosis with ADH, low-grade DCIS has to be distinguished from ductal hyperplastic, non-atypical, lesions. The key words for this differential diagnosis are cell monomorphism vs. polymorphism, architectural regularity vs. disorder and diffuse strong vs. modulated ER expression for DCIS and hyperplastic lesions, respectively [9, 128, 134].

Intermediate-grade DCIS display nuclear features (and morphologic characteristics) in between low- and high-grade DCIS [128, 134].

Pleomorphic cells with large nuclear size with prominent nucleoli and mitosis connote high-grade DCIS. Solid or flat (clinging) pattern of growth and comedo necrosis are often seen in this lesion (Fig. 11.4) [9, 128, 134].

The presence of invasive or microinvasive breast cancer has to be excluded before establishing any definite diagnosis of DCIS. The presence of IBC can be usually ruled out based on morphologic assessment. However, in particular cases, especially in small specimens, immunohistochemical evaluation of myoepithelial cell markers (e.g., p63, calponin) that are retained in DCIS and absent in IBC can be useful diagnostic tools [9].

11.5.3 Molecular Pathology

The morphologic variability of DCIS is mirrored by its molecular heterogeneity. ADH and low-grade DCIS display similar immunophenotypes and genetic aberrations. Both ADH and low-grade DCIS are characterized by strong expression of ER and a nearly-identical pattern of recurrent genetic aberration including, losses of 16q, gains of 1q and 16p, that are commonly found in lesions of low-grade ER-positive breast neoplasia family [3].

It is more difficult to identify common molecular denominators in high-grade DCIS since they display heterogeneous immunophenotypic and genetic features. However, the recurrent genetic aberrations detected in low-grade lesions are uncommonly found in high-grade DCIS, suggesting nuclear classification is able to properly identified different entities that mostly evolve through distinct pathways [3]. Moreover, gene expression profile analyses have identified differentially expressed gene in low- and high-grade DCIS [16, 135]. Balleine et al. conceived a "molecular grading" model of DCIS that identified low- and high-grade lesions based on gene expression and comparative genomic hybridization data. In this study, the combination of routine histopathological features of DCIS, including nuclear grade and Ki67 score, was able to predict the "molecular grading" in the 96% of the cases [16]. As for the majority of histopathological "intermediates," no distinct molecular characteristics have been identified in DCIS of intermediate nuclear grade that have been shown to split between molecular low-grade and high-grade group [16, 17].

Gene expression profile studies have also demonstrated that the whole spectrum of the intrinsic molecular subtypes

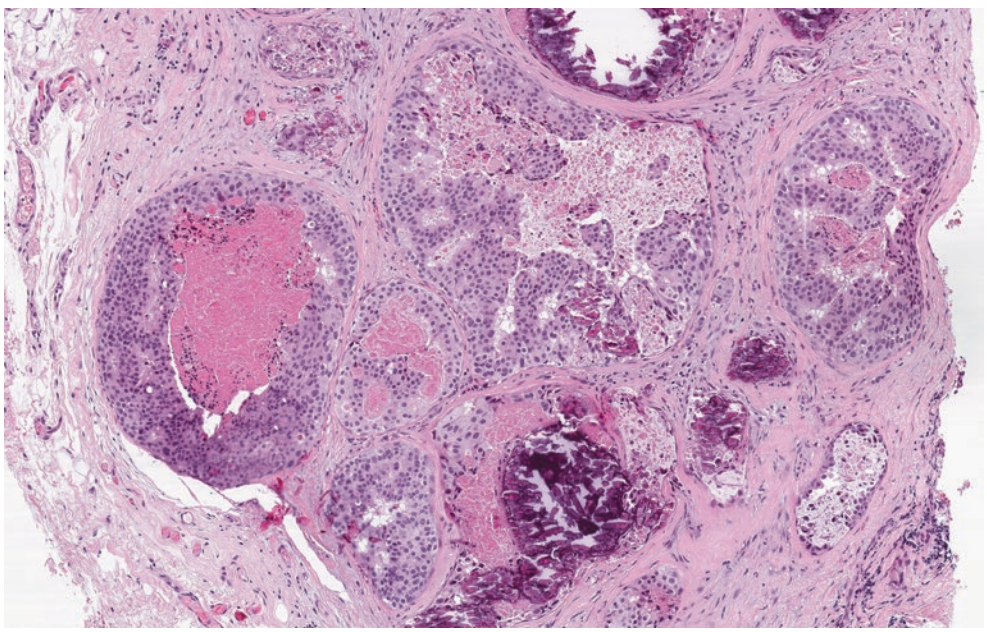

Fig. 11.4 Histological features of high-grade ductal carcinoma in situ (DCIS) from a core needle biopsy. In this intraductal carcinoma of the breast, comedo necrosis can be observed in the central luminal area, as well as peripheral calcifications (hematoxylin and eosin, original magnification 50×)

of IBC are encountered in DCIS [136–140], albeit with a higher frequencies of luminal B and HER2 positive neoplasia [136]. Far away from being completed, the current molecular knowledge on DCIS suggests that in routine practice, a good morphology-based nuclear classification and the evaluation of hormonal receptor status, HER2 expression, and Ki-67 proliferation index by immunohistochemistry can classify DCIS in distinct molecular and ultimately clinical entities. Indeed, beside classification purposes, the great effort of molecular studies on DCIS have been directed toward the identification of predictive biomarkers for the risk of progression and the biological mechanisms of DCIS-IBC evolution.

11.5.4 Clinical Implications and Subsequent Risk of Invasive Breast Cancer

While morphological and molecular data suggest that ADH, DCIS, and IBC are likely to be phylogenetically related, these diagnoses have substantially different clinical repercussions. Indeed, women with ADH have approximately three- to fivefold increased risk of developing breast cancer [27, 141, 142], either DCIS and IBC, while DCIS confers substantially higher risk of developing IDC (eight- to tenfold increased risk) [3, 143] with an absolute risk of progression to IBC at 10 years ranging from 20 to 53% [143–147]. Though the relative risk for ADH is low, absolute risk data have shown a cumulative risk for either DCIS or IBC of 30% at 25 years of follow-up [30], and a 5.7% 10-year cumulative risk of IBC after a diagnosis of ADH [148]. Moreover, as a B3-defined lesion, a diagnosis of ADH does not entail only a risk of later IBC development but also the risk of concurrent associated malignancy when detected in small bioptic specimens. Indeed, the intrinsic limitation of all presurgical diagnostic/screening procedures is that pathologists can reason on the areas surrounding the sampled lesions only in terms of probabilistic logic. Therefore, any categorical syllogism should be avoided in the diagnosis of ADH given that a surgical excision may easily upgrade the diagnosis from a B3 to a B5, with a risk of underestimation for VAB biopsies that ranges from 0 to 65% [68, 149–151]. This could represent, at least in part, the reason underpinning the historical and current conduct of removing ADH.

Given the high risk of recurrent/progression subtended by DCIS, the vast majority of patients are still subjected to surgical treatment followed by radiation and/or prophylactic systemic therapies (e.g., tamoxifen) [152]. However, not all DCIS patient will recur or progress to invasive cancer. The critical issue and need for clinician and pathologists is to better stratify patients with DCIS enabling appropriate treatment selection. Nowadays, the potential selection of low-risk patients remains dependent upon combination of traditional clinical and histopathological features as those include in validated prognostic tools such as the Van Nuys Prognostic Index (VNPI) [153, 154] and the predictive nomogram from MSKCC. A modified Oncotype DX (Genomic Health, Redwood City, CA, USA) recurrence score for IBC has been implemented for DCIS [155]. This assay is based on the expression of seven cancer-related genes and five reference genes to generate a score that give a probability of DCIS recurrence at 10 years. Although it has been validated in large prospective cohorts [156, 157], it is not currently used in clinical practice since even the low-risk group had an 11% risk of any recurrence, which is not enough low to consider to spare radiotherapy in these patients [158, 159]. Among the routinely assessed biological markers (ER, PR, HER2 and Ki-67), none is strictly recommended in clinical practice. ER-positive DCIS have a lower risk of recurrence as compared to HER2-positive or triple negative lesions [130]. Risk assessment in patients with HER2-positive DCIS have suggested that HER2 overexpression was only associated with increased risk of noninvasive recurrence [160–163].

Although there have been numerous efforts to develop molecular biomarkers to predict which patients are likely to develop invasive disease following a diagnosis of DCIS, there is currently no test with demonstrated clinical utility to identify this population. It is possible that current investigation into the biological determinants of the phenomenon of progression from in situ to invasive disease will bring more useful molecular markers to predict accurately the progression from DCIS to IBC.

11.5.5 Modelling Progression from DCIS to Invasive Breast Cancer

There are many fascinating theories of progression from DCIS to IBC, most of which fall broadly into two categories. According to the "genomic theory," invasiveness is an acquired behavior that relies on specific genetic aberrations occurring in the neoplastic cells. To support this hypothesis, several models relying on Darwinian evolution principles have been recently provided [164]. Such studies focused mainly on the in-depth genetic analyses of synchronous ipsilateral DCIS and IBCs. When analyzed as a group, similar pattern of genetic aberrations [165–169] and similar gene expression profiles [140, 170] have been found in DCIS and synchronous IBC. However, recent studies based on pairwise comparisons between DCIS and IBC have revealed the existence of significant genetic differences, which are distinct from patient to patient, confirming previous observations that DCIS and IBC are lesions harboring only a few recurrent somatic molecular alterations [171, 172]. Interestingly, molecular analyses taking into account intra-tumor heterogeneity of both DCIS and IBC occurring synchronously in

close proximity, revealing that that these neoplasms show extensive intralesional genetic heterogeneity [171, 172]. Based on these data, DCIS may be depicted as a mosaic of tumor cells harboring both founder genetic aberrations (i.e., clonally detected in the vsast majority of tumor cells) as well as private mutations (i.e., present only in a subpopulation of cells). Tumor progression may occur by means of selection of specific genetic aberrations (clonal selection), which are different from patient to patient, suggesting that transition from DCIS to IBC may represent a convergent phenotype driven by Darwinian selection [164].

On the other hand, the identification of specific characteristics in the stroma surrounding DCIS and its tumor microenvironment, lead to the "non-genomic theory," where the progression from DCIS to IBC is not necessarily dependent on the acquisition of additional genetic alterations. To this end, several evidences have been provided to explain the substantial lack of genomic and transcriptomic differences between DCIS and IBC. Besides forming a physical barrier, myoepithelial cells also actively secrete in the extracellular matrix several components and protease inhibitors. In particular, recent observations support the hypothesis that the remodeling of the DCIS extracellular matrix, under certain conditions, may favor the progression to invasive disease [173–176]. Additionally, gene expression studies showed that substantial changes may occur during progression from DCIS to IBC in various cells composing the tumor microenvironment, such as fibroblasts, myoepithelial cells, and leukocytes [177–179]. However, the biologic processes underpinning such differences in gene expression remain unclear. There are several evidences to suggest that the normal myoepithelium may act as tumor suppressor on DCIS [180–182]. Indeed, both myoepithelial cells and fibroblasts surrounding the in situ lesions have been shown to harbor a rather simple genome, with the substantial absence of clonal genetic aberrations [183]. Consequently, it has been suggested that epigenetic alterations in the stroma may be involved in the progression from DCIS to IBC through the alteration of the protective effect of the normal myoepithelium [184–186]. Clinical evidence have underlined the important predictive and prognostic role of the host immune response in breast cancer [187–189]. Although few recent studies have reported on the characteristic of the immune milieu of DCIS [190–192], the role of immune microenvironment in the progression from DCIS to IBC have yet to be elucidated.

Both the genomic and the non-genomic standard models have important deficiencies, given that, alone, they are undoubtedly not able to embrace the extraordinary complexity that underpins the natural history of IBC. A paradigm shift toward new frameworks encompassing multiple systems of breast cancer genomics, epigenomics, and transcriptomics is needed. This would allow the implementation in the field of breast cancer of a comprehensive "theory of everything" in which IBCs, pre-invasive alterations, and non-obligate precursors are stratified using integrative models at an individualized level.

Prognostic and Predictive Role of Genetic Signatures

12

Giancarlo Pruneri and Francesca Boggio

12.1 Gene Expression Reveals Inter-tumor Heterogeneity: BC Intrinsic Subtypes

A robust body of evidence, initiated by the seminal studies of Dr. Perou's group at the dawn of the new millennium [1, 2] and repeatedly confirmed over the following decade, has convincingly demonstrated that breast cancer (BC) is a heterogeneous disease further classifiable in at least four molecular intrinsic subtypes (luminal A and B, HER2 enriched, basal-like, and normal breast), based on hierarchical clustering of the "intrinsic genes" (i.e., genes with minimal variation within a tumor sample, but maximal variation between different patients) expression profile. These studies were originally based on genome-wide gene expression profiling from microarray datasets and progressed to a PCR-based test with a list of 50 genes (the PAM50 gene signature) [3, 4] (Fig. 12.1).

Recently, the NanoString nCounter^{DX} Analysis System has been shown to provide more precise and accurate measures of mRNA expression levels in formalin-fixed, paraffin-embedded (FFPE) tissue when compared to PCR [5]. Actually, PCR-based assays require excessive optimization from archival FFPE samples, thus introducing amplification biases, due to high mRNA fragmentation and cross-links to protein upon fixation. Luminal A and B subtypes are largely distinguished by the expression of two main biological processes: proliferation-/cell cycle-related and luminal/hormone-regulated pathways. Compared to luminal A, luminal B tumors are characterized by higher expression of proliferation-/cell cycle-related genes or proteins (e.g., Ki-67) and lower expression of several luminal-related genes or proteins such as the progesterone receptor (PgR) and FOXA1, while estrogen receptor (ER) is expressed at similar levels in the two subtypes. ICH-classified early BC patients usually receive adjuvant systemic treatment in addition to local treatment (surgery and radiation therapy) depending on their clinicopathological subtype. Current guidelines indicate that all patients with ER-positive disease should receive at least 5 years of adjuvant endocrine therapy (ET) [6–8]. One of the milestones of the current classification is the distinction between luminal A-like and luminal B-like tumors with significant different clinical outcomes, resulting in different indication of adjuvant cytotoxic therapy [8]. The indication for chemotherapy (CHT) in patients with luminal disease has traditionally been based on the prognostic factors of tumor size, histological grade, Ki-67 levels, ER and PgR expression, and number of involved lymph nodes. Nevertheless, studies suggest a high variability on criteria used to add CHT in the setting of luminal disease [9]. Previous studies showed that more than 60% of hormone receptor-positive BC patients receive adjuvant cytotoxic therapy. However, other authors provided evidence that only 4–5% of these women would likely benefit of this therapy [10]. Considering that serious and even life-threatening toxicities (bleeding, neutropenic fever, transfusion requirement, congestive heart failure, secondary malignancy, and peripheral neuropathy) occur in approximately 1–2% of patients, it is evident that conceiving a more specific prognostic system is mandatory in order to identify patients who can avoid CHT. The St. Gallen International Expert Consensus Panel adopted an intrinsic subtype-based approach for recommending adjuvant systemic therapies (i.e., ET, CHT, and anti-HER2 therapy) in early BC [8]. Although acknowledging the higher accuracy and reproducibility of gene expression assays, the panel recognized that they are not easily available for all BC patients, due to technical and especially economical reasons. As a result, immunohistochemistry (IHC)-based methods with antibodies recognizing ER and PgR, HER2, and Ki-67 are currently used as a surrogate for intrinsic subtypes, as detailed in Fig. 12.2.

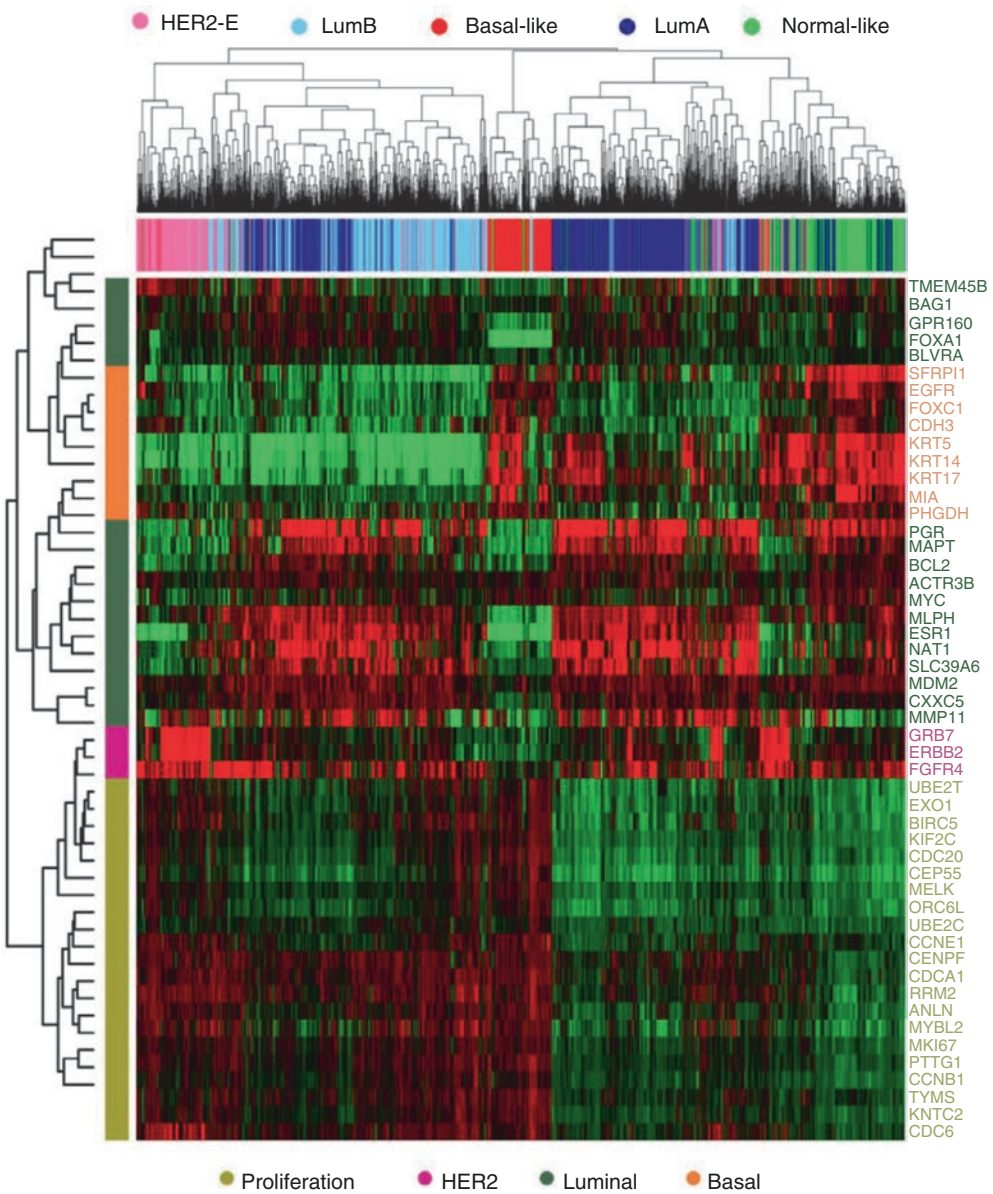

Fig. 12.1 Intrinsic subtype identification using the PAM50 classifier. The subtype calls of each sample are shown below the array tree. The expression values are shown as *red*/*green* according to their relative expression level [4]

Although the identification of intrinsic subtypes by IHC is widely distributed and relatively inexpensive, it is limited by interobserver variability and technical reproducibility [11]. Furthermore, several studies proved that IHC is not completely reproducible in identifying intrinsic subtypes, possibly due to the fact that four antigens do not fully recapitulate an intrinsic subtype originally identified by the expression of 50 genes: across the IHC-identified subtypes, the discordance rate is 38% for luminal A and 49% for luminal B [4]. Studies in the neoadjuvant setting provided indirect evidence that luminal A are less sensitive to CHT than luminal B tumors, thus achieving a significant lower rate of pathological complete response (pCR) when treated by different CHT schemes [4]. This is further sustained by the fact that pCR is prognostic in luminal B, but not in luminal A BC patients. The 2015 St. Gallen International Expert Consensus [12] recognized that luminal A-like BC are less responsive to CHT and should be therefore treated with ET only, with the exception of cases with extensive (four or more lymph nodes) axillary involvement. Oppositely, CHT in combination with ET is usually recommended for luminal B-like BC patients, unless they are bearing clinicopathological low-risk features, including T1 size, no or limited (1–3 nodes, pN1a) nodal involvement, absence of peritumoral vascular invasion, and very high ER/PgR and/or low Ki-67 values. Collectively, these data provided the rationale

for a better identification of which population of ER-positive (luminal) BC has a risk of relapse low enough to allow sparing a noneffective and potentially harming CHT treatment.

Intrinsic subtype	Clinico-pathologic surrogate definition
Luminal A	**'Luminal A-like'** *all of:* ER and PgR positive HER2 negative Ki-67 'low' Recurrence risk 'low' based on multi-gene-expression assay (if available)
Luminal B	**'Luminal B-like (HER2 negative)'** ER positive HER2 negative and *at least one of:* Ki-67 'high' PgR 'negative or low' Recurrence risk 'high' based on multi-gene-expression assay (if available) **'Luminal B-like (HER2 positive)'** ER positive HER2 over-expressed or amplified Any Ki-67 Any PgR
Erb-B2 overexpression	**'HER2 positive (non-luminal)'** HER2 over-expressed or amplified ER and PgR absent
'Basal-like'	**'Triple negative (ductal)'** ER and PgR absent HER2 negative

Fig. 12.2 Immunohistochemical surrogate definition of luminal intrinsic subtypes [8]

12.2 Multiparametric Molecular Markers: The Candidates

Using different techniques to measure mRNA levels, including RT-PCR and DNA microarrays, the assays shown in Fig. 12.3 have been basically designed to measure the risk of BC recurrence.

12.3 MammaPrint® 70-Gene Recurrence BC Assay

MammaPrint® is one of the first gene expression arrays approved by FDA for commercial use. It measures the mRNA expression of 70 genes, focusing primarily on proliferation, with additional genes associated with angiogenesis, metastasis, invasion, and stromal integrity [13–16]. This test was developed without an a priori knowledge of the role of the involved genes using a data-driven approach. Initially, about 5000 genes were found to be significantly deregulated across 78 BC patients treated at the Netherlands Cancer Institute [13]. All the patients were node negative, with tumor measuring less than 5 cm in diameter, were aged <55 years, and were selected irrespectively of their hormonal receptor status. Using a supervised classification method by correlating the expression of each gene with the disease outcome, the authors ended up with a core of 70 candidates bearing significant prognostic value [13]. The expression profile of these genes allowed to identify two patient subgroups, with "good prognosis" or "poor prognosis," having appreciable different risks to develop distant metastasis within 5 years. When the patients were classified according to the St. Gallen and National Institute of Health (NIH) criteria, the 70-genes score was found to be able to reduce the risk of overtreatment by

Fig. 12.3 Multigene prognostic tests for BC patients [Cobain EF, Hayes DF Curr Treat Options Oncol 2015]

25–30%. In particular, MammaPrint®, St. Gallen, and NIH systems assigned 40, 15, and 7% of the patients to the low-risk category, respectively. In a multivariable analysis, MammaPrint® showed a stronger independent prognostic ability than the matched clinicopathologic factors [17, 18]. The assay was then tested in a larger series of 295 patients including either ER-positive or ER-negative BC from the same institution, confirming its prognostic ability in predicting 10-year survival outcome. In particular, within the lymph node-negative sub-cohort (151 patients), the 10-year distant disease-free survival was 87% for the low-risk group and 44% for the high-risk group [19]. These data provided evidence that MammaPrint® was an high performing test in prognosticating ER-positive BC patients, outdoing current clinicopathological characteristics, while its clinical validity was much lower in the ER-negative setting, where nearly all of the patients were classified as high risk. Along this line, a number of retrospective analyses confirmed that only ER-positive patients within the high-risk category did benefit from adjuvant CHT [19–23] suggesting that MammaPrint® could also be used as a predictive tool. The first prospective study (RASTER), conducted in 16 community hospitals in the Netherlands, confirmed the feasibility of the 70-genes test [23] and evaluated its overall performance rate. The study enrolled 427 patients younger than 61 years with T1–T3, node-negative BC, irrespective to their hormonal receptor status. Patients received the adjuvant systemic treatment recommended by the 2004 Dutch Institute of Healthcare Improvement guidelines [24], also taking into account physicians' and patients' preferences. The results of the 70-genes classification were compared with Adjuvant! Online (AOL) [25]. This is a web-based tool for estimating risk of relapse and mortality and illustrating the benefits provided by various treatment regimens for newly diagnosed BC patients. The estimates for risk of death are derived from the Surveillance, Epidemiology, and End Results (SEER) data. AOL!® estimates recurrence by adding 14% to the mortality risk to account for the risk of contralateral breast cancer and local/regional events unlikely to result in breast cancer mortality. The estimates of treatment benefit are derived from available clinical trial results and data from the 1995 Overview meta-analyses of randomized adjuvant chemotherapy and hormone therapy trials for breast cancer [26], with supplemental information from the 2000 Overview [27]. AOL!® and MammaPrint® yielded to a 38% discordance rate in risk estimations, with most of the discordant cases being low risk according to the 70-gene signature and high risk according to AOL!®. The majority (98%) of these patients who did not receive adjuvant CHT showed an uneventful clinical course. Based on these data, it has been concluded that patients pertaining to the MammaPrint® low-risk group would spare CHT without any negative impact on recurrence rate [22]. The first independent validation study, performed by the TRANSBIG research consortium, used samples from 302 patients younger than 60 years and with node-negative, T1–T2 BC. This study confirmed the ability of MammaPrint® in discriminating patients' outcome with Hazard Ratio of 2.79 (95%CI, 1.60-4.87) and 2.32 (95%CI, 1.35-4.0) respectively, for distant metastasis and overall survival, outperforming clinicopathological characteristics [28]. According to the evidence that up to 25–30% of node-positive BC patients would remain free of distant metastasis even without any adjuvant CHT [29], a retrospective study selected 241 T1, T2, or operable T3, pN1a (1–3 metastatic lymph nodes) BC patients [20]. In this cohort, good-prognosis patients (41%) showed a 91% 10-year distant metastasis-free survival and a 96% BC-specific survival, respectively, while both the survival rates were 76% in the poor-prognosis group. Multivariable analysis showed that the 70-gene signature was the most powerful independent predictor for BC-specific survival, with a HR of 7.17, confirming its utility in identifying patients who can safely spare adjuvant CHT even if node positive [20]. Straver et al. [16] assessed the role of 70-gene assay in the neoadjuvant setting in a cohort of 171 patients with BC larger than 3 cm and/or with positive lymph nodes at diagnosis, finding that, as expected, 86% of the patients showed the high-risk signature. The rate of pCR was 20% for high-risk and 0% for low-risk patients [16]. In February 2007, the TRANSBIG consortium launched a multicenter, prospective, and randomized controlled study, the "microarray for node-negative disease may avoid CHT" trial, whose results have been eventually presented in 2016 at the AACR meeting and published soon thereafter [30, 31]. Out of the 11,288 patients enrolled, the trial assessed the risk in 6693 early BC patients by either AOL or the 70-gene assay. The 2142 (31.2%) patients with discordant results have been randomized to receive the adjuvant treatment dictated by AOL or gene expression profile, i.e., ET only for low-risk patients and ET + CHT for high-risk patients [30, 31]. The remaining patients, placed into the same risk category by both methods, were treated in accordance with the current guidelines (ET for the low-risk group and ET + CHT for the high-risk group). A total of 1550 patients (23.2%) were classified as high clinical risk and low genomic risk. At 5 years, the rate of survival without distant metastasis in this group was 94.7% (95% CI, 92.5–96.2) among those not receiving CHT. The absolute difference in survival rate between these patients and those who received CHT was 1.5% points [30, 31].

12.4 Oncotype DX® (Genomic Health 21-Gene Recurrence Score)

This assay evaluates the RNA expression of a panel of 21 genes (16 cancer-related genes and five reference genes) by RT-PCR, providing information about the 10-year risk of distant recurrence (DR). The 21-genes panel works in FFPE samples and includes genes involved in tumor cell proliferation (representing five of the 16 cancer-related genes),

invasion, HER2, and hormone response. The relative expression levels of these genes is calculated by a mathematical algorithm mostly weighting proliferation genes that generate the Recurrence Score (RS), expressed as a value between 0 and 100. RS provides a quantitative risk of distant recurrence and stratifies patients in three categories: low risk (RS < 18), intermediate risk (RS 18–30), and high risk (RS > 30) [32]. RS has been validated as an independent prognostic measure of the risk of recurrence for women with ER-positive, lymph node-negative early BC treated by ET only, outperforming traditional clinicopathological characteristics of patient age, tumor size, and grade [32, 33]. In 2010, a retrospective study examined specimen collected within the ATAC trial with the objective to evaluate the prognostic value of the Oncotype in the postmenopausal setting [34]. The ATAC trial evaluated the efficacy and safety of 5 years of anastrozole, tamoxifen, or the combination of both in postmenopausal women and selected more than 5000 women with localized invasive BC and ER-positive disease [35]. 76% of the specimens from this collection was then used to confirm the performance of RS in elderly patients, demonstrating that RS was an independent predictor of recurrence in both nodes-negative and nodes-positive patients [34]. Moreover, the RS was found to be a strong predictive factor of benefit from cyclophosphamide, doxorubicin, and fluorouracil and fluorouracil (CAF) in ER-positive, node-positive, postmenopausal BC patients. Patients classified as low risk did not derive any benefit from CHT, while a significant advantage from treatment with CAF was observed in patients with a high RS [36]. Likewise, in a cohort of 89 patients with locally advanced BC treated preoperatively with paclitaxel and doxorubicin, the probability of pCR was shown to increase along with RS [37]. Oncotype DX® RS is widely used in the USA, allowing to spare CHT in approximately one third of the cases [38–40] and resulting in overall cost reduction for the health system [41]. A prospective clinical study, the Trial Assigning IndividuaLized Options for Treatment (Rx) (TAILORx), is currently seeking to incorporate the Oncotype DX® test into clinical decision-making, in order to spare women unnecessary treatment if CHT is not likely to be of substantial benefit [42]. TAILORx recruited more than 10,000 women with node-negative, ER- and/or PgR-positive, HER2-negative invasive BC. For this trial, the original RS threshold values have been modified as follows: below 11 (vs. <18) for the low-risk group, from 11 to 25 (vs. 18–30) for the intermediate-risk group, and above 25 (vs. ≥31) for the high-risk group. Low- and high-risk patients have been assigned to ET only or ET + CHT, respectively, while patients with an intermediate (11–25) RS have been randomly assigned to receive ET + CHT or ET only. Sparano et al. [43] recently reported an interim analysis of the TAILORx trial. Patients had tumors measuring 1.1–5.0 cm in the greatest dimension (or 0.6–1.0 cm and G2/G3 tumor grade) and met established guidelines for the consideration of adjuvant CHT on the basis of clinicopathological features. A total of 1626 patients were assigned to receive ET without CHT if they had a recurrence score of 0–10, indicating a very low risk of recurrence. The 5-year rate of invasive DFS was 93.8% (95% CI 92.4–94.9), the rate of freedom from recurrence of BC at a distant site was 99.3% (95% CI, 98.7–99.6), and the rate of OS was 98.0% (95% CI, 97.1–98.6). These data supported the application of 21-genes assay to select patients who may be safely spared CHT treatment [43]. Several studies argued that RS does not provide prognostic information beyond traditional clinicopathological characteristics (i.e., ER/PR receptor, Ki-67 labeling index, and tumor grade), criticizing the cost-effectiveness of the Oncotype DX test [44–52]. In particular, Gage et al. [53] recently interrogated a population of 540 BC patients, reporting that 55% of the study population that would have met the criteria for Oncotype DX® testing (node-negative, ER-positive, HER2-negative invasive BC) would be easily classified in the low- and high-risk category by traditional tools, thus not needing additional information. Specifically, patients with high tumor grade or low (<20%) ER immunoreactivity should be considered at high risk of distant relapse, while patients with low tumor grade and highly ER and PgR express tumors at low risk. The authors concluded that only patients bearing intermediate features would benefit of the Oncotype DX® testing, leading to significant cost savings [53]. Taking into account that RS increases in relation to the levels of proliferation genes and that patients with higher RS benefit from adjuvant CHT, Baxter et al. [54] investigated the prognostic relevance of traditional biomarkers of proliferation (mitotic count and Ki-67 labeling index) in 226 ER-positive, HER2-negative, T1/T2, node-negative BC patients referred to British Columbia Cancer Agency in 2007–2011. The authors found that tumors with a low/intermediate Nottingham grading or low mitotic count were unlikely to be classified as high risk by Oncotype DX®, suggesting to test only patients with high histological score [54].

12.5 EndoPredict®

The EndoPredict® (EP) assay was developed for early, ER-positive, HER2-negative BCs, in order to identify patients with a low rate of recurrence without adjuvant cytotoxic therapy. Based on a RT-PCR method, EP evaluates the expression levels of eight cancer genes (AZGP1, BIRC5, DHCR7, IL6ST, MGP, RBBP8, STC2, UBE2C) and three control genes (CALM2, OAZ1, RPL37A) in FFPE tissue. These genes are related to tumor proliferation and to hormone receptor activity, but do not include ESR1, PgR, or HER2, at variance with Oncotype DX® and PAM50 assays. EP classifies patients treated with adjuvant ET only into a low- or a high-risk category, and it is feasible in a decentralized setting [55–57]. The EP score ranges between 0 and 15 with a threshold of 5 to discriminate between the low- and

high-risk categories. EP was developed and validated in over 1000 postmenopausal, node-negative and node-positive ER-positive and HER2-negative BC samples, retrospectively collected in prospective clinical trials [58]. Continuous EP score proved its prognostic role for distant recurrence, outperforming the established clinicopathological variables of ER immunoreactivity, Ki-67 labeling index, and AOL. The EP score has been subsequently integrated by the clinical characteristics of nodal status and tumor size to create a linear model risk score called EPclin that in turn proved to be a powerful prognostic marker, resulting in a 10-year recurrence rate of 4% for the EPclin low-risk group and 22–28% for the high-risk group [59]. EPclin identifies a subgroup of patients with an excellent long-term prognosis after 5 years of ET, confirming its prognostic ability for both early and late relapse and suggesting that the low-risk patient subgroup might not need an extended ET [58]. The EPclin score has also been found to outperform purely clinical risk classifications (St. Gallen, German S3, and NCCN). Among 1702 ER-positive/HER2-negative, postmenopausal women treated with exclusive ET, 58–61% of patients classified as high/intermediate risk according to clinical guidelines were reassigned to the low-risk group by the EPclin score [60]. In a retrospective study dealing with 167 patients with ER-positive, HER2-negative BC, EPclin score led to a change of the planned therapy in 37.7% of patients, shifting to CHT in 12.3% and to exclusive ET in 25% [61]. The interaction between EP score and CHT has also been investigated: Bertucci et al. [62] collected 553 ER-positive and HER2-negative BC pretreatment core biopsies samples for which documentation of pathological response to anthracycline-based neoadjuvant CHT was available, finding that the high-risk group had a higher pCR rate than the low-risk group (17 vs. 7%). Martin et al. [63] reported a prospective-retrospective clinical validation trial designed to investigate whether EP can safely be used to identify node-positive BC patients who can avoid CHT. In this cohort of 1246 ER-positive, HER2-negative, node-positive, CHT (5-fluorouracil, epirubicin, and cyclophosphamide with or without 8 weekly courses of paclitaxel)-treated BC patients, 25% were classified as low risk on the basis of the EP score. In this subgroup, 93% of the patients showed a distant metastasis-free survival, compared to 70% in the high-risk group.

12.6 PAM50® and Risk of Recurrence (ROR) Score

This assay was developed to classify tumors according to the intrinsic subtype (see above) and to improve the classification concordance reported by investigators and is based on the relative expression of 50 genes [3]. Provided that the data are normalized, the test is considered a robust assay with a high concordance between laboratories [64]. The PAM50 classifier was validated in a cohort of 348 patients receiving tamoxifen, where it was found to outperform IHC in providing prognostic information and in predicting tamoxifen efficacy [65]. In a population of 151 ER early-stage BC patients, PAM50 achieved a good level of agreement with Oncotype DX® in identifying both high (luminal B and RS > 31)- and low-risk groups (luminal A and RS < 18) [66]. Within the group of Oncotype DX® intermediate RS, PAM50 classified 59% of the patients as luminal A, 33% as luminal B, and 8% as HER2 enriched. Moreover, Ki-67 labeling index was found to be reliable in distinguishing luminal A from luminal B and low-risk from high-risk RS tumors but not between the intermediate- and low-risk RS categories [66]. Adopting an algorithm that incorporates gene expression data, intrinsic subtype, and tumor size, Parker et al. [3] created the risk of recurrence (ROR) score (Prosigna), which stratifies patients in high, medium, and low subsets. The clinical utility of PAM50 and ROR score as a prognostic tool has been repeatedly reported in the ER-positive, HER2-negative setting [65, 67, 68].

12.7 Rotterdam 76-Gene Signature

This assay was developed at the Erasmus University Cancer Center in Rotterdam and made commercially available in 2005. The 76 genes included in this assay are mainly related to proliferation. The test was developed from the analysis of 115 women with node-negative BC (ER positive and ER negative), not receiving any adjuvant treatment and followed for more than 8 years, and differentiates patients in two categories, i.e., good signature or poor signature [69]. It has been reported to be highly predictive of distant relapse at 5 and 10 years. Desmedt et al. [70] found in a cohort of 198 node-negative untreated patients that the 5- and 10-year time to distant metastasis was 98 and 94% for the good profile group and 76 and 73% for the poor signature group, respectively. These data stemmed from retrospective analyses and still need to be confirmed in prospective randomized studies. The analytic validity, clinical utility, and reproducibility across different laboratories have not yet been confirmed.

12.8 Genomic Grade Index

Histologic grade is one of the best-established prognostic biomarkers in BC, providing reliable information regarding tumor behavior [71, 72]. However, the Elston-Ellis histological grading system shows low reproducibility among pathologists [73] and does not provide clear prognostic information for patient with grade 2, which represents the majority of cases [74]. The genomic grade index (GGI) was developed

with the aim of grading breast tumors more accurately than the conventional histological grade in the ER-positive, HER2-negative setting [75]. It was developed in 189 BC patients and validated in an independent cohort of 597 cases. The authors created a two-tier classification system based on the differential expression of 97 genes mainly involved in cell cycle regulation and proliferation. The level of expression of these genes was found to reclassify grade 2 tumors into high and low genomic grade category. High GGI score patients were associated with a higher risk of recurrence than low GGI score patients (HR = 3.61, 95% CI = 2.25–5.78) [76]. Loi et al. [77] demonstrated the prognostic ability of GGI in stratifying luminal tumors, reporting that luminal A and B tumors fall into the GGI low risk and high risk, respectively. The role of GGI in predicting pathological response to neoadjuvant CHT was investigated in 229 fine-needle biopsies of BC patients treated with a taxane- and anthracycline-containing neoadjuvant therapy. In this study, a high GGI score was an independent predictor of response to CHT [78].

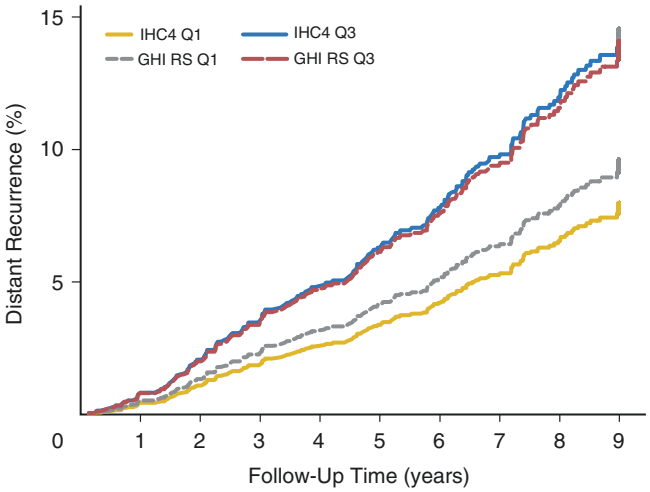

Fig. 12.4 Example of predicted time to distant recurrence for a node-negative postmenopausal patient with a G3 1–2 cm tumor treated with anastrozole who is at either the 25th (quartile 1 [Q1]) or 75th (Q3) percentile of the IHC4 score (score for four immunohistochemical markers: estrogen receptor, progesterone receptor, human epidermal growth factor receptor 2, and Ki-67) or the Oncotype DX® Genomic Health recurrence score (GHI-RS) [82]

12.9 BC Index (BCI)

It is a RT-PCR-based assay working in FFPE samples, based on the HOXB13-to-IL17BR expression ratio (H:I ratio) and the molecular grade index (a five-gene molecular grade index, primarily consisting of proliferation-related genes) [79]. This assay was developed using a cohort of ER-positive tamoxifen-treated BC patients and has been shown to provide an individual risk of distant BC recurrence based on a continuous risk model [80]. The main strength of the BCI is its capability of predicting the risk of both early (within 5 years) and late (10 years) recurrences in ER-positive, node-negative BC. Indeed, the assay was retrospectively evaluated in two cohorts of 317 and 358, ER-positive, node-negative tamoxifen-treated patients. In both cohorts, continuous BCI was found the most significant prognostic factor beyond standard clinicopathologic factors, both for early and late events [81].

12.10 Comparative Evaluation of Prognostic Performance of Multigene Tests and Clinicopathological Characteristics

Most of the comparative data on multigene prognosticators have been obtained by Dr. Dowsett lab taking advantage of the samples prospectively collected within the TransATAC, the translational substudy of the Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial [35]. The ATAC trial randomized ER-positive, HER2-negative BC patients to receive exclusively tamoxifen or anastrozole for 5 years, with distant relapse as the primary end point. Cuzick et al. [82] comparatively analyzed the performance of Oncotype DX RS and IHC4 score (resulting from the immunohistochemical evaluation of ER, PgR, HER2, and Ki-67 integrated into the IHC4 score). The authors found that the information provided by the IHC4 score and Oncotype DX® were similar and that little additional prognostic value was seen combining both scores (Fig. 12.4).

Dowsett et al. [68] then compared the prognostic relevance of PAM50 ROR score with Oncotype DX RS and IHC4 in 940 ER-positive BC patients. The ROR score added significant prognostic information for distant relapse in the whole population ($p < 0.001$) and in HER2-negative/node-negative patients. Likewise, PAM50 ROR provided additional prognostic information beyond Oncotype DX® RS in the overall population and within each subgroup. Interestingly, relatively similar information was provided by ROR and IHC4 in all patients. Buus et al. [83] recently compared the prognostic information provided by Oncotype DX®, EP/EPclin, and clinical treatment score (CTS, obtained by integrating the prognostic information from nodal status, tumor size, histopathological grade, age, and anastrozole or tamoxifen treatment) in 928 ER-positive, HER2-negative BC patients enrolled in the anastrozole and tamoxifen arms of the ATAC trial, with distant relapse-free survival as the primary end point. In the overall population, EP and EPclin provided substantially more prognostic information than Oncotype DX RS, especially with regard to the risk of late relapse and in node-positive patients. In a prospective comparison study, conducted on 665 patients with ER-positive, node-negative BC patients, BCI was com-

pared with the Oncotype DX® 21-genes recurrence score. Both the assays demonstrated significant prognostic ability for early distant recurrence, while only BCI was significant for late distant recurrence [84].

12.11 Concordance Among Gene Expression Tests

It has been demonstrated that gene expression-based tests show only moderate concordance. For example, Oncotype Dx® and EndoPredict® had a 24% discordance in a study reported by Dowsett et al. [83]. This level of concordance is similar to that reported between Oncotype Dx- and Ki67-based risk algorithms. The fact that even gene expression-based tests show a nonnegligible discordance rate when ran in a single patient, coupled with the reality of medical practice in countries where gene expression-based tests are not affordable owing to high cost (in Italy, the out-of-pocket cost for patients is >$4000), underlines the importance to limit the use of gene expression tests to subgroups of ER-positive BC patients and to put efforts to validate Ki-67 (as a surrogate of proliferation) as a predictive marker for CHT benefit.

12.12 Toward a Rationale Use of the Multigene BC Prognosticators

The aforementioned gene expression-based prognostic tests are highly reliable in informing on ER-positive/node-negative BC patients prognosis, and most of them achieved a level of evidence 1B, being validated in samples retrospectively collected within prospective randomized clinical trial. Furthermore, MammaPrint® and Oncotype DX® have been recently validated in prospective clinical trials using molecular data as a randomization factor. This notwithstanding, the multigene tests are not widely used in the daily practice, especially for their high costs and the need of sample centralization. A meta-analysis of BC microarray gene expression profiling data [85] demonstrated that they are all basically looking at the same process: tumor cell proliferation. In other words, they essentially discriminate ER-positive BCs with low proliferation (luminal A intrinsic subtype) and low clinical risk, from ER-positive BCs with high proliferation (luminal B intrinsic subtype) and high clinical risk [85–87]. Multigene tests are used for assessing whether a patient with an early ER-positive BC should receive CHT, and in this regard they may be considered as a potential biomarker. Although their analytical and clinical validity has been convincingly demonstrated, uncertainties remain concerning their clinical utility. A biomarker has clinical utility if its application is associated with a significant survival benefit: it should outperform preexisting clinicopathological indicators or, alternatively, provide comparable information at lower cost, less invasively, or with less morbidity. Nevertheless, these advantages are still not enough for achieving clinical validity: as stated by the recently issued ASCO guidelines for the use of biomarkers in early BC [88], "the magnitude of the benefit must be clinically meaningful and outweigh risks, costs, and/or inconvenience associated with use of the test and the degree of benefit required to recommend for or against a treatment must be tempered with clinical judgment and patient perspective." For example, giving adjuvant CHT to triple negative, node-positive BC patients is of clinical utility beyond any doubt: the 10-year likelihood of incurable distant recurrence in this setting would exceed 50% in the absence of adjuvant CHT that indeed reduces the risk of recurrence by 30%, with a 15–20% absolute benefit and an odd of fatal, life-threatening, or permanent life-changing toxicities accounting for 2–3%. On the other hand, the 10-year risk of recurrence for luminal A-like BC patients (ER/PgR highly expressed, HER2 negative, <20% Ki-67, and/or G1) does not exceed 10% with ET only. This means that adding CHT, that would reduce the risk of recurrence by 30% in this setting as well, would yield to a 3% absolute benefit, which is roughly the same figure of patients potentially harmed. The 2015 St. Gallen International Expert Consensus [12] recognizes that luminal A-like BCs are less responsive to CHT and should be therefore treated with ET only, with the exception of cases with extensive (four or more lymph nodes) axillary involvement. Oppositely, CHT in combination with ET is usually recommended for luminal B-like BC patients, unless they are bearing clinicopathological low-risk features, including T1 size, no or limited (1–3 nodes, pN1a) nodal involvement, absence of peritumoral vascular invasion, and very high ER/PgR and/or low Ki-67 values, as well as multiparameter molecular markers of favorable prognosis [12]. The fact that these multigene tests have been validated only for node-negative patients (with the exception of MammaPrint® that has been used in 1–3 node-positive patients within the MINDACT trial) is anything but trivial in the clinical practice. ET is usually delivered to patients with luminal tumors characterized by favorable prognostic markers, including high levels of ER/PgR immunoreactivity, small T size (T1/T2), and absence of lymph node involvement, thus questioning the usefulness of running multigene tests in N0 luminal patients. Oppositely, patients with extensive lymph node involvement usually receive CHT irrespective of the biology of their tumor. As a consequence, multigene tests would be clinically useful specifically in patients with 1–3 positive lymph nodes. In this regard, Gnant et al. [89] recently investigated the prognostic role of PAM50 ROR in 543 patients with one to three node-positive BC treated with 5 years of adjuvant ET only within two phase III adjuvant trials: ABCSG-8 and ATAC. The authors found that the patients with one positive

lymph node classified as low risk by PAM50 ROR had a 6.6% risk of distant recurrence at 10 years (95% CI 3.3–12.8%). By contrast, low-risk patients with two or three positive lymph nodes nearly doubled the risk of distant recurrence to 12% (95% CI 6.6–22.8%). Assuming that CHT could reduce the risk of recurrence by 30%, these data prompt to speculate that ROR low-risk patients should receive CHT when 2–3 lymph nodes are involved, while the benefit of any further treatment in patients with just one metastatic lymph node would be negligible. Interestingly, patients without any lymph node involvement are more frequently classified as low risk by different multigene tests. Notwithstanding these data, the putative value of genomic tests in decision-making of luminal BC patients with 1–3 node-positive disease remains to be established. The MINDACT trial [30] reported that the 5-year rate of survival without distant metastasis in the clinical high-risk/molecular low-risk group was 94.7%, indipendently of the occurrence of lymph node metastasis. There are three further prospective phase III randomized trials (TAILORx and RxPONDER using Oncotype DX® and ASTER 70s using genomic grade) currently addressing the role of multigene tests in predicting adjuvant CHT benefit also in patients with up to three node-positive luminal BC, providing soon level 1 evidence on their clinical utility in daily practice. For the time being, ASCO guidelines recommend not to use multigene tests for ER-positive BC patients with lymph node involvement [88].

Special Types of Breast Cancer and Non-epithelial Tumors

13

Giovanni Mazzarol and Sara Pirola

13.1 Introduction and Historical Perspective

Since the early twenties of the past century, when according to Dr. Borst only five breast tumor subtypes had been identified, the histopathological classification of breast carcinomas has been profoundly modified, in order to refine its diagnostic efficiency and to embody the results flourishing from basic science [1, 48]. Histopathology has been therefore relentlessly evolving for the accomplishment of two main tasks: providing prognostic information and predicting the response to surgical and medical treatments. In the early seventies, Dr. Haagensen pointed out in his book entitled *Diseases of the Breast* his "…hope to sort out from among them (breast tumors)…, additional characteristic types of breast carcinomas," in an attempt to ascertain their clinical-pathological correlation. He emphasized the need to consider in situ lesions as "fully malignant," recommending the same "drastic" surgical cure usually applied to invasive tumors [2]. This attitude clearly illustrates how physicians have been tailoring the treatment of breast cancer to histopathological features since the beginning of modern oncology.

Pathologists have been deeply involved into breast cancer care by then, developing the concept of invasive breast cancer of special type, which carries obvious "useful clinical correlates and prognostic implications" [3]. Along this line, Japanese authors developed a morphological classification dissecting tubule-papillary, solid-tubular, and scirrhous patterns according to their private risk of relapse [4]. The painstaking evaluation of tumor histology allowed the recognition of different coexisting patterns [5]. In particular, combined features of special type carcinomas have been described in up to 30% of breast carcinomas of NST (no special type). The frequent occurrence of morphological tumor heterogeneity prompted pathologists to recognize mixed types of breast tumors, which may hinder the clinical relevance of histological classification. The overall percentage of the special component has been described according to different series and authors, ranging from over 50% to at least 90% [3]. Actually, the lack of agreement in the cutoff by which a specific histological subtype should be considered as predominant has weakened the clinical impact of subgrouping breast carcinomas [6, 7].

13.2 Mucinous Carcinoma

Mucinous carcinomas have pushing margins with typical gelatinous, soft cut surface.

The neoplastic cells have intracellular mucin with solid, micropapillary, cribriform, and tubular formations, floating in pools of extracellular mucin. "Signet ring" cells may also be present, rarely being the predominant feature [46]. Multiple sections are required in paucicellular form to detect the neoplastic cells to establish the diagnosis. Delicate bands of fibrovascular connective tissue can be observed within the mucous lakes. This characteristic histology should be present in at least 90% of the tumor. Almost all tumors express strong ER and PgR and rarely overexpress HER-2/neu oncoprotein. According to different series, the frequency is up to 2%. They have excellent prognosis with a 10-year overall survival up to 80–100% [8, 9] (Fig. 13.1a).

13.3 Tubular Carcinomas

They are ill-defined, usually small neoplasm with stellate appearance. They are characterized by an irregular haphazard collection of angulated, oval, or elongated well-formed tubules, with a central lumen; typically, they have a single

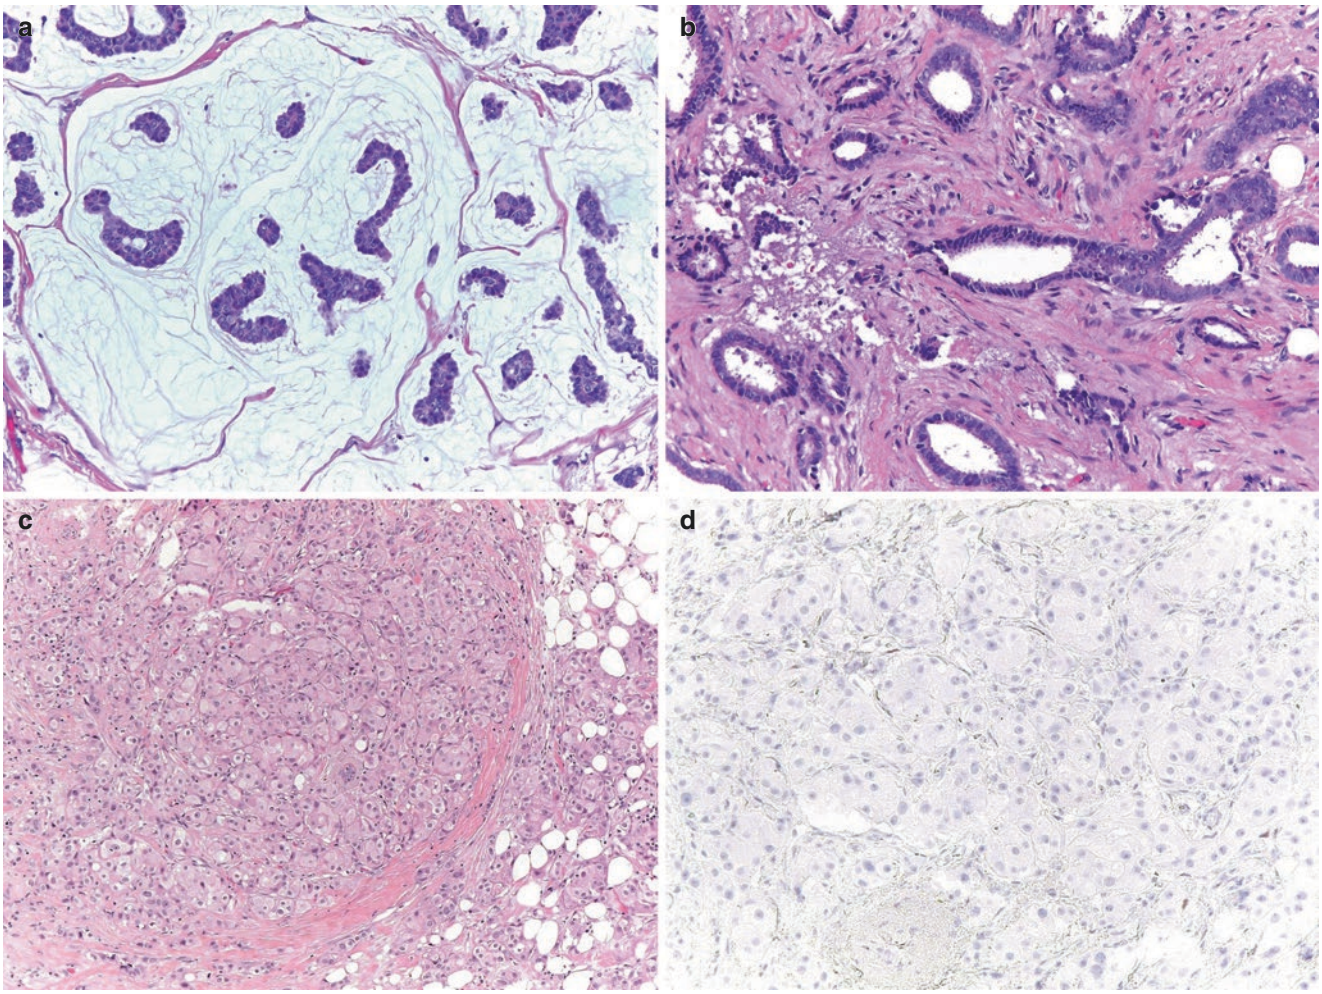

Fig. 13.1 (**a**) Mucinous carcinoma shows neoplastic cells floating in mucous lake. (**b**) Tubular carcinoma with angulated single layer glands in desmoplastic stroma. (**c**) Apocrine carcinoma with eosinophilic large cytoplasm. (**d**) Negative estrogen receptor immunohistology in the very same apocrine carcinoma depicted in (**c**)

layer of small, monomorphic epithelial cells often showing apical "snouts." They show desmoplastic changes and/or stromal elastosis. Tubular carcinoma shows low cytologic atypia with rare mitoses. Calcifications are often present. These features should be present in more than 90% of the lesion. Conventional types of ductal intraepithelial neoplasia (DIN) may be present, and coexistent columnar cell lesions including flat epithelial atypia and lobular neoplasia are common in the proximity of tubular carcinoma. They extensively express ER and PgR and they do not overexpress HER-2/neu oncoprotein. They account of less than 2% of carcinomas, and the survival at 10 years is up to 99–100% [6, 10] (Fig. 13.1b).

13.4 Apocrine Carcinoma

They may show a brownish-tan cut surface. They have cytological features of apocrine cells, and two types of cells could be observed: type A cells (large, with abundant eosinophilic granular cytoplasm with enlarged rounded hyperchromatic nuclei and prominent nucleoli) or type B cells with foamy cytoplasm containing lipid droplets resembling histiocytes or sebaceous differentiation. Tumor cells with bizarre, multilobulated nuclei may be present. The apocrine morphology needs to be seen in more than 90% of the cancer cells. An intraepithelial apocrine component (DIN) with high nuclear grade is often present. They typically express androgen recep-

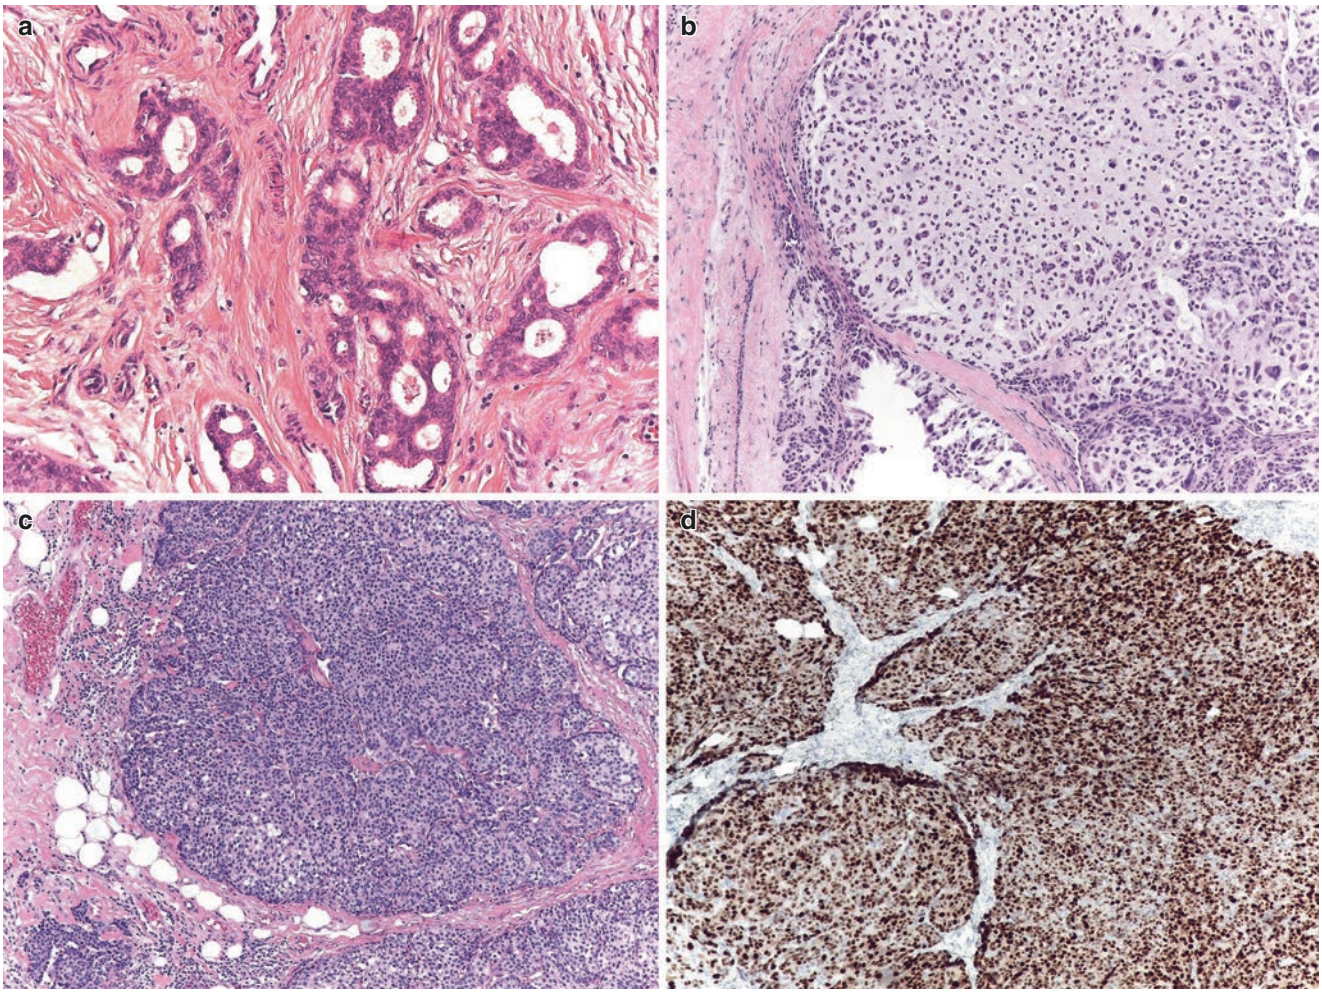

Fig. 13.2 (**a**) Cribriform carcinoma with typical fenestrated glands. (**b**) Metaplastic carcinoma with direct transition from epithelial cells to mesenchymal component (matrix-producing). (**c**) Papillary carcinoma showing solid pattern with fibrovascular core. (**d**) Positive estrogen receptor immunohistology in the very same papillary carcinoma depicted in (**c**)

tors and are triple negative, even though sometimes they may overexpress HER-2/neu oncoprotein. According to different series, they account to 1–4% of the carcinomas. The pure form has a 10-year survival >95% [11, 12] (Fig. 13.1c, d).

13.5 Cribriform Carcinoma

They show angulated and fenestrated cribriform glands as in ductal intraepithelial neoplasia (DIN) of cribriform type with low or intermediate nuclear grade cellularity. Osteoclastic-like giant cells have been reported in some cases. Mitosis is rare. In the mixed cribriform carcinoma form, more than 50% show a cribriform pattern, but areas (10–49%) of non-tubular less differentiated type are also present. In the vast majority of cases, adjacent DIN with cribriform and micropapillary growth pattern is present. They express ER and PgR but usually do not overexpress HER-2/neu oncoprotein. In the pure form, they represent up to 4% of breast carcinomas, with a 10-year survival of 90–100% [6, 13] (Fig. 13.2a).

13.6 Medullary Carcinomas

They are well circumscribed, with a soft, gray/tan cut surface. Medullary carcinomas have histologic circumscription with pushing, expansive margins (smooth, rounded contour). They grow in a syncytial pattern of solid clusters of tumor cells forming anastomosing cords and sheets. Neoplastic cells have severe nuclear atypia, prominent nucleoli, and

indistinct cell borders with high mitotic count. The lymphoplasmacytic infiltration (composed almost entirely of either lymphocytes or plasma cells) is often present throughout the tumor. They are triple-negative carcinomas with a good prognosis if strict histologic criteria are accomplished (up to 95% survival) [14, 15].

13.7 Metaplastic Carcinomas

They are carcinomas with a variable percentage of mesenchymal differentiation. They could be subdivided in two categories: carcinomas with squamous and/or spindle cell metaplasia (low-grade adenosquamous carcinoma, fibromatosis-like metaplastic carcinoma, squamous cell carcinoma, and spindle cell carcinoma) and carcinomas with heterologous metaplasia.

Carcinomas with heterologous metaplasia are poorly differentiated duct carcinomas associated with mesenchymal elements, most commonly chondroid, osseous, and rhabdomyoid, but also lipomatous and angiomatous. The heterologous elements can be either well differentiated with minimal atypia or sarcomatous as for tumors originating in soft tissues. If there is a direct transition from epithelial to the mesenchymal components without an intervening spindle cell component, the term "matrix-producing carcinoma" has been used (Fig. 13.2b).

Metaplastic carcinomas are triple negative, although occasional tumors with focal positivity for ER and/or HER-2/neu are encountered in the mesenchymal component. The frequency is up to 5% of the carcinomas, and the overall survival at 5 years is 18–81% according to stage at the presentation [16, 17].

13.8 Squamous Cell Carcinomas

Squamous cell carcinomas arising in the breast parenchyma are exceedingly rare and usually represent metastatic squamous carcinoma. In their pure form, they often appear as cystic lesion with keratin debris, simulating necrosis. Intercellular bridges and keratin pearls are observed and spindle or acantholytic in appearance as well. They are triple-negative carcinomas with a survival at 5 years ranging from 81 to 46.9% if metastases (both regional and distant) are absent or present at the time of diagnosis [18].

13.9 Papillary Carcinoma

Papillary carcinomas have a predominantly papillary morphology (>90%) harboring papillae formed by malignant epithelial cells and fibrovascular cores. If the individual papillary fronds become crowded and are not separated by spaces, the term solid papillary carcinoma is used (Fig. 13.2c, d). An intraepithelial component (DIN), often also demonstrating a papillary architecture, is usually present. Neuroendocrine features have been consistently reported. ER and PgR positivity and HER-2/neu negativity is the most frequent phenotype. The prevalence varies according to different series from 0.04 to 2.7% with an overall survival of >90% at 5 years [19].

13.10 Micropapillary Carcinoma

Micropapillary carcinomas are arranged in micropapillary, tubuloalveolar, or morular clusters and lie within optical clear stromal spaces (shrinkage artifact), simulating lymphatic/vascular spaces. They lack fibrovascular cores, sometimes containing mucinous material. Typically, the cells have the apical surface polarized to the outside, finely granular or dense eosinophilic cytoplasm, and intermediate-to-high-grade nuclei with frequent mitoses. The majority of tumors are associated with an intraductal component of micropapillary and cribriform patterns and show extensive peritumoral vascular invasion paralleled by a prevalence of axillary lymph node metastasis significantly higher than ductal carcinoma NST. They variably express ER, PgR, and HER-2/neu [20].

13.11 Salivary Gland-Type Carcinomas

The most common subtype of salivary gland-type carcinomas is represented by adenoid cystic carcinoma. These tumors are usually well circumscribed with small cystic areas. They are formed by adenoid and basaloid cells forming true glandular spaces and pseudo-lumina. Sebaceous cells and squamous metaplasia of luminal cells may be present. They grow with an irregular, infiltrating pattern showing solid, cribriform, and trabecular-tubular arrangements, even if a mixture pattern may often be observed. As for their salivary gland counterpart, high-grade carcinomas have >30% of solid growth, while well-differentiated forms show exclusively a cyst and glandular appearance. Tumors with an intermediate differentiation show <30% of solid pattern. Mitotic count is usually low [21]. They are triple-negative carcinomas with an excellent prognosis when well differentiated (up to 90%) at 10 years. The remaining subtypes of salivary gland-type carcinomas, i.e., mucoepidermoid and acinic cell carcinomas, are exceedingly rare and resemble morphologically their salivary gland counterpart.

13.12 Rare Types of Breast Carcinoma

Few cases of tubulo-lobular carcinoma have been reported. These tumors are classic type of lobular carcinomas intermingled with well-formed single layer glands. Other very uncommon breast cancer subtypes are represented by lipid-

rich carcinoma, which shows extensive foamy appearance due to intracytoplasmic lipid accumulation, glycogen-rich carcinoma, secretory and hypersecretory carcinoma, and osteoclast-like giant cell carcinoma. Neuroendocrine small cell carcinomas have morphological features similar to their lung counterpart.

13.13 Non-epithelial Tumors

Primary mesenchymal tumor of the breast represents a heterogeneous group of neoplasm by far less frequent than pure epithelial neoplasm. Non-epithelial neoplasm could be subdivided in mixed (fibroepithelial neoplasms) and in pure mesenchymal form [22]. The most relevant entities of the first group are fibroadenomas and phyllode tumors. Fibroadenoma is a well-circumscribed biphasic (fibroepithelial) neoplasm showing stromal proliferation around glands (pericanalicular pattern) or compressing cleft-like ducts (intracanalicular pattern). The ducts are lined by two cell layers of luminal epithelial cells and myoepithelial cells. Fibroadenomas and phyllode tumors could be considered a continuum degree of progressive malignancy of the stromal component, which in the high-grade phyllode tumors is definitely sarcomatous (so-called cystosarcoma phyllodes). The stroma is loosely cellular, with regular spindled cells and collagen, and it may sometimes exhibit multinucleated giant cells, extensive myxoid changes, or hyalinization [23].

Areas of stromal hypercellularity may be seen within a fibroadenoma, leading to a diagnosis of cellular fibroadenomas because the typical leaflike architecture of phyllode tumors is absent or focal. Mitotic figures are uncommon. The epithelial component of fibroadenoma can show varying degrees of epithelial hyperplasia, particularly in young women. Squamous or apocrine metaplasia may also occasionally be observed. Whenever papillary apocrine changes, cysts, epithelial calcifications, and sclerosing adenosis occur, these tumors have been classified as complex fibroadenomas. Rarely, atypical ductal hyperplasia, lobular neoplasia, ductal intraepithelial neoplasia (DIN), or carcinoma may occur within fibroadenomas [24].

Benign phyllode tumors resemble intracanalicular fibroadenomas, and the hallmark of the tumor is the formation of stromal leaflike processes protruding into cystic spaces. Phyllode tumors are classified as benign, borderline, and malignant. In benign tumors, the mitotic count should not exceed 2 × 10 HPF. Borderline and malignant phyllode tumors are distinguished on the basis of the degree of stromal cellularity, stromal atypia, stromal overgrowth, tumor borders, and mitotic activity (3–9 × 10 HPF in borderline and >9 in malignant phyllode tumors). Local recurrences can occur in all types of phyllode tumors, with the highest prevalence for the malignant type, and distant metastases have been reported almost exclusively in malignant tumors [25, 26].

The second group of pure mesenchymal tumors mirrors the morphological features of their counterparts primarily arising in soft tissues [27]. Breast sarcomas must be differentiated from metaplastic carcinoma, due to their different surgical and clinical management. As a matter of fact, the sarcomatous component of a triple-negative carcinoma with extensive metaplastic features may outgrow the epithelial component, thus leading to a misdiagnosis of primary pure sarcoma. Therefore, focal remnants of carcinoma should be scrutinized in tumors showing prominent mesenchymal differentiation.

Vascular lesions include benign hemangioma and angiomatosis, atypical vascular proliferations, and angiosarcomas. Angiosarcomas may develop following radiation therapy for breast cancer or, less commonly, as primary neoplasms arising in patients with no prior history of radiation [28–31].

Tumors showing adipocyte differentiation include lipoma, a benign tumor composed of mature adipocytes without atypia, sometimes incorporating small vessels (angiolipoma), and liposarcoma that represents its malignant counterpart [32].

Schwannoma and neurofibroma of the breast derive from the sheath of peripheral nerves; most of them arise in the mammary subcutaneous tissue, even if parenchymal lesions have also been described [33].

Primary granular cell tumor of the breast is a benign neoplasm derived from Schwann cells of peripheral nerves and composed of compact nests of cells with prominent eosinophilic cytoplasmic granules, which are PAS positive and strongly immunoreactive for CD68 and S100 protein [34].

Myofibroblastoma is a benign, well circumscribed, pseudoencapsulated mammary stromal spindle cell tumor with prominent myofibroblastic differentiation, immunoreactive for desmin, smooth muscle actin, and CD34. They show broad bands of hyalinized collagen in the absence of any mammary duct and lobules [35].

Desmoid-type fibromatosis of the breast is a locally infiltrative, histologically low-grade proliferation of spindle cells and collagen. It rarely occurs within the breast parenchyma, frequently arising from the pectoral fascia [36].

Nodular fasciitis is a self-limiting, mass-forming fibroblastic/myofibroblastic proliferation. Inflammatory myofibroblastic tumor is a usually low-grade neoplasm composed of myofibroblastic spindle cells with prominent admixed inflammatory cells, most commonly plasma cells [37].

Pseudoangiomatous stromal hyperplasia is a benign disease in which the stromal cells form a complex pattern of anastomosing empty spaces in a dense collagenous stroma coexisting with duct and lobular epithelium. The spaces rarely contain a few red blood cells. Myofibroblasts (usually CD34 and calponin immunoreactive) line the slit-like spaces, resembling endothelial cells [38].

Leiomyoma and leiomyosarcoma of the breast show distinct smooth muscle differentiation [39, 40].

Pure rhabdomyosarcoma and osteosarcoma of the breast are composed of cells showing varying degrees of skeletal muscle differentiation or osteoid formation [41, 42].

Periductal stromal tumor is a rare lesion of low-grade sarcoma behavior [43].

The most frequent subtypes of primary lymphomas of the breast are diffuse large B-cell non-Hodgkin lymphomas, not otherwise specified (DLBCL), extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT) type, and follicular lymphoma. Rare cases of Burkitt lymphoma, lymphoblastic lymphoma of either B-cell or T-cell type, and peripheral T-cell lymphomas have also been reported. Hodgkin and non-Hodgkin lymphomas originating from nodal sites may secondarily involve the breast [44].

Metastasis to the breast represents up to 1.3% of all mammary malignant tumors, including melanoma and carcinomas of the lung, ovary, prostate, kidney, and stomach [45].

Pathology After Neoadjuvant Treatments

14

W. Fraser Symmans

14.1 Approach and Methods

14.1.1 Pathologic Examination of Post-neoadjuvant Resection Specimens

The main objective is to accurately identify the sites of primary tumor bed (that may or may not contain residual cancer cells) and any residual lymph node metastases, so that the extent of residual cancer can be measured and reported. Of course, the tumor bed can become very subtle after effective neoadjuvant chemotherapy, and improving treatments make this ever more likely. Posttreatment residual disease is often detected by light palpation of the sliced breast specimen even more easily than it is observed by visual inspection. Sometimes that is in an area of ill-defined fibrosis. Fortunately, the communication between pathologists, surgeons, and radiologists has greatly improved and, combined with innovations in preoperative localization, has greatly improved the precision of pathologic evaluation.

Recommendations from an international multidisciplinary committee describe the approach and methods in two publications [1, 2]. For example, a current best standard involves clinical communication through medical records (electronic) to include radiologic reports; placement of metallic clips in each site of primary disease and the biopsy-proven positive lymph node prior to treatment, either a localization wire or radioactive metal seed into the primary tumor and clipped node; and sentinel lymph node biopsy procedure. For example, placement of a radiologic clip in a positive axillary node before treatment increases the accuracy of posttreatment sentinel node biopsy to a clinically acceptable level (false-negative rate of 2%) [3, 4].

Each procedural advance enables pathologists to more accurately identify and evaluate posttreatment specimens. But their effectiveness requires that pathologists have access to specimen radiography to locate metallic clips, coils, seeds, or even calcifications within the specimen and in macroscopic slices of the specimen. Thus, the pathologists can distinguish contiguous from multifocal tumor bed and produce a visual map of the sliced specimen to indicate the sites of the disease and the locations of tissue sampling for histopathologic sections on slides. Indeed, a visual map is critical for accurate pathology, and this can take the form of radiograph, printed digital radiograph, photograph, or sketch (with measurements annotated). The pathologist and technician can draw and label the site of each lesion of interest and each tissue sample for histopathology directly onto the map and then scan that image and save the file with the pathology record. When the pathologist reviews the corresponding slides days later, it will be obvious how any residual disease in the slides relates to the original map. This critical step, although simple, will greatly improve the accuracy of reporting the site, extent, and stage of residual disease. Often times it will also decrease the number of tissue blocks and slides for histopathology, thereby decreasing costs and time as it concentrates the pathologist's attention to the appropriate areas of the specimen.

Typically, an intraoperative evaluation of the primary resection specimen (presence of tumor bed and margins assessment) will be requested. Accurate specimen radiography available to the pathologist expedites this assessment, when combined with gross examination of the sliced specimen, and reduces the need for frozen sections of margins. Intraoperative evaluation of sentinel lymph nodes might also be requested, and this can take the form of touch preparation cytology or frozen section. There are pros and cons to either approach. Each is accurate in practiced hands, and cytology preserves all of the tissue for permanent histopathology sections, whereas frozen section allows for estimation of the size of any metastasis. Molecular approaches to nodal assessment are also possible, but have not been accurately calibrated to estimate the nodal burden of residual disease. If immunohistochemistry for epithelial cells (cytokeratins) is

W. Fraser Symmans, M.D.

e-mail: fsymmans@mdanderson.org

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_14

to be performed on sentinel nodes, then it is better on the permanent section. This can be helpful to identify remaining tumor cells because cytoreduction can occur in metastases as seen in primary disease.

Taken together, these methods increase the accuracy and efficiency of pathologic evaluation and enable accurate determination of the presence of any residual disease (versus pCR), as well as its 'yp' stage and residual cancer burden (RCB), as described in detail below. Moreover, the most important part of pathologic assessment is the gross pathologic-radiologic correlation and the resultant map of tissue sections that occurs on the day of surgery. Therefore, it is very helpful to familiarize the trainees and support technical staff who handle these specimens as to the objectives of pathologic evaluation posttreatment, so that they understand what is required from their work. Online videos of how actual resection samples are handled can be found linked to the following site: www.mdanderson.org/breastcancer/RCB (Internet search terms: residual cancer burden breast) [5, 6].

14.2 After Neoadjuvant Chemotherapy

14.2.1 Prognostic Importance of Pathologic Complete Response (pCR)

Pathologic complete response (pCR) after neoadjuvant chemotherapy has been recognized since the earliest neoadjuvant trials, to be an excellent response with favorable prognosis. Furthermore, it can be inferred from reading any standard pathology report and easily extracted from case records. Thus, the pCR rate of a chemotherapy treatment is a recognized benchmark of efficacy.

Prescient trials of neoadjuvant chemotherapy demonstrated an increase in pCR rate from the addition of a taxane- to anthracycline-based chemotherapy, also from weekly paclitaxel treatment schedule (versus 3 weekly), and from the addition of HER2-targeted treatment to chemotherapy [7–11]. In each example, a subsequently reported adjuvant trial, sufficiently large for survival analysis, demonstrated improved survival outcomes for the treatment that had increased the pCR rate [12–16]. Indeed, randomized neoadjuvant chemotherapy trials have become accepted for clinical development of new treatments for breast cancer, with pCR as an endpoint for accelerated regulatory approval, but still conditional on demonstrated survival benefit for full approval of the treatment [6]. There is some controversy about the prognostic meaning of observed differences in pCR rate, but greater understanding of pathology, phenotype, and statistical issues will hopefully inform progress [17–20].

One claim that most can agree on is that patients who achieve pCR do have favorable prognosis. Clinical investigators and members of the US Food and Drug Administration collaborated to compare the prognosis of pCR versus residual disease (RD) in a meta-analysis that included the majority of mature multicenter neoadjuvant trials [21]. The meta-analysis clearly demonstrated that pCR afforded improved survival, no matter the treatment received. This result also held in each of the main subtypes of breast cancer defined by hormone receptor and HER2 status, although there was not significant prognostic difference in grade 1–2 HR+/HER2−, and modest prognostic effect in HR+/HER2+ disease [21] and the prognosis of pCR in HER2+ disease did not appear to be as good as for other subtypes [21]. However, two important points must be considered. Firstly, these neoadjuvant trials evaluated the primary endpoint of response retrospectively during an era when the pathology community was not broadly engaged in the clinical trial process, and procedures for localizing treated tumor bed preoperatively and standardized procedures for evaluating post-neoadjuvant specimens were very uncommon. Secondly, the follow-up was insufficient to observe long-term prognosis, since fewer than 10% of subjects were remaining at risk beyond 5 years of follow-up [22]. Nonetheless, this meta-analysis was critically important to demonstrate the global experience that pCR is a surrogate endpoint for better prognosis [21].

14.2.2 Prognostic Tools to Categorize Prognostic Risk of Residual Disease

There are two main prognostic tools based on an estimate of the extent of residual disease: AJCC stage ('yp' stage categories) and residual cancer burden (RCB). There are also other tools that combine the assessments of residual disease with information about the disease before treatment began: Miller-Payne system and the Neo-Bioscore (CPSEG) categories. Other systems also exist, but are used less commonly.

14.2.2.1 Stage

The AJCC staging system after neoadjuvant chemotherapy ('yp' stage) is generally similar to the usual 'p' stage of an untreated resected breast cancer, except that it accounts for cytoreduction of a tumor bed at the primary or metastatic site by requiring that the tumor size be the largest residual focus of invasive cancer—without intervening fibrosis. The new 8th edition retains this same definition for measurement when determining ypT and ypN stage (in press). However, it is unusual to have residual primary tumor without intervening fibrosis between nests or masses of cancer cells, and pathologists' assessment of ypT size may vary based on this interpretation. Nonetheless, the categories of 'yp' stage are generally prognostic in breast cancer and within the major subtypes [23, 24].

14.2.2.2 RCB

The residual cancer burden (RCB) is an index score that is derived from the two-dimensional measurements of the extent of residual primary invasive cancer, the histopathologic estimate of the proportion of that area that contains residual invasive cancer, the number of positive lymph nodes, and the size of the largest metastasis (Table 14.1). These variables are entered into an online website to calculate the score and resultant category. RCB scores are prognostic, independent of 'yp' stage and pretreatment 'c' stage, and exhibit good reproducibility between pathologists [5, 25]. So too, the distribution of RCB index scores for residual disease is also classified as minimal, moderate, and extensive RCB (i.e., RCB-I, RCB-II, and RCB-III), and those RCB classes are prognostic [5]. The RCB system has web-based protocols, examples, and educational videos, in addition to the calculator: www.mdanderson.org/breastcancer/RCB.

There are important differences between the 'yp' stage and RCB system, particularly with respect to the measurements recorded for primary tumor and lymph nodes. Tumor size for ypT includes the largest continuous focus of residual invasive cancer, without fibrosis. On the other hand, RCB requires measurement of the extent of the residual invasive cancer related to the tumor bed. This allows for multiple foci of residual cancer in a tumor bed to be included as one overall tumor measurement. Of course, the estimate of cellularity in that tumor area will correct for low cellularity or tracts of fibrosis separating cellular foci. Therefore, we would expect that largest dimension for RCB can be larger than the ypT size, since many tumors regress in a nonuniform way (Fig. 14.1).

The definition of metastatic size in nodes (e.g., to determine macro- versus micrometastasis or isolated tumor cells) for ypN stage is also based on the largest contiguous tumor focus. On the other hand, the size of the largest metastasis for RCB allows intervening fibrosis within a residual metastasis. So again, the metastasis size for RCB can be larger than the size determination for ypN stage, since residual metastases can have nonuniform distribution of cancer cells within the metastatic site.

Lymphovascular emboli are sometimes the only identifiable residual primary cancer, and this can lead to confusion. Firstly, it should be distinguished from intraductal cancer. Secondly, it should be considered to be residual invasive disease. The staging system does not directly address this issue, but the case should not be defined as pCR. The RCB system considers this to be invasive disease and recommends the extent be estimated as if it were invasive disease. This can be problematic if there are only rare isolated foci scattered in the breast. In that setting, it can be reasonable to use the largest focus. But if there are multiple foci, then it is better to estimate the overall area involved and a very low percent cellularity in that area.

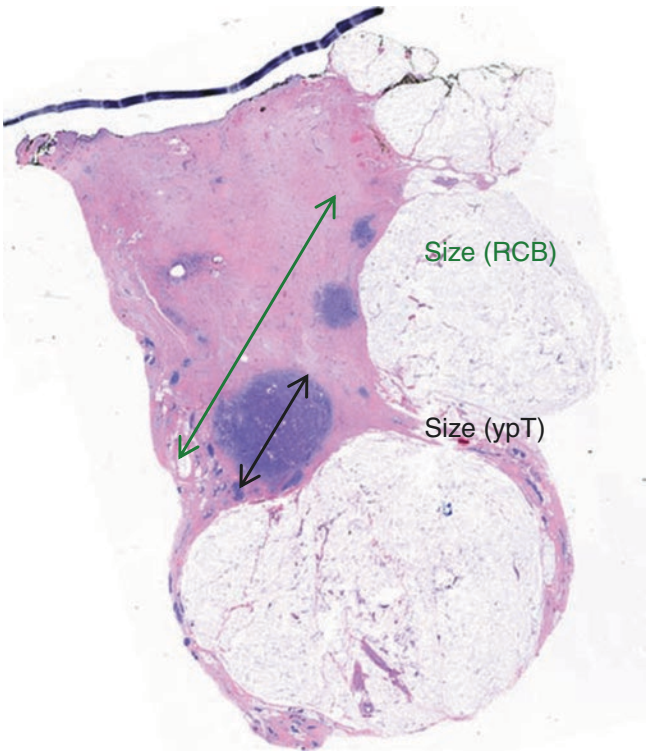

Fig. 14.1 Illustration of the different criteria for measuring residual invasive cancer size for ypT versus extent of residual invasive cancer for calculation of RCB. This same difference in approach also applies to the measurement of nodal metastases

The most common challenges for pathologists using the RCB system are (1) failure to realize that the primary tumor bed area for RCB is defined from the combined information from gross examination of the specimen and subsequent histopathologic study of the corresponding slides and (2) overestimation of the average cancer cellularity within the area of the primary tumor bed. As with any resected tumor, the macroscopic measurements are preliminary results that may be revised after review of the corresponding microscopic findings. Thus, the tumor bed for final measurements in the RCB formula and for assessment of cancer cellularity is ultimately defined from the histopathologic assessment (Fig. 14.2). The RCB website contains pictures and videos to prime pathologists as to how to assess average cellularity across an area, and these are helpful to avoid the mistake of taking cellularity estimates only within concentrated foci of cancer cells in the tumor area—since that approach would not provide the average cellularity. Hence, the average cellularity of residual invasive cancer in the tumor bed for RCB can be lower than the cellularity of the most concentrated tumor focus that one might record for genomic testing, and it represents cancer cellularity per area rather than cancer cellularity per nucleus.

Overall, the RCB has been independently validated, provides prognostic information that is independent of 'yp' stage, and is relevant within each phenotypic subtype

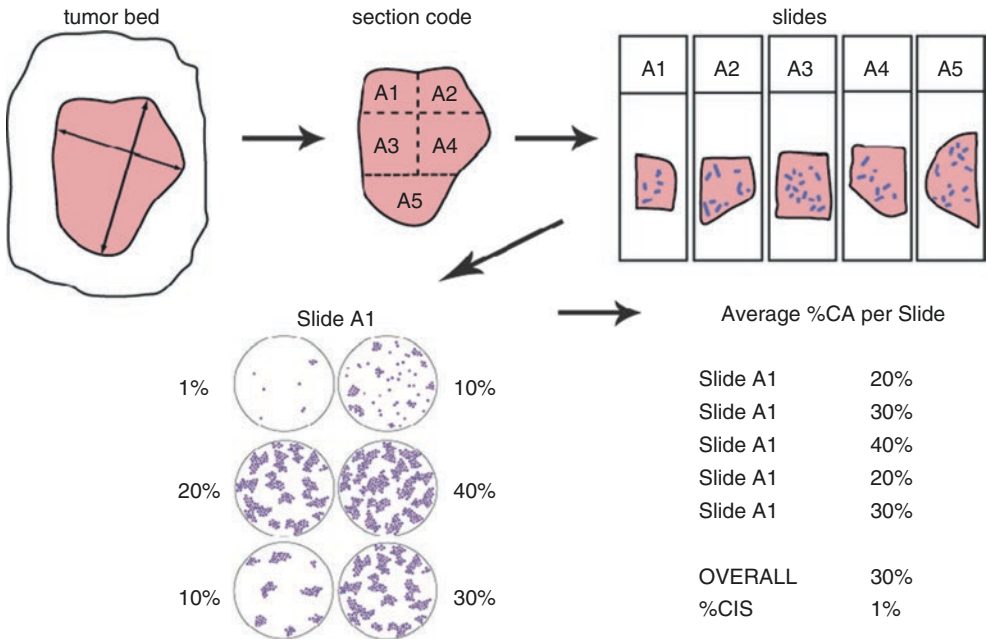

Fig. 14.2 Schema for mapping gross and histopathologic findings from the largest residual primary tumor bed to define the dimensions and average cellularity of the residual invasive tumor bed for calculation of RCB

(reported in abstract by Symmans et al. San Antonio Breast Cancer Symposium 2013, manuscript under review). Its greatest potential for use within clinical trials has barely been tested: to compare the distributions of RCB index scores between experimental and control populations from a randomized trial. That would enable every participant in the trial to contribute relevant information about response and prognosis.

14.2.2.3 Miller-Payne

The Miller-Payne system compares the cellularity of the residual invasive cancer to the cellularity of the cancer in the pretreatment core biopsy. The five categories of relative cytoreduction are prognostic [26]. Although residual tumor size and nodal status are not considered, there is correlation between lesser stage and cytoreduction [27]. This system has not been evaluated compared to stage or within the phenotypic subtypes of breast cancer.

14.2.2.4 Neo-Bioscore (CPSEG)

The CPSEG system is a nomogram that adds risk integer scores (0–2) for the following individual criteria: clinical stage (cT, cN) before treatment, pathologic stage after treatment (ypT, ypN), estrogen receptor status, and histopathologic grade before treatment, to produce 7 prognostic groups (Table 14.2) [28]. This system has been independently validated as prognostic [29, 30]. Recently, the system was revised to include HER2-positive status as a favorable prognostic criterion because response and survival has been improved by addition of HER2-targeted therapy to chemotherapy and renamed as Neo-Bioscore [31]. The advantages of CPSEG/Neo-Bioscore are that the system uses existing standard data and is readily accessible to retrospective databases. However, it is broadly relevant to breast cancer, and the prognostic meaning of some of these variables included in Neo-Bioscore might vary according to the subtype of disease—particularly as practice approaches to neoadjuvant therapy and types of treatment used are becoming more subtype specific. Indeed, the subtype specificity and applicability to new treatment paradigms will be a challenge for all of the prognostic tools.

14.2.3 Cellular and Molecular Characteristics of Residual Disease

It would seem likely that the biological characteristics of residual disease would add clinically relevant information to the extent of residual disease. For example, response (RCB) and predicted endocrine sensitivity (SET index) appear to independently influence the prognosis after sequential neoadjuvant chemotherapy followed by adjuvant endocrine therapy, possibly with interactive synergy [32]. Also, the residual proliferation index after chemotherapy can add to the prognosis of RCB [33]. Also, the presence of abundant lymphocytes associated with residual cancer imparts a more favorable prognosis when there is more than minimal residual disease [34]. Descriptive studies have also identified mutations within posttreatment residual disease (e.g., *JAK2* mutations in triple-negative cancer) [35, 36]. So there is some precedent to pursue these associations further. However, one does need to be aware that low cellularity can influence the accuracy of molecular testing. The key questions for progress will be

to identify when additional cellular or molecular characteristics of residual disease add meaningful information to the extent of disease, to avoid strongly correlated variables, and to specifically identify phenotype-specific indications for this approach.

Another consideration is whether to repeat routine molecular tests on residual disease. Certainly, a reasonable case can be made to repeat hormone receptor and HER2 tests if the original results before treatment were negative and there is reasonable suspicion that there might be positive receptor status. One can argue that the potential benefit from adjuvant treatment, when a false-negative original result is corrected, far outweighs the expense of repeat testing—so long as clinical-pathologic judgment is used to select cases where the overall picture raises suspicion for false-negative result. On the other hand, there is at least one study describing worse prognosis when the residual disease turned HER2 negative after neoadjuvant chemotherapy with HER2-targeted therapy [37]. However, there is no clinical justification for withholding adjuvant HER2-targeted therapy from these patients. Generally, retesting should be considered when original results were negative and a false-negative result is possible, but otherwise not.

14.3 After Neoadjuvant Endocrine Therapy

Neoadjuvant endocrine therapy is considerably less common than chemotherapy, but there are several trials that have utilized this approach, and several conclusions can be made based on current knowledge. The principles of specimen evaluation (described above) apply equally to any post-neoadjuvant specimen. Unfortunately, clinical trials have not directly compared different prognostic pathology tools (described above) after months of neoadjuvant endocrine therapy, although it might be reasonable to assume that those tools would be informative. However, the main finding from studies to date is that pharmacodynamic suppression of proliferation (e.g., Ki67 immunostain) after exposure to endocrine therapy is a hallmark of tumors that have sensitivity to endocrine therapy. Consequently, the preoperative endocrine therapy prognostic index (PEPI score) is currently recommended as the best prognostic tool for pathologists to use after neoadjuvant endocrine therapy [38]. PEPI is a nomogram that adds the scores for posttreatment ypT, ypN, ER status, and the percent residual cancer cells that express Ki67 (Table 14.3). The total score (0–12) is summarized into three prognostic groups: PEPI score 0, PEPI scores 1–3, and PEPI scores ≥4 [38]. There has not been independent validation of prognostic validity of PEPI yet, but we expect that those results will be reported soon.

14.4 Novel Treatments

It is reasonable to expect that the principles of specimen evaluation after neoadjuvant treatment will apply to novel treatments and that additional biological information might become useful. However, one cannot assume that the definitions of response won't improve or become specific to classes of treatment or that differences in response rates will necessarily predict differences in survival. We have already observed this: the prognosis relating to residual disease is influenced by sensitivity to other adjuvant treatments after surgery in relevant subtypes of breast cancer [32]. So the efficacy of novel treatments can be assessed within the neoadjuvant model, and we can also learn of the effects on tumors, but fundamental principles must still apply: prospective clinical trials, randomization, and obtaining subsequent follow-up for survival.

Some novel treatments are being evaluated as adjuvant treatment after neoadjuvant treatment and surgery, wherein patients become eligible based on an estimate of their residual prognostic risk. That is largely defined by the extent of residual cancer and the disease subtype. Such studies should not naively expose patients with minimal residual disease to the risks of experimental treatments, if the defined minimal disease has excellent prognosis. Also, such studies should collect detailed pathology information from standardized pathology methods, so that the investigators can determine whether pathology findings after neoadjuvant treatment can identify the patients who would benefit from the post-neoadjuvant novel treatment.

14.5 Summary

Neoadjuvant treatment has become increasingly popular as a standard treatment, and in clinical trials, it becomes increasingly obvious that the prognostic pathologic information from residual disease outweighs the information from untreated disease. However, pathologists may be unaware that a patient received neoadjuvant treatment, ill-equipped to identify and map the extent of residual disease, have limited experience with such specimens, or simply be reluctant to change their practice to support clinical trials. Thus, global standards are needed to the methods of pathology evaluation of specimens after neoadjuvant treatment. Indeed, an international committee, representing clinical trial groups, already recommended that all cases should report the necessary information to report the following after neoadjuvant chemotherapy:

1. pCR (ypT0/is, ypN0 or ypT0, ypN0) versus residual disease
2. AJCC stage (ypT, ypN)
3. residual cancer burden (RCB) [1, 2]

If neoadjuvant endocrine therapy was administered, then PEPI index should also be reported. These information provide important prognostic information, and pathologists should adjust their practice to report them for clinical trials and routinely. Furthermore, use of a standardized method for pathologic evaluation is reproducible, adds no cost to patient care, and is usually more efficient of time and costs. However, the accuracy and efficiency of this approach does require modest support from hospitals to enable specimen radiography and to provide resources to image and create a map of where tissue sections relate to macroscopic findings in the specimen, and that also requires the support from the multidisciplinary breast cancer team to garner the necessary resources. Finally, posttreatment residual disease should sometimes be retested for standard molecular markers, if there is reasonable suspicion that the pretreatment result might have been a false-negative result, or to evaluate pharmacodynamics changes in levels of ER or Ki67 after neoadjuvant endocrine therapy.

Breast Cancer Genomics

15

Maurizio Scaltriti

15.1 Introduction

Recent large-scale next-generation sequencing (NGS) studies defined the landscape of genomic aberrations in breast cancer. Copy number variations, missense mutations, and small insertion/deletions of certain genes can be associated with carcinogenesis and tumor progression. These so-called cancer drivers supposedly confer either growth advantages or protection from therapeutic stress.

Some of these genomic alterations can be inherited, but the vast majority occurs in somatic cells by stochastic events in DNA editing/repair and environmental mutagens.

In primary breast tumors, the most frequently altered genes are *TP53*, *PIK3CA*, *MYC*, *CCND1*, *PTEN*, *ERBB2*, *ZNF703/FGFR1* locus, *GATA3*, *RB1*, and *MAP3K1* [1]. This scenario, however, can change in the metastatic setting and/or in tumors subjected to pharmacological pressure. An archetypal example of this divergence is the mutation rate of *ESR1*, the gene encoding for estrogen receptor alpha (Fig. 15.1). While mutations in this gene are found in less than 1% of primary tumors, up to one-third of patients relapsing from anti-endocrine therapy have tumors harboring *ESR1* mutations [2].

Adding another layer of complexity, it is now possible to use mathematical approaches to define mutational signatures associated to specific genomic rearrangements, gene expression patterns, or clinical features [3, 4]. Although these signatures may define more precisely the genomic status of the tumors and can provide some prognostic information, their exploitability in the clinic is debatable.

In this chapter, I will focus on the possibilities that practice oncologists currently have to offer rational therapeutic options based on genomic analysis.

15.2 Change in Mentality

It is generally thought that genomic testing is appropriate only for patients who have exhausted standard therapy or have orphan tumors that lack a standard therapy. However, I contend that with the current possibilities of analyzing tumor samples by targeted exome sequencing (see below), each patient with advanced disease or with high-risk prognostic situations should at least be given the opportunity of being informed about genomic approaches other than following the standard protocols. Not having genomic infrastructures or not being a recruiting center for clinical trials is not a valid argument to refute this possibility. As I will describe below, anybody can easily submit ordinary formalin-fixed paraffin-embedded (FFPE) samples to certified companies that can sequence the tumor DNA in matter of weeks. Although the cost of this procedure can be burdensome, it may be affordable for the majority of the patients.

Patients should at least be informed about this possibility, explaining very clearly that this analysis will not provide a "magic pill," but it can potentially uncover genomic vulnerabilities in the tumor, and in turn help in choosing the specific targeted therapies. Obviously, the oncologist also has to explain that, should this be the case, the matching therapeutic option may be either available as standard of care or, conversely, part of experimental studies that are not necessarily available in the same geographic area. The patient has to decide whether undertaking this path is worthwhile, with very little influence from the treating physician.

No real advances in medicine (or in science in general) have ever been made by just following the existing paradigms and not thinking outside the box. The word "conventional" in medical care is a very dangerous one. Without reaching "Newtonian" extremes, I believe there is a need for a radical change in the way cancer patients are managed and treated. The gap between the first lines of research and the current clinical practice is too wide and too often is seen as the difference between science fiction and the real world. This has to change.

15.3 What We Can Realistically Do

The genome of the tumors can be analyzed in several ways. Whole genome sequencing (WGS) provides a detailed map of single nucleotide variations (SNVs), insertions and deletions (indels), gene translocations, and copy number changes. WGS is certainly the most complete approach, but has a number of important caveats. It generates an enormous amount of information, but most of it is of unknown clinical importance. It requires a relatively high amount of tissue, not always available from tumor biopsies. Moreover, besides the still prohibitive costs for its standard application in the clinical setting, WGS entails complex informatics analysis and big data storage. Whole exome sequencing (WES) provides the same map of genomic aberrations (with the exception of gene translocations) present in the genes that are expressed in mRNA. WES requires less material and cost is lower compared to WGS, but, although the amount of information generated is also reduced, it still involves a level of analytical work not wanted (and not needed) in the clinical practice. A more targeted approach to sequence the genome seems to be more reasonable for the widespread clinical implementation of this technology.

The field started with the detection of single gene mutations that allowed some patient stratification for certain therapies (e.g., KRAS detection in colon cancer) or the detection of germinal alterations linked to increased risk of developing cancer (e.g., BRCA1/BRCA2 mutations in both ovarian and breast cancer). Subsequent advances included the detection of well-known gene mutations (so-called hotspots) associated with tumor onset and/or resistance to therapy. Although merely diagnostic, these tests were useful to better stratify patients for clinical trials testing novel targeted agents.

The real revolution in the field was the development of targeted (or capture-based) exome sequencing platforms, in both research and clinical settings. From ~200 ng of DNA or less it is now possible to gather genomic information that is easily interpretable and can strongly influence the practice of treating medical oncologists. This technology does not require specific sample preparation and is commercially available and usually friendly to order online. Samples can be shipped at room temperature, and results are returned in the form of an easily interpretable report in 4–6 weeks.

This approach ensures deep exome sequencing (high-gene coverage) of a selected number of genes (usually a few hundred) considered important for tumor progression and resistance to therapy. A comprehensive analysis of the coding sequences of these genes may inform on the intrinsic genomic vulnerabilities of the tumor and therefore its possible sensitivity toward a given targeted therapy (e.g., *PIK3CA* mutations for PI3Kα inhibitors or *BRCA1/BRCA2* mutations for PARP inhibitors). Moreover, targeted exome sequencing can in some instances inform on the genomic instability of the tumor, perhaps rendering it more likely to respond to DNA-damaging agents or provide prognostic information (e.g., *TP53* mutations). Moreover, thanks to the quantification of the allele frequencies of each mutated genes, it can reveal the presence of different subclonal populations within the tumors and roughly estimate the level of tumor heterogeneity. Similarly, targeted exome sequencing can estimate the mutational load of the tumor, based on the number of driver and passenger mutations, especially when associated with mutations of genes involved in DNA repair.

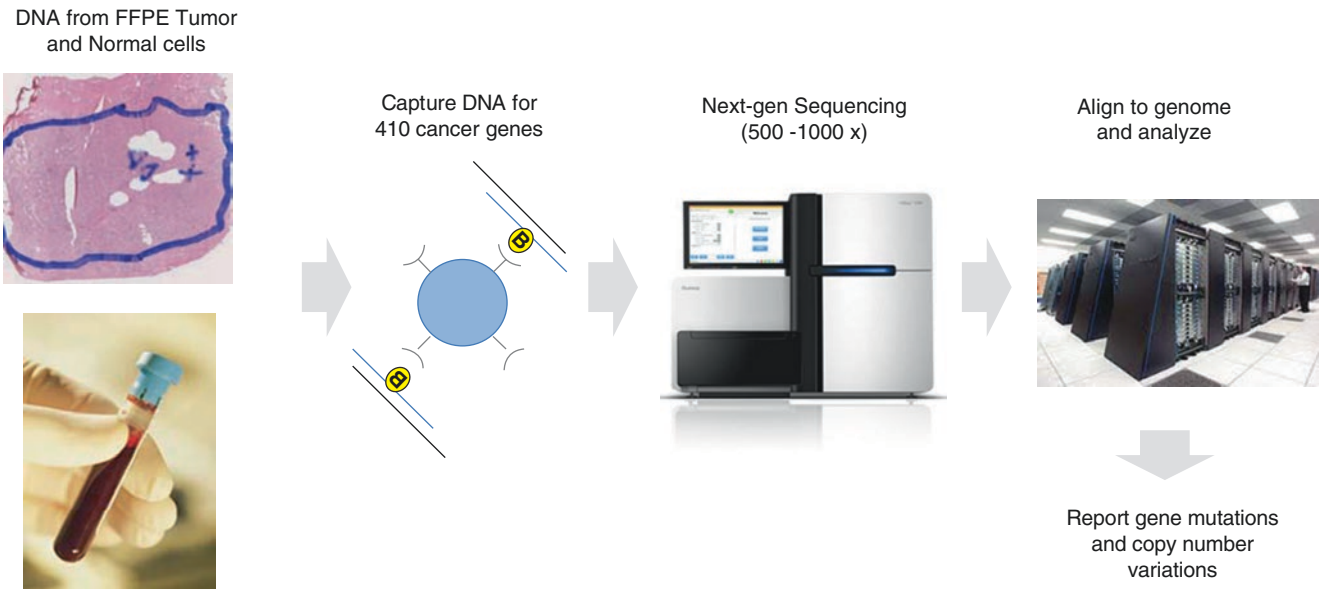

Fig. 15.2 MSK-IMPACT targeted exome sequencing platform. DNA is extracted from either tissue or blood and only protein-coding exons of 410 cancer-associated genes are sequenced

Not ignorable is also the possibility to uncover possible not-so-obvious drivers present at a relatively low frequency. Two valid examples in breast cancer are HER2 and AKT1 mutations, which strongly predict for response to pan-HER kinase inhibitor neratinib [5] and AKT kinase inhibitors [6], respectively.

In addition to Clinical Laboratory Improvement Amendments (CLIA)-certified companies that provide this service, several cancer centers worldwide have developed their in-house platforms. One of the most successful examples is the MSK-Integrated Mutation Profiling of Actionable Cancer Targets (MSK-IMPACT), a targeted exome sequencing platform developed at Memorial Sloan Kettering Cancer Center (MSKCC) [7, 8]. The MSK-IMPACT platform has a track record of performing in small FFPE biopsies and cell blocks and ensures a deep sequencing coverage of 410 key cancer-associated genes (Fig. 15.2). To date, more than 10,000 patients (more than 1000 breast cancer patients) had their tumor sequenced with this platform at MSKCC, with ~60% of the cases having metastatic disease. Thanks to this effort, an unprecedented percentage of patients are entering in clinical trials and being treated with rationale-based targeted therapies. Some of these patients are experiencing exceptional responses unlikely to be seen with "canonical" therapies.

The accumulation of sequencing reports from breast cancer patients also allows identifying novel correlations between certain genomic alterations and sensitivity to given therapy. Moreover, this high number of cases permits to uncover new hotspot mutations and/or new drivers of disease.

15.4 Tumor Heterogeneity

Most tumors are thought to originate from a parental clone that accumulates genetic aberrations during carcinogenesis. As a result, these aberrations are present in the majority of, if not all, tumor cells in the neoplasm. During tumor progression, however, spatially distinct subclones characterized by heterogeneous somatic mutations and chromosomal imbalances may arise from the parental clone [9]. The aberrations that arise during subclonal evolution are thought to be the result of the selective pressure exerted by the tumor environment and/or as an adaptive response to antitumor therapy.

It is widely accepted that the sensitivity to a given drug depends on tumor heterogeneity. The proportion of tumor cells that express the target of interest or harbor the mutation determinant of sensitivity may vary among the different metastatic sites (inter-tumor heterogeneity) or within single lesions (intra-tumor heterogeneity). Therefore, tumor heterogeneity can predict the degree of drug sensitivity and possibly the selection of resistant clones.

Such heterogeneity of subclones within the primary tumor or metastases represents a major challenge in the management of cancer for a number of reasons. Tumor biopsies are invasive procedures and may be associated with complications [10] and significant costs. Additionally, a single biopsy may be subject to tumor sampling bias and thus fail to capture the therapeutically relevant mutations [9, 11, 12]. Furthermore, in those tumors with several metastatic sites, the sampling bias is surely amplified as there is well-described genomic branching of the tumors [9, 11–15]. As a

result, intra-tumoral heterogeneity may explain the difficulties encountered in the validation of oncology biomarkers and for prediction of therapeutic resistance.

A number of studies have shown that ctDNA may be isolated from blood [16–18]. Early studies of ctDNA demonstrated that polymerase chain reaction (PCR)-based assays could accurately detect the mutations that have already been identified in the tumor bulk [19–24]. In preliminary studies it has been shown that targeted and genome-wide NGS of ctDNA is a feasible approach and can be employed to identify genomic alterations in the ctDNA [20, 25–30]. NGS ctDNA assays can potentially provide an easily obtainable and minimally invasive surrogate for tumor tissue biopsies that will markedly facilitate identifying potential targets to guide treatment decisions. It may also provide a potentially sensitive and specific biomarker that can be monitored in real time during therapy.

Collectively, understanding the extent to which the genetic heterogeneity among subclonal populations in the same patient converges to a similar and targetable phenotype may contribute to more rationale-based therapeutic approaches.

15.5 Sequencing to Understand Drug Resistance

Resistance to therapy can be pre-existing (intrinsic) due to the presence of concurrent aberrations. In breast cancer the presence of certain genomic aberrations can predict the response to given therapeutic agents. HER2 amplification, for example, is a determinant of sensitivity to drugs such as trastuzumab, pertuzumab, lapatinib, or trastuzumab emtansine (T-DM1). The presence of *PIK3CA*-activating mutations, on the contrary, is associated with resistance to these agents (with the exception of T-DM1 [31]). However, harboring these *PIK3CA* mutations is required to respond to PI3K p110α inhibitors [32, 33].

More frequently, drug resistance can arise upon therapeutic pressure via either loss of the therapeutic target [34] or positive selection of resistant clones [35, 36]. In fact, the constant pharmacological pressure may favor the fitness of tumor cells harboring certain genomic features and result in acquisition of drug resistance.

This occurrence is very well known, for example, in EGFR-mutant lung cancer, where the acquisition of the T790M gatekeeper mutation in EGFR or the amplification of other receptor tyrosine kinases such as MET or HER2 represents the majority of the mechanisms of resistance to the anti-EGFR molecule erlotinib. In breast cancer, several genomic mechanisms of acquired therapy resistance have been recently validated in the clinic. The selection of cells harboring *ESR1* mutations following endocrine therapy in ER-positive tumors is perhaps the most obvious example [2]. There are also evidences that the regeneration of a functional *BRCA2* upon therapy with PARP inhibitors leads to emergence of drug resistance [37]. Another example is the discovery of parallel genomic evolution occurring in patients treated with a PI3K p110α inhibitor where PTEN expression was lost over time via six different genetic mechanisms [12]. In this work, we discovered that different genomic aberrations but leading to the same convergent resistance phenotype can coexist in different metastatic lesions. The tumor genomic evolution during pharmacological stress was studied in a patient with metastatic breast cancer treated with the PI3Kα inhibitor BYL719 achieving a lasting clinical response, after which drug resistance emerged and died shortly thereafter. A rapid autopsy was performed and a total of 14 metastatic sites were collected and sequenced. When compared to the pretreatment tumor, all metastatic lesions had a copy loss of *PTEN*, and those lesions that became refractory to PI3Kα inhibition had additional and different *PTEN* genetic alterations (either copy number loss or missense mutations), resulting in the loss of PTEN expression (Fig. 15.3). Acquired biallelic loss of *PTEN* was found in one additional patient treated with BYL719, whereas in two patients *PIK3CA* mutations present in the primary tumor were no longer detected at the time of progression. These findings were functionally characterized in the laboratory using both in vitro and in vivo preclinical models that confirmed the causative role of *PTEN* knockdown in inducing resistance to PI3Kα inhibition.

This work is an archetypical example that access to metastatic lesions of patients who initially responded and then progressed to a given targeted therapy is crucial to elucidate the role of tumor heterogeneity and genetic evolution in the acquisition of drug resistance. Moreover, it also underscores the power of rapid autopsies of particularly informative patients (e.g., exceptional responders—see below) in uncovering novel genomic aberrations associated with drug sensitivity.

Without relying on these extreme cases, however, it is reasonable considering to re-biopsy at disease progression for genomic sequencing. In addition to confirm the origin, morphology, and the HER2/ER status of the tumor, this practice can inform of genomic vulnerabilities lost or gained during the treatment. This is of pivotal importance as it may uncover mechanisms of acquired resistance to therapy and set the stage for the next therapeutic option.

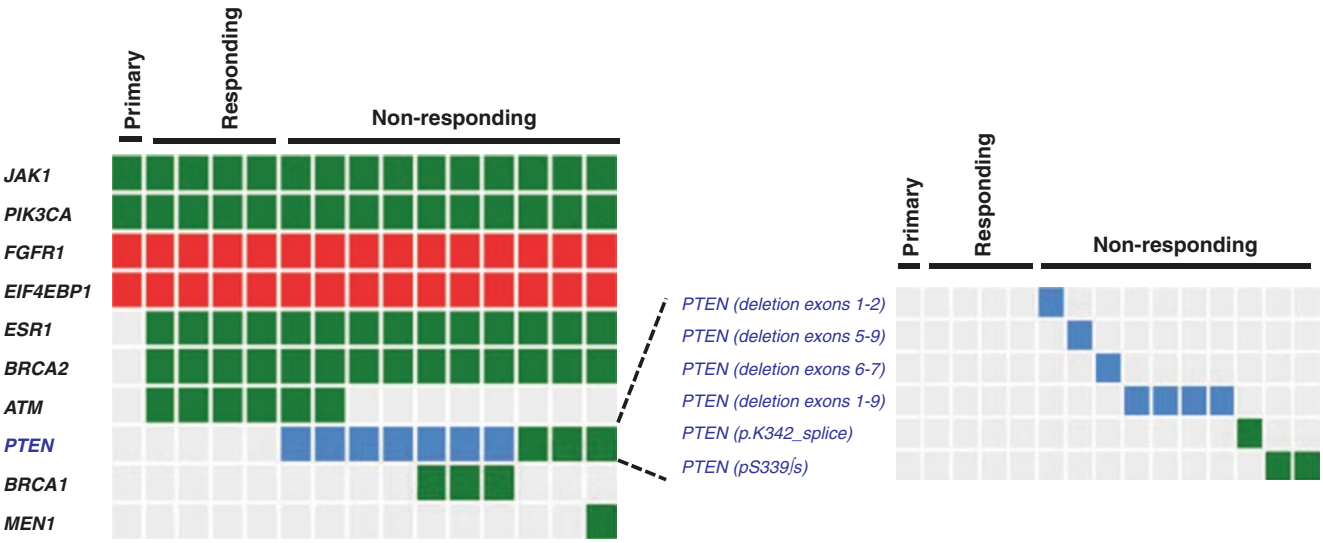

Fig. 15.3 Convergent evolution resulting in genomic loss of *PTEN* in metastatic lesions from a breast cancer patient treated with a selective PI3Kα inhibitor

15.6 Exceptional Responders

Among the population of patients treated with either chemotherapy of targeted agents, there are rare cases that, unpredictably, show much higher-than-expected (or lower-than-expected) clinical responses. Examples of exceptional responders can be HER2-positive metastatic breast cancer patients that respond to trastuzumab-based therapy for a decade or show durable pathological complete response to trastuzumab without concomitant chemotherapy [38] or triple-negative breast cancer patients with metastatic disease that show durable response to cytotoxic chemotherapy. But perhaps the best examples are those patients that already progressed to every standard of care options but still achieve dramatic and/or durable response to investigational agents.

The tumors from these patients are likely to have particular molecular/genomic characteristics that render them exquisitely sensitive to the therapy. Samples obtained from patients catalogued as exceptional responders (or exceptional resistant) represent an invaluable source of material to study the intrinsic determinants of drug sensitivity and/or tumor evolution upon therapeutic pressure. These samples should be analyzed as thoroughly as possible, with all the available resources. In some of these cases, oncologists chose (wisely) to collaborate with academic centers that have the possibility to perform both WES and WGS. Besides mutations or changes in gene copy numbers, these tumors may harbor gene rearrangements or alterations in noncoding DNA (e.g., gene promoters, enhancers). If tissue procurement is not a limiting factor (i.e., surgical removal of the primary tumor or distant metastases), RNA sequencing or other platforms that consent to evaluate the gene expression profile of these lesions are strongly advised. Results from these analyses can potentially identify genomic or transcriptomic markers of response (or resistance) that, if confirmed in larger cohort of patients, will allow a more rational patient stratification.

Unfortunately, also exceptional responders may recur to therapy and develop drug resistance. As mentioned above (and if the onset of a different tumor is discarded), these lesions are likely to be the results of a selection of cells bearing genomic aberrations that confer fitness under the pharmacological pressure. Thus, they should be analyzed as deeply as possible and confront their genomic landscape with the one of the matched therapy-sensitive tumors. Each individual case may indicate possible mechanisms of drug resistance that can be confirmed using publicly available data and/or by testing the hypotheses in the laboratory.

15.7 Therapeutic Plan of Action

Once we have gathered the sequencing data of our tumor samples, we need to interpret the results and explore possible therapeutic options. The ability to identify patients with tumors harboring specific genomic vulnerabilities and match

them to the most appropriate therapy is central. At least four different scenarios may be in front of us:

1. We discover genomic aberrations that are targetable and for which there are FDA-approved drugs for that indication. This is obviously the best possible situation.
2. The genomic alterations present in our tumor sample indicate that one or more FDA-approved agents may be effective in this particular case but these agents are not registered for their use in breast cancer patients. In these circumstances it is generally feasible to ask for compassionate use of these drugs. This requires some extra work and ultimately depends on the positive response of the pharmaceutical companies, but it would be unethical not to attempt it.
3. The sequencing results uncover actionable mutations or gene amplifications that would justify the inclusion of the patient into an existing clinical trial testing the activity of a compound still under investigation. This scenario is likely the major deterrent for the broad use of genomic testing as routine diagnostic practice. As a matter of fact, one common argument made against the genomic characterization of tumor samples is the lack of available clinical trials in the geographic area of interest. In other words, the oncologist may wonder why the patient should be sequenced if there are no options to offer a therapeutic strategy based on the genomic data. This point deserves some considerations. First of all, it is very unlikely that every oncologist is aware of every clinical trial open and enrolling at a given time in their geographic area. Secondly, the term "geographic area" is very subjective. Some patients may be intimidated of traveling hundreds of kilometers or even consider a clinical study abroad, but some others may think that the chance of receiving a rationale-based therapy is worth the hassle.
4. The last scenario is the most frustrating. Actionable genomic aberrations are identified, but only experimental drugs under investigation for other tumor types could potentially be used to achieve clinical benefits.

Despite these premises, it is undeniable that a major limitation in developing precision medicine approaches is the fact that only few cancer drivers are represented at a relatively high frequency. As a matter of fact, we calculate that 85% of all hotspot mutations affect <5% of any cancer type in which they are found [39]. This problem can be partially overcome by enrolling patients based on genomic alterations rather than tumor type, following the concept of the "basket" clinical trial. This formula consents to test investigational drugs to a variegated patient population harboring the same genomic aberration. An example is the recently published results from patients with BRAF-mutant solid tumors treated with the small molecule BRAF inhibitor vemurafenib [40]. In this study, they found that the BRAF V600 mutation is a targetable oncogene in several cancer types other than melanoma. Dramatic responses were observed in cancers that would have had no therapeutic options if the patients were not part of this study. A patient with a rare case of BRAF-mutant breast cancer, for example, could be treated with vemurafenib by either compassionate use or by being enrolled in such trial (scenario n. 2). Similarly, breast tumors with a *NTRK* fusion (rare but often extremely dependent on this gene translocation) could be treated with NTRK inhibitors as part of an existing basket trial testing these compounds (scenario n. 3 or 4).

Other examples are the ongoing clinical trials testing the activity of the pan-HER inhibitor neratinib and the AKT inhibitor AZD5363 in HER2-mutant and AKT1-mutant tumors, respectively. Recent large-scale NGS studies have revealed recurrent activating *ERBB2* (the gene-encoding HER2) mutations across a wide variety of cancer types. In breast cancer, these activating mutations are relatively rare (~2%) and typically mutually exclusive with amplification of the gene [41]. These patients, therefore, are excluded from receiving conventional anti-HER2 therapy. Similarly, *AKT1* E17K mutations arise in ~3% of breast cancers, and despite compelling preclinical data that supports a central role for oncogenic AKT1 in the pathogenesis of many cancers, it remains unknown whether mutant *AKT1* is a rational therapeutic target. In both cases, heavily pretreated metastatic breast cancer patients are experiencing impressive responses to inhibitors of these kinases are given in combination with the ER degrader fulvestrant. These studies are currently being carried out only in selected institutions, but they represent proofs of concept that targeted therapies based on genetic characterization may provide clinical benefit even in patients that exhausted any other therapeutic options. The long-term objective is to expand these studies to more hospitals and bring these targeted agents to early-phase treatments in selected patient populations.

A parallel approach to predict the most effective therapy based on genetic data is the use of patient-derived xenografts (PDXs) harboring the same genomic aberrations found in the analyzed tumor. In some cases the xenograft model may be derived from the same tumor lesion that has been sequenced. Although this practice is widely used in translational research in cancer centers via academic collaboration, it is not as diffused in the clinical practice. It is, however, possible to ship fresh tumor samples to specialized companies that can provide this service. The use of PDXs is particularly useful in those cases where the rationale for the use of a given drug is not very strong or there are multiple therapeutic options available.

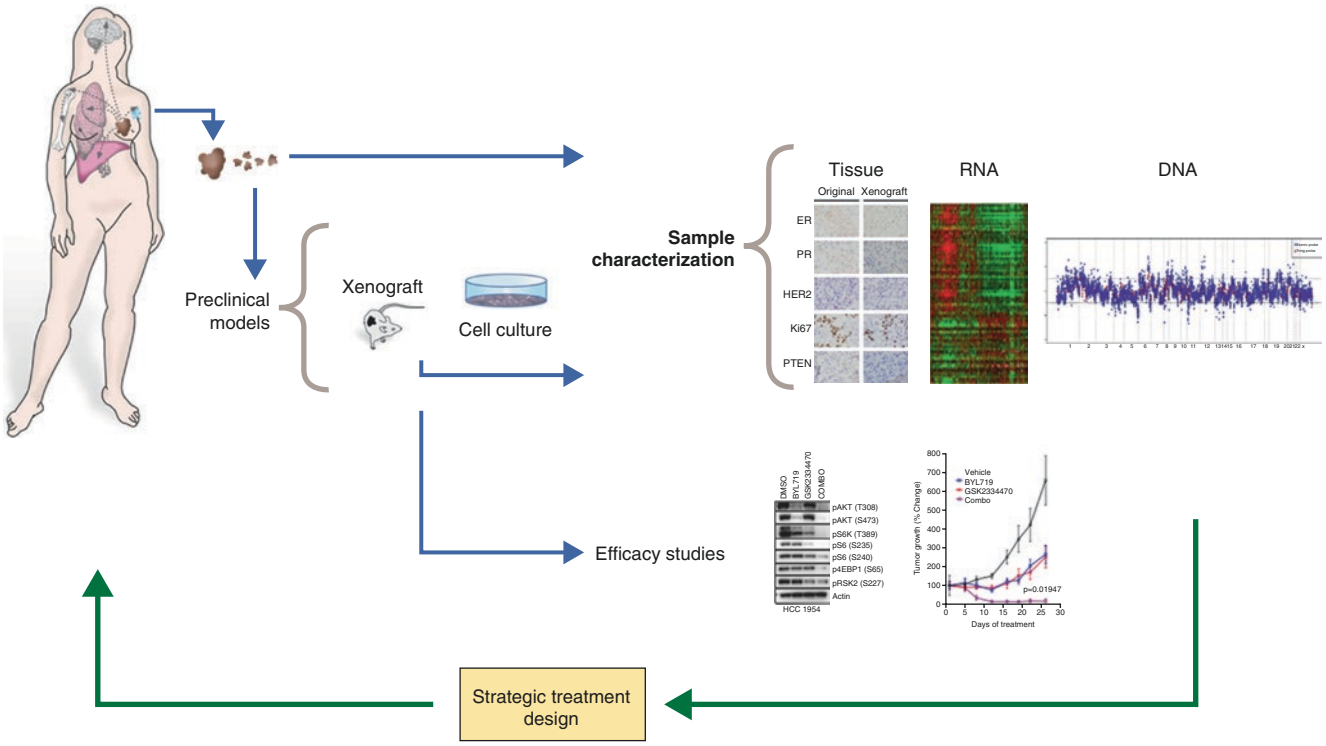

Fig. 15.4 Personalized medicine approach. Tissue from either primary tumors or metastatic lesions is characterized by canonical techniques and next-generation sequencing. In parallel, preclinical models from the same samples can be established to test rationale-based therapeutic options

Conclusions

Increased accessibility to targeted platforms and the expansion of clinical studies that enroll patients based on the genetic vulnerabilities will be key to move toward personalized medicine. An interesting pilot experiment to increase the number of patients undergoing genetic testing followed by matched targeted therapy is the Spanish study AGATA (NCT02445482). To be enrolled in this study, patients belonging to a defined geographic area have to consent that a committee of both clinical and translational investigators will suggest their enrollment in the most appropriate clinical studies based on their sequencing data. In principle, the more participating centers, the more available clinical trials that can recruit these patients. Moreover, this approach may speed the accrual of many of these studies with patients that, supposedly, are more likely to respond to the investigational therapies.

Another benefit of genomic sequencing that should not be underestimated is the detection of gene aberrations predictive of lack of response to given therapies. Perhaps the genomic results will not identify an actionable gene or pathway, but will indicate which compound should not be chosen for that patient, avoiding the toxicity and economic burden of treatments that will most likely fail. KRAS mutations, for example, are well known to limit the sensitivity to cetuximab in colon cancer. In breast cancer, the presence of *ESR1* mutations is indicative of resistance to tamoxifen and/or aromatase inhibitors [2], the loss of *PTEN* is sufficient to discourage the therapy with specific PI3Kα inhibitors [12], and the loss of *RB* renders CDK4/6 inhibitors ineffective [42].

It is tempting to imagine that soon every breast cancer patient will have their tumor DNA sequenced, perhaps multiple times, in order to monitor disease progression, thus enabling a rational use of molecularly guided therapies (Fig. 15.4). Similar to the antibiogram that is normally done for bacterial infection to choose the most effective antibiotic, the genomic aberrations of each tumor may one day be used to routinely indicate the most appropriate antitumor therapy for each patient.

The Pathology Report

16

Andrea Vingiani and Giuseppe Viale

16.1 Introduction

An accurate pathological assessment of core biopsies or resection specimens provides important information on the major features of breast cancer, such as tumor type, size, biological characteristics, lymph node status, stage, and extent of residual disease in case of neoadjuvant chemotherapy, and is crucial for ensuring an appropriate patient management. In the era of molecular medicine and tailored therapies, the pathologic assessment of primary tumor still represents an essential guide for oncologists and surgeons to inform the choice of the best treatment options available for individual patients. Therefore, the management of patients with breast cancer detected through imaging or symptomatic presentation depends heavily on the quality of the pathology service.

Pathologists deal routinely with breast cancer samples, either as surgical resection specimens (both intraoperatively and after fixation and embedding) or as core biopsies and fine needle aspiration cytologies for the preoperative diagnosis of primary tumor or of distant metastases. The foremost means of communication with treating physicians, surgeons, radiologists and radiotherapists (and ultimately the patients) is represented by the pathology report.

Pathology reports may look different in appearance, at the discretion of each specific pathologist, taking into account clinician preferences, institutional policies, and individual practice, but it is mandatory they provide all clinically relevant information. An accurate and detailed pathology report of breast cancer, in addition to the histopathological diagnosis, must include all the prognostic parameters derived from the morphological examination and the immunohistochemical and molecular assessments and the predictive parameters useful for evaluating the efficacy of local and systemic treatments. In this regard, several guidelines for pathological reporting have been issued in the past years, and the most widely used are those of the Association of Directors of Anatomic and Surgical Pathology (ADASP), the College of American Pathologist (CAP), and the Royal College of Pathologists (RCP). These recommendations are drafted as a sort of checklist, a framework to assist pathologist in the completion of an exhaustive pathology report, encouraging healthcare professionals to use common terminology and definitions for breast diseases, and to harmonize the way of classifying breast cancer. In the following sections we will discuss general principles of specimen handling and sampling, as well as all principal parameters to be included in the pathology report, focusing on prognostic and predictive markers.

16.2 Pathology Request Form

An efficient multidisciplinary approach to patient care implies a precise exchange of information among different health-care professionals. Therefore, after the diagnostic procedures or the surgical intervention, any individual specimen submitted to the pathology laboratory should be accompanied by a comprehensive request form, providing the pathologists with all clinically relevant information, inclusive of:

- Patient personal data and demographic information, including name, surname, date of birth, sex, and ethnicity.
- Type of specimen, such as fine needle aspiration cytology; core biopsies; vacuum-assisted biopsy (VAB); lumpectomy and mastectomy, with or without locoregional lymph nodes; and number of specimen containers submitted, identifying each separately.
- Date and time of surgery.
- Clinical history and previous findings, including breast laterality, number and size of lesions, location within the breast, imaging data (mammography, ultrasound, MRI),

history of previous malignancies, neoadjuvant therapy, including comments on clinical or radiological response. Drawings can be very helpful.
- Previous biopsy or cytology results for each lesion, with relevant details and laboratory of origin, whenever available.
- Method of localization used.
- In resected specimens, drawings or description indicating the position of the orientating clips/sutures. Surgeon should orientate all breast cancer resection specimens. Each breast unit should establish a code of orientation, using either different lengths or number of sutures and/or metal clips or ink. The code should be anatomically relevant and assist in accurate evaluation of the specimen and its margins.
- Whether any relevant marker (most frequently microcalcifications) was identified on imaging of the specimen, if performed.
- For axillary specimens: whether a sentinel lymph node (specifying if an intraoperative assessment is requested or a routine analysis on formalin-fixed, paraffin-embedded sections), a lymph node sampling or a completion axillary dissection (indicating levels dissected) is submitted for pathological examination.

16.3 Specimen Handling and Sampling

Surgical specimens must be handled to ensure good preservation of all the morphological and biological characteristics of the tumor cells. Inadequate fixation may cause extensive morphological artifacts, loss of tissue antigenicity, and degradation of nucleic acids (especially mRNA), making specimen not suitable for a reliable assessment of prognostic and predictive parameters (i.e., hormone receptors, HER2, Ki-67 labeling index, and molecular analysis).

After surgical removal, specimen should be sent immediately to the pathology lab. According to local policies, pathologists may dissect the specimens either on fresh state or after formalin fixation, but in any case a prompt and accurate fixation must be ensured, thus preventing tissue autolysis. In case of delayed sampling, the specimens should be immediately placed in an adequate volume of fixative, at least ten times that of the specimen, and cut through the tumor from the fascial plane toward the surface of the sample, to ensure adequate penetration of fixative into the tumor tissue, especially in large and fatty mammary glands. Refrigeration and vacuum packing may also be helpful in delaying autolysis. The American Society of Clinical Oncology/College of American Pathology (ASCO/CAP) guidelines advocate promptly placing the breast specimens into fixative within 1 h after surgical removal to minimize cold ischemia time and maintaining the samples in 10% neutral buffered formalin (NBF) for 6 h to 72 h, for ensuring best preservation of tissue antigenicity for assessment of HER2 and hormone receptor status [1, 2].

In samples of non-palpable lesions, intraoperative radiography of the specimen or macroscopic examination by a pathologist is particularly useful to confirm the success of the excision procedure. This is also highly recommended for wide local resections (quadrantectomies or lumpectomies), to allow confirmation of the presence of the abnormality and of its location in the specimen, thus facilitating immediate re-excision if the lesion is close to or involving a margin.

Once received in the laboratory, pathologists should examine the specimen, recording the type of excision, its dimensions along the three spatial axes, the presence or absence of skin, and/or nipple and axillary tissue. Relevant surgical margins or the entire specimen surface should be inked so that the margins of excision can be easily determined histologically. Therapeutic surgical procedures, as quadrantectomy or mastectomy, according to Surgical Guidelines for the management of breast cancer, usually require tissue removal from the subcutis to the pectoral fascia, which are considered anatomical planes rather than surgical margins. However, in case of central excision, breast tissue remains at the superficial (close to the nipple-areola complex) surface, requiring careful margin assessment. Therefore, it is important for the pathologist to be aware of the type of excision, in order to manage surgical margins properly.

Afterward, pathologist should slice the specimen at intervals of approximately 3–5 mm, preferably along sagittal planes, enabling easy X-ray mapping of the specimens in case of non-palpable lesions with calcifications or tissue distortion, in order to ensure high-confidence localization. The sampling technique, however, may vary according to the type and size of the samples and also according to local protocols or pathologists' preferences; therefore, some degree of flexibility is allowed. The number of blocks of invasive tumors to be prepared for microscopic examination can vary with tumor size, but it is usually of at least three blocks per tumor nodule. The peritumoral tissue should also be submitted for histology to identify associated DCIS, peritumoral lymphovascular invasion, and to allow surrounding normal breast tissue to be used as an internal immunohistochemical control for the assessment of hormone receptor and HER2 status. It may be possible to sample the lesion and its adjacent radial margin in one block in case of very small lesions, but in the vast majority of the cases, resection margins must be examined in several blocks. Particular attention must be paid to the areolar margin, due to high gland density and possible tumor extension

in lactiferous ducts, particularly for DCIS. In mastectomy specimens, sagittal sections of the nipple should be taken to exclude Paget's disease, while a coronal section of nipple and retro-areolar tissue is recommended to assess possible nipple duct involvement by DCIS.

For DCIS specimens, the number of blocks sampled is variable according to the size of the specimen and of the lesion. For small specimens, especially when radiologic assessment is unavailable, sampling of the entire tissue is recommended. For larger specimens, the pathologist should sample representative blocks (at least one block for each centimeter of the lesion) from the entire involved area, to scrutinize the sample for any possible area of invasive carcinoma, and including the site of any previous core biopsy.

Ultimately, details of the macroscopic features of the specimen must be recorded, especially tumor size and distances to all margins. In the presence of multiple tumors, the distance between tumors themselves and between each tumor and resection margins should be recorded. It is recommended to sample the tissue between tumor nodules, to ascertain if the neoplastic foci are truly separated (multifocal or multicentric tumors) or instead interconnected. The axillary tail of the specimen should be inspected for the presence of intramammary or low axillary lymph nodes.

Neoadjuvant systemic therapy is frequently administered to patients with large, locally advanced, or inflammatory breast cancers, with the aim to reduce the tumor size allowing breast-conserving surgery and tumor downstaging. It also provides the opportunity to assess response to treatment after a reasonably short time of exposure to the treatment (see related chapter). However, significant difficulties and variability exists in methods for pathologic assessment of response to neoadjuvant therapy. Recently guidelines issued by the Breast International Group-North American Breast Cancer Group (BIG/NABCG) [3, 4] recommend practical methods for a standardized pathologic assessment of the breast specimen following neoadjuvant therapy. Briefly, it is mandatory to identify macroscopically the tumor bed before any sampling and to record the two axes of the largest cross section of the entire area involved. Obvious remaining tumor should also be measured. It is strongly recommended that an image of the sliced specimen be taken (photograph or drawing) and then used to create a map of the carefully oriented tissue blocks collected. This will allow pathologists to obtain an accurate and comprehensive histological image of residual tumor, ultimately assuring a precise assessment of residual disease and staging. Extent of sampling should be determined by the pretreatment tumor size; an entire cross section of the tumor bed taken for each cm of the pretreatment tumor size (for a total number of approximately 15 blocks in most cases) should be sufficient to reliably document the pathological response.

16.4 The Pathology Report: A Synopsis

The following are the main parameters that should be carefully evaluated and clearly reported in the pathology report. Their assessment methods and clinical relevance will be briefly discussed.

16.5 Tumor Type

Breast cancer is considered a heterogeneous disease, made up of several different subtypes with variable morphological and biological features, different prognosis and response to systemic therapy. WHO histopathologic classification is based on characteristics seen upon light microscopy of biopsy specimens [5]. Two most common histopathological types collectively represent approximately 70–80% of breast cancers, namely, invasive ductal carcinoma, no special type (IDC NST) or invasive lobular carcinoma (ILC).

Among less common tumor histotypes, some "special" tumor types are per se associated with intrinsically peculiar prognostic profile. Tubular and cribriform carcinomas, for example, are characterized by an almost indolent clinical course with an extremely good overall survival [6], and the adenoid cystic carcinomas carry a very favorable prognosis in the vast majority of the cases [7]. On the contrary, metaplastic carcinomas are associated with significant worse clinical outcome then the IDC NST [8].

The fact remains, however, that for the vast majority of breast cancer (IDC NST and ILC), morphological classification is unable to meaningfully reflect the vast heterogeneity in terms of biological features, prognosis and response to systemic therapy, failing to assist the oncologist in planning adequate systemic treatment. It is also arguable if IDC and ILC do actually reflect clinical differences, and whether ILC per se constitutes a prognostically favorable group [9, 10].

16.6 Tumor Size

An accurate measurement of tumor size is mandatory, as it represents the first parameter of breast cancer staging. TNM classification still represents one of the most powerful prognosticators in breast cancer [11], being statistically correlated with risk of recurrence, metastatization, and overall survival. Identification of the tumor edge is also a prerequisite for a reliable assessment of resection margin status.

The maximum dimension of invasive tumors should be measured macroscopically, paying attention to irregularly shaped or multi-lobulated lesions. When tumor measurement is not feasible, then the tumor size identified by imaging, based on ultrasound, mammography, or MRI, should be used

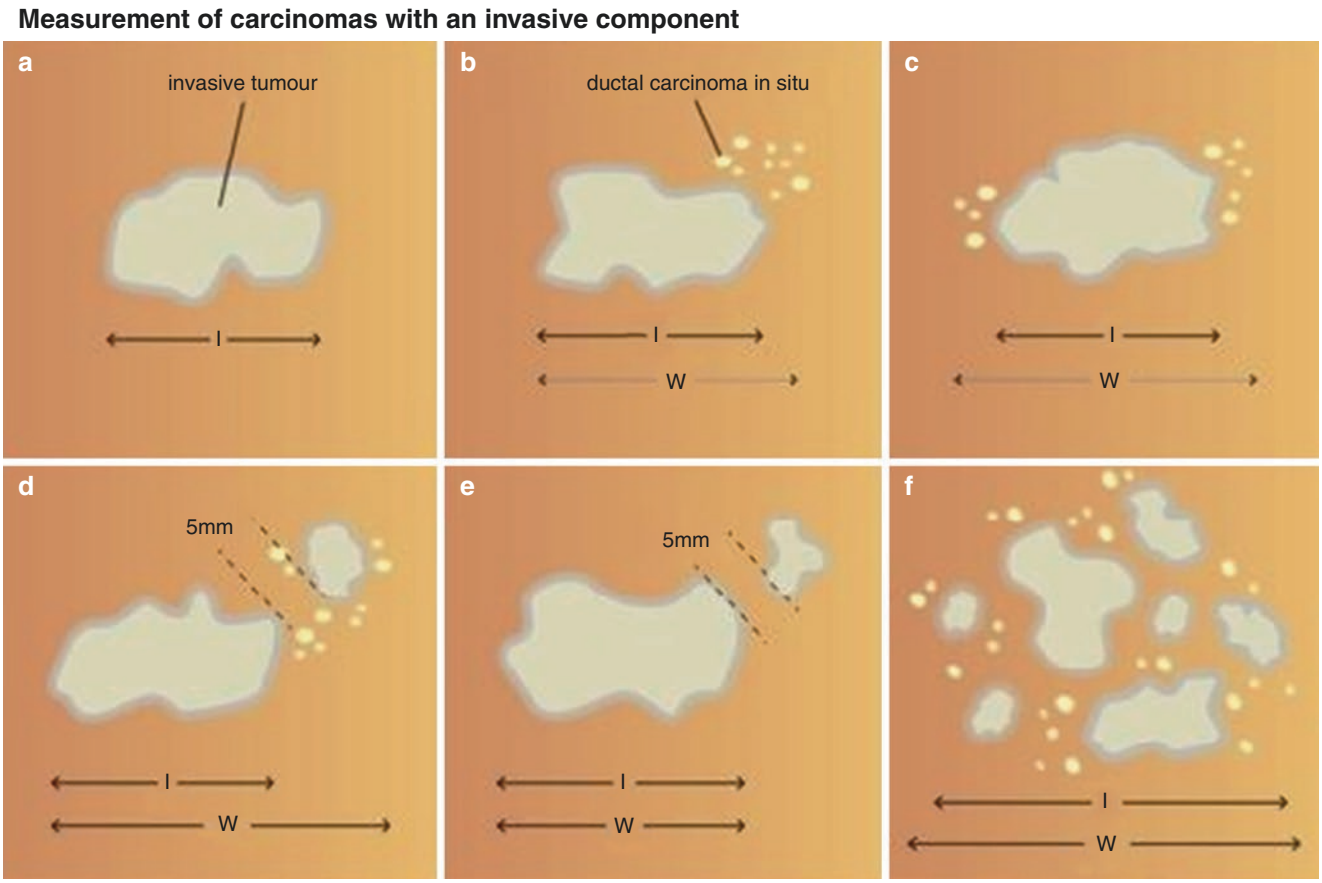

Fig. 16.1 Illustrations of how to measure invasive and whole tumor sizes in various scenarios [12]

as the best available record of true tumor size, replacing pathological size assessment. In case of discrepancy between the macroscopic and the microscopic size occurs, then the latter should be recorded, provided that the plane of the maximum dimension of the lesion has been included in the slide. The assessment of the whole tumor size including in situ carcinoma should be recorded, reporting also relative percentages of invasive tumor and DCIS. In tumors composed predominantly of DCIS but with multiple foci of (micro)invasion, measurement of the invasive tumor should correspond to maximum axis of the area occupied by invasive foci, as shown in Fig. 16.1, along with other frequent scenarios.

On rare occasions, pathologists may find it challenging to determine whether two adjacent tumor foci represent satellite foci or one lesion mimicking this process due to plane of sectioning. In this regard, the presence of intervening normal tissue and increasing distance between foci are features suggesting that these are more likely to be multiple foci than a single process. A distance of 5 mm or greater is often used to define separate foci. In case of clear-cut distinct multiple tumor masses, pathologists should record if the neoplastic foci are in the same breast quadrants or at a distance of less than 5 cm (multifocal tumors) or in different quadrants or at a greater distance (multicentric tumors).

16.7 Histological Grade

Invasive carcinomas are routinely graded, and grade is now widely recognized as a powerful prognostic factor, significantly associated with clinical outcome [13–15]. Assessment of histological grade has become more objective with modifications of the Patey and Scarff [16] method first by Bloom and Richardson [17] and more recently by Elston and Ellis [18]. Histological grading involves the assessment of three components of tumor morphology: tubule/acinar formation, nuclear atypia/pleomorphism, and number of mitoses. Each parameter is scored from 1 to 3, and the sum gives the overall histological grade as follows: Grade 1 (well differentiated) = scores of 3 to 5, Grade 2 (moderately differentiated) = scores of 6 to 7,

and Grade 3 (poorly differentiated) = scores of 8 or 9. Below are briefly discussed criteria involved in tumor grading:

- *Tubule/acinar formation*: all tumor area should be scanned, assessing semiquantitatively the proportion occupied by tubule formation. This assessment is generally carried out during the initial low-power scan of the tumor sections. Tumors showing >75%, 10–75%, or <10% of tubule formation are scored 1, 2, or 3, respectively.
- *Nuclear atypia/pleomorphism*: assessed comparing tumor nuclear size and shape with normal luminal cells. This is the parameter mostly affected by interobserver variability; breast specialist pathologists seem to report higher grades than nonspecialists [19].
- *Mitoses*: accurate mitotic count requires optimally fixed and processed specimens. Mitoses should be counted in ten high-power fields (40× objective). The mitotic score is dependent
- on the high-power field diameter; in this regard tables of conversion with different scoring tiers according to the actual field diameter of the microscope are available. At least ten fields should be counted at the periphery of the tumor, where it has been demonstrated that proliferative activity is greatest [20, 21]. If there is variation in the number of mitoses in different areas of the tumor, the area with the highest mitotic count should be taken into account. If the mitotic score falls very close to a score cut point, additional ten high-power fields should be evaluated, assigning the highest score.

In core biopsies, notwithstanding paucity common low cellularity of the samples, assessment of grade is recommended, especially if the patient is a candidate to neoadjuvant treatment. There is about 70% agreement of grade on core biopsy with the corresponding surgical specimen [22, 23]. If both core biopsy and surgical specimen are available, grading should be scored on the latter. Assessment of grade in the surgical specimens after neoadjuvant systemic therapy may be unreliable, due to the effect of the cytotoxic drugs on the morphology and the mitotic index of the tumor cells.

16.8 Peritumoral Lymphovascular Invasion

Lymphovascular invasion (LVI) mirrors the ability of cancer cells to invade lymphatics and blood vessels, and it is correlated to a higher likelihood of nodal or distant metastases. LVI in a peritumoral location is unanimously regarded as an important prognostic factor in patients with lymph node-negative invasive breast cancer, providing independent information about both local recurrence and survival [24–26]. It is therefore important to record in the pathology report whether or not it is present. Given the difficulties in the morphological distinction between lymphatics and blood vessels, findings should be categorized as "lymphovascular spaces" rather than as specific channels. This is supported by evidence identifying that most tumor emboli are present in lymphatic channels.

At the microscopic level, stromal retraction artifact around neoplastic cell nests can mimic vascular invasion; therefore, a clear rim of endothelium should be identified. Other clues in recognizing lymphovascular invasion is the presence of nearby vascular channels or the location of tumor cells within spaces with erythrocytes and/or thrombi

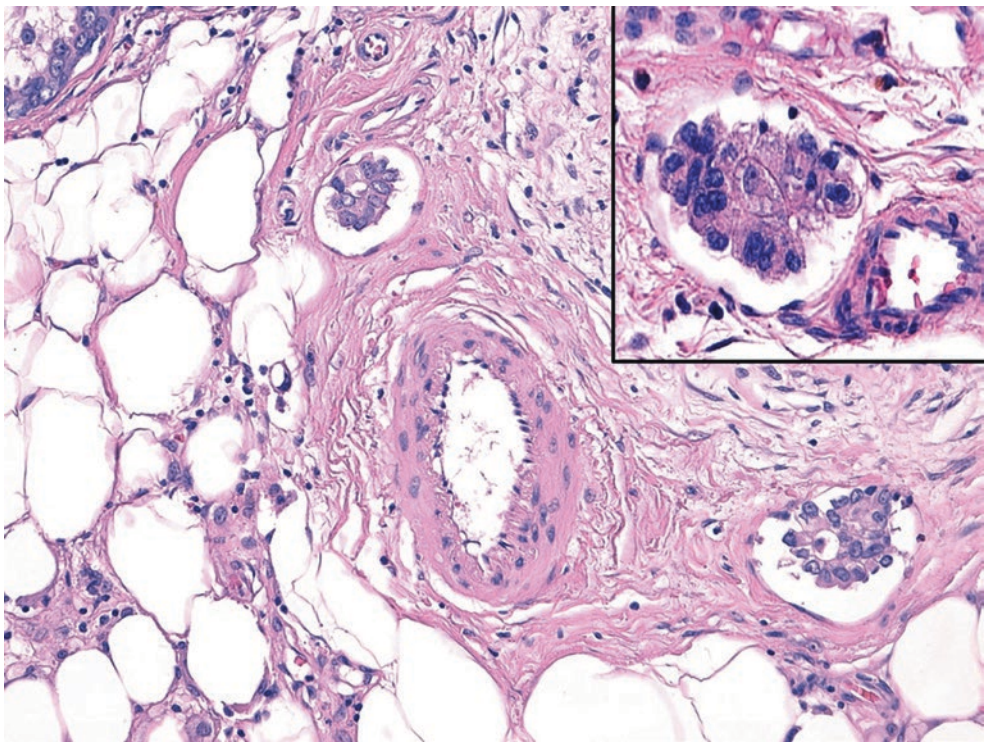

Fig. 16.2 An example of lymphovascular invasion

(Fig. 16.2). In difficult cases immunohistochemistry can be of help to identify the endothelial lining (CD34, CD31, and D2-40 antibodies) [27].

16.9 Surgical Margins Status

Breast-conserving surgery (BCS) in combination with adjuvant local and systemic therapies has become the standard of care for early small tumors, thus reducing physical and psychological morbidity. Despite these advantages, BCS has a higher risk of local recurrence than mastectomy [28–33]. The strongest predictor of local recurrence is surgical margin status [34–36].

According to the number of positive margins and the remaining amount of breast tissue, positive margins are managed with re-excision or mastectomy, eventually resulting in poor cosmetic outcome and high medical cost. Since early invasive cancer and DCIS nowadays represent a significant fraction of breast surgical specimens, the pathologic assessment of surgical margins is crucial, requiring close correlation between the surgical procedure and pathological examination. In particular, pathologists should be aware of the depth of tissue excised and whether the surgeon has excised all the tissue from the subcutaneous to the pectoral fascia. All distances between invasive cancer and DCIS should be recorded or, at least, the closest ones. According to current recommendations, margins are considered free of invasive tumor when the ink does not touch the tumor. For DCIS, margins are considered free when the closest tumor nest is 2 mm away from the surgical margin.

As previously mentioned, careful orientation of the surgical specimen is mandatory, as this prevents discordance with postoperative margin orientation, which occurs in 31% of surgeries [37]. In comparison to permanent histopathologic staining, intraoperatory pathological assessment of surgical margins may result in significant decrease of re-excisions. In particular, macroscopic examination, frozen section analysis, and imprint cytology have been demonstrated to be associated with re-excision rate of 3–11%, against an average 35% rate for permanent histopathologic staining-surgical margin assessment [38, 39].

16.10 Nodal Status and Sentinel Lymph Node Biopsy

Axillary node status is the most important prognostic indicator in breast cancer. Therefore, careful assessment of nodal status is mandatory. If axillary dissection has been performed, all lymph nodes must be carefully dissected and examined histologically. Pathology report should include the total number of lymph nodes identified and the number of involved lymph nodes, specifying whether macro- or micrometastases. Of note, nodes with isolated tumor cell only (<0.2 mm) are not considered positive for metastasis [40, 41].

However, axillary dissection is not infrequently associated with side effects, such as arm lymphedema, paresthesia, pain, and motor deficit. Moreover, with the implementation of screening programs, an increasing number of patients with node-negative early breast cancer were subjected to unnecessary axillary dissection. Hence, the need for a diagnostic procedure capable of discriminating patients for whom completion axillary dissection could be avoided. Sentinel lymph node biopsy (SLNB), a technique initially devised for penile cancer and melanoma, relies on the assumption that lymphatic spread of cancer cells occurs orderly and sequentially along the lymphatic drainage; hence, there must be a lymph node supposed to be the first metastasis recipient and from which the disease can subsequently spread to the remaining lymph nodes. Phase III clinical trials by Veronesi's and Giuliano's groups convincingly demonstrated that breast cancer patients with a negative SLNB could safely avoid axillary dissection [42–44]. Since these seminal works, SLNB entered the clinical arena, and pathologists put their efforts in defining the most accurate way for SLNB analysis, leading to a surprisingly variegated panorama, with no universally accepted protocols. Some institutions adopted an intraoperative frozen section assessment, to avoid a second surgery in case of a positive SLNB, using different protocols with regard to the number of sections examined and the cutting intervals; others adopted assessment of lymph node status on permanent sections, also using immunohistochemical stains, with the goal of achieving high sensitivity. More recently, intraoperative molecular assessment, using reverse transcription-PCR assays for cytokeratin-19 (one-step nucleic acid amplification, OSNA), entered the clinical practice [45–47]. The obsession to look for even minimal sentinel lymph node involvement, however, was eventually challenged by the evidence that patients with isolated tumor cells or micrometastasis only in the sentinel lymph node could be safely spared completion axillary dissection without any adverse effect on outcome [48]. This led to questioning the need for axillary dissection also for patients with small and clinically node-negative breast cancer, but histologically positive sentinel node. The ACOSOG Z0011 trial randomized 891 patients with clinically T1–2, breast cancer, and histologically positive SLNB, to undergo axillary dissection or not. When the ACOSOG Z0011 was initially reported with a median follow-up of 6.3 years, regional recurrence after SLND alone for women with 1 or 2 positive sentinel lymph nodes was surprisingly low (0.9%), and completion axillary dissection did not significantly reduce regional recurrence or improve survival [49, 50].

Further data analysis, with nearly 10 years of median follow-up, still showed a remarkably low regional recurrence rate of 1.5% for SLND alone [51].

Following the report of these results, completion axillary dissection is no longer recommended for patients with small early breast cancer undergoing breast-conserving surgery and whole breast irradiation, even in case of metastasis to one or two sentinel lymph nodes.

16.11 Biological Features of Breast Carcinoma

Adjuvant systemic therapy of breast cancer is mainly informed by the biological characteristics of the primary tumor, including hormone receptor and HER2 status, and the assessment of the proliferation fraction [52]. It is therefore mandatory that the final pathological report includes an accurate evaluation of these parameters.

As previously mentioned, a reliable assessment of these biological features requires an optimized pre-analytical phase, with proper fixation of the specimen. One of the most important steps for optimal testing is the choice of the block to be submitted for the assays: it should be taken at the invasive edge of the lesion, including normal breast parenchyma, and must be representative of the invasive component of the tumor. In bilateral breast cancer, samples from both tumors should undergo biological characterization, given the high frequency of phenotype discordances in bilateral cancer; for multifocal or multicentric disease, ideally all the different foci should be evaluated, but in the vast majority of cases they exhibit similar morphological and biological phenotype. A reasonable approach would be to assess first whether the different tumor foci show the same morphological features (i.e., tumor type and grade) or they are different. In the former case, it may be acceptable to assess hormone receptors, HER2 and proliferative index in only one nodule, whereas in the latter it is recommended to test all the foci that are morphologically different. In multifocal or multicentric disease, in case the nodule assessed for biological characteristic shows a triple negative phenotype, it is highly recommended to test further foci, seeking for clones with different biological features amenable to hormonal or targeted therapy.

16.12 Estrogen and Progesterone Receptor Status

ER plays crucial roles in breast carcinogenesis; it was first identified in the 1960s and used in breast cancer clinical management since mid-1970s. It is universally considered one of the most important biomarkers for breast cancer classification, as a primary indicator of endocrine responsiveness, thus guiding oncologist in planning patient treatment [53]. ER status has been shown to be the major determinant of breast cancer molecular subtype by gene expression profiling studies [54]. ER-positive tumors comprise up to 75% of all breast cancer patients [55] and are largely well differentiated, less aggressive, and associated with better outcome after surgery than the ER-negative ones [56, 57]. ER has been considered as the most powerful single predictive factor identified in breast cancer [58–60], given the fact that approximately 50% of patients with ER-positive disease benefit from endocrine therapy [61].

The panelists of the St. Gallen Consensus in 2009 suggested to consider positive for ER and progesterone receptor (PgR) those tumors showing at least 1% immunoreactive cells [62]. This definition has been subsequently endorsed by the ASCO/CAP guideline recommendations for ER and PgR immunohistochemical testing [63]. Reporting the actual percentage of neoplastic cells showing definite nuclear immunoreactivity has also been recommended, because the higher the number of positive cells the larger is the expected benefit from endocrine therapies. Scoring system taking into account also the staining intensity (like the H-score or the Allred score) is considered optional. The ASCO/CAP guidelines covered technical aspects of the pre-analytical and analytical steps of the immunohistochemical, interpretation, scoring, and reporting of the results, aiming to increase accuracy and reproducibility. One of the most useful recommendations to avoid false-negative results in ER testing is to evaluate systematically the immunoreactivity of the nonneoplastic breast tissue surrounding the tumor. Ductal and lobular luminal cells are invariably heterogeneous for ER and PgR immunoreactivity, whereas myoepithelial and stromal cells are invariably negative thus providing a built-in positive and negative control of the sensitivity and the specificity of the reaction (Fig. 16.3).

While in certain subsets of cases ER-positive tumors may be negative for PgR, conferring lower sensitivity to antiestrogen therapy, especially in the metastatic setting, the reversed phenotype (ER negative and PgR positive) is very rarely true. Almost all the cases with such an aberrant phenotype are due to a false-negative assay for ER or, less frequently, a false-positive assay for PgR, and the pathologists should be encouraged to repeat the test, possibly on a different block before rendering this unusual report.

16.13 HER2

Human epidermal growth factor receptor 2 (HER2)-positive [1] breast cancer (BC) accounts for 15–20% of early breast cancer, and it is characterized by an aggressive behavior and poor response to conventional chemotherapy (CHT) [64, 65]. HER2 drives tumorigenesis mostly through protein overexpression in his wild-type form and pathway hyperactivation. Cancer promotion by HER2 kinase domain activating

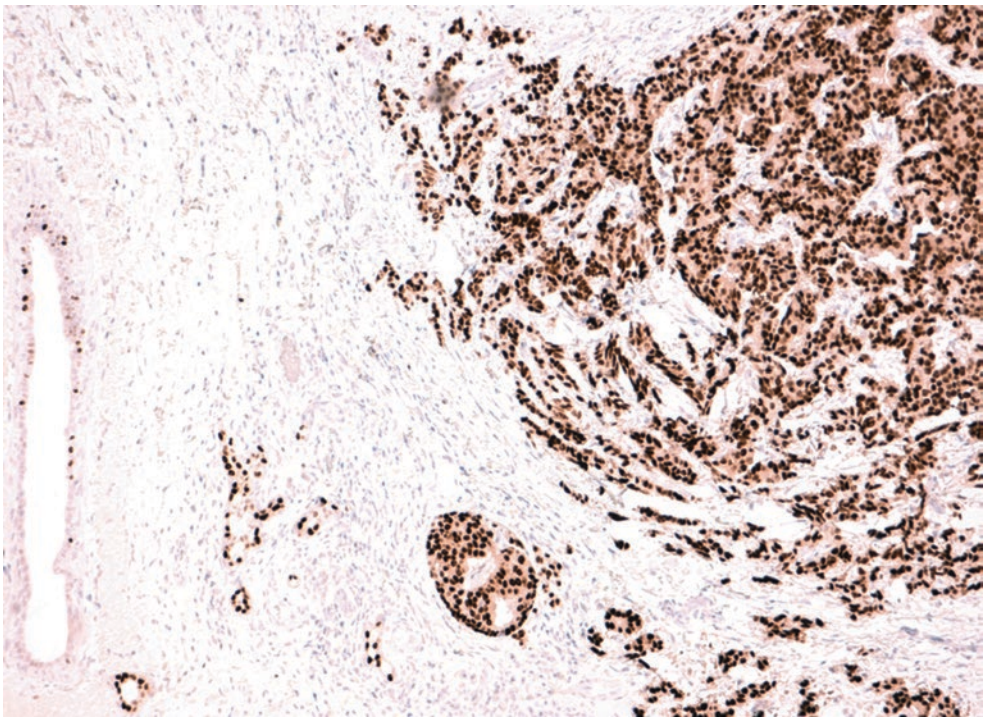

Fig. 16.3 Invasive ductal carcinoma NST showing diffuse (100%) intense positivity for ER. On the left a normal breast duct, showing heterogeneous staining

mutations has been rarely (3%) reported in the absence of protein overexpression [66–68]. The development and the clinical use of HER2-targeted therapies (antibodies and tyrosine kinase inhibitors) [69] led to a dramatic improvement of the outcome for patients with HER2-positive (HER2+) breast cancer [70–75]. HER2 pathways may be even more efficiently inhibited by combination therapies (dual blockade), as demonstrated in the metastatic and neoadjuvant setting [76–79], and currently tested within phase III randomized trials in the adjuvant setting [80]. Despite the efforts for standardizing HER2 testing, its reproducibility still represent a significant issue: central pathology review of locally assessed samples collected within prospective clinical trials reported concordance rates in the assessment of HER2 status by immunohistochemistry or in situ hybridization assays ranging from 77.5 to 96% [81–83]. In this regard, guidelines describing how to optimally perform the immunohistochemical (IHC) and in situ hybridization (ISH) assays for assessing HER2 status and evaluate and score the results have been issued and regularly updated [1]. Briefly, the 2013 ASCO/CAP guidelines define HER2-positive (score 3+) breast carcinoma as tumors containing more than 10% of cells with complete and intense circumferential membrane staining by IHC. ISH-positive breast carcinoma is defined as showing an average HER2 copy number ≥6.0 signals/cell or average HER2 copy number ≥4.0 signals/cell and a HER2 to chromosome 17 centromere (CEP17) ratio ≥2.0. Cases presenting weak to moderate circumferential membrane staining in more than 10% of tumor cells, or intense, complete and circumferential membrane staining in less than 10% of tumor cells should be classified as equivocal (score 2+) by IHC, while cases presenting HER2 to 17 centromere (CEP17) ratio <2.0 with an average HER2 copy number ≥4.0 and <6.0 signals per cell are considered equivocal by ISH. Equivocal cases require further assessment with the alternative assay or re-testing with the same assay of different tumor blocks or synchronous nodal metastases if available. Incomplete, faint, or barely perceptible membrane staining in more than 10% of tumor cells (score 1+) and no staining observed or incomplete, faint, or barely perceptible membrane staining in less than 10% of tumor cells (score 0) would confidently classify breast cancers as HER2 negative by IHC, while ISH-negative cases are characterized by a HER2 to chromosome 17 centromere (CEP17) ratio <2.0 with an average HER2 copy number <4.0 (Fig. 16.4).

16.14 Ki-67 Labeling Index

Tumor proliferation is one of the most powerful tools in breast cancer prognostication. The protein identified by the Ki-67 antibody is expressed in all proliferating cells during late G1, S, G2, and M phases of the cell cycle, peaking in the G2-M phases. In clinical practice, tumor proliferative fraction is most commonly assessed by the immunohistochemical staining of the Ki-67 antigen, using the MIB-1 monoclonal antibody [84].

The prognostic and predictive value of tumor proliferation has been extensively investigated in both the neoadjuvant and adjuvant settings [85, 86] and has been corroborated by gene expression analysis and molecular prognostic signatures, whereby the identification of intrinsic breast cancer molecular subtypes (i.e., Luminal A vs. Luminal B) or the distinction between aggressive or more indolent tumors

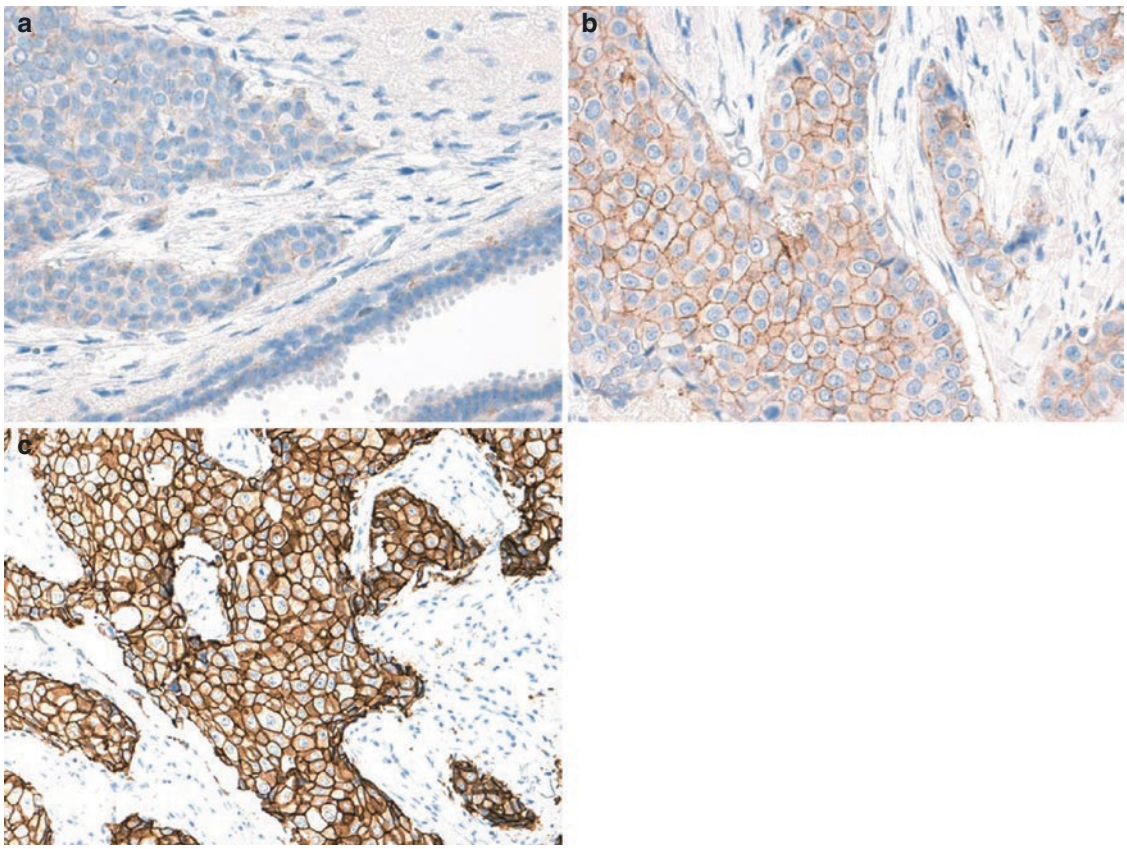

Fig. 16.4 Immunohistochemistry for HER2. Score 1+ (**a**); score 2+ (**b**); score 3+ (**c**)

relies mainly on proliferation-related genes [54, 87–92]. Therefore, accuracy of Ki-67 scoring is still a crucial issue, and huge efforts had been spent in improving consistency and in identifying the ideal cutoff value.

In 2010, the panelists of the International Ki-67 in Breast Cancer Working Group met in London and issued comprehensive recommendations aiming to achieve a harmonized, reproducible, and accurate methodology. Substantially, they suggested to assess Ki-67 labeling index on full-face sections, in at least three high-power (×40 objective) fields after an initial overview of the whole section, scoring at least 500 malignant invasive cells, preferably at the invasive edge of the tumor [93].

In their pivotal study, Cheang and colleagues [94] showed that a 14% cutoff was reliably able to discriminate tumors belonging to the Luminal A and Luminal B molecular subtypes. They found a Luminal A prevalence among ER-positive samples of approximately 60%. On the contrary, applying this same cutoff, other authors found an opposite prevalence of Luminal A and Luminal B cases. Consequently, at the 2013 St. Gallen Conference [95], the 14% cutoff for Ki-67 was challenged, and the majority of the panelists proposed to raise it to 20% for a better subclassification of luminal tumors. At the same time, Prat and colleagues [96] suggested to include high PgR expression (>20%) as an additional parameter for identifying the Luminal A subtype, along with ER positivity, HER2 negativity, and <14% Ki-67 labeling index. Maisonneuve et al. tested these new parameters in 9415 ER-positive and HER2-negative early breast cancer patients, treated between 1994 and 2006 and followed up at the European Institute of Oncology in Milan [97]. According to the 2011 St. Gallen criteria (Ki-67 cutoff of 14%), they found that 33% of the tumors would have been classified as Luminal A and 66% as Luminal B. Using the 2013 criteria (Ki-67 at 20% and adding PgR with the 20% cutoff), 43% of the tumors qualified for Luminal A and 57% for Luminal B. Interestingly, distant disease-free interval of the patients with low-proliferating tumors (Ki-67 < 14%) was not affected by PgR. Conversely, patients with tumors showing an intermediate Ki-67 labeling index (between 14 and 19%) had a significant different outcome according to PgR status, suggesting to classify as Luminal A tumors with either low (<14%) Ki-67 labeling index or with an intermediate labeling index (14–19%) and PgR of >20%. Luminal B tumors would be defined by either high Ki-67 labeling index (20% or more) or an intermediate Ki-67 and PgR _20%. Using this definition, 52% of the 9415 tumors qualified for Luminal A and 48% for Luminal B, with a significantly different clinical outcome of the patients (HR: 1.75, 95% CI: 1.42–2.11), after adjustment for clinicopathological variables including pT, pN, tumor grade, peritumoral vascular invasion, menopausal status, and systemic therapy.

16.15 Epilogue

The histopathological and biological characteristics of breast carcinoma are essential parameters to inform the choice of the systemic treatments. Hence, the pathology report of breast cancer must be complete and accurate, and include all the relevant features of the tumor. Recommendations have been issued by several national and international organizations on how to best evaluate and report these features and are continuously updated. It is the responsibility of each individual pathologist to follow all the available recommendations and guidelines strictly. The role of the pathologists in the multidisciplinary approach to breast cancer patients cannot be overemphasized, and the pathology report is their most important contribution.

17.1 Normal Risk Population

Alfonso Frigerio

Abstract Mammography screening is one of the revolutionary advances in the fight against breast cancer, alongside breast-conserving surgery. Few medical interventions have been so extensively evidence-based and yet subjected to persistent critiques. The clear scientific evidence of the efficacy of screening in reducing breast cancer mortality is discussed. Benefits provided by screening are substantial, well above any negative effect. In the age of modern treatment, early detection still contributes to breast cancer mortality reduction.

A full appreciation is advocated for organized screening programs and the added value they provide in terms of high quality, equitable health service, and as the optimal environment where best capitalize on the new advances in treatment. Future evolution might include (a) tailored, risk-based protocols, in the first place extending the age range of offered screening; (b) new imaging tools; and (c) optimization of existing programs, through better monitoring, training, and research—always abiding by the big caveats: evidence of efficacy, incremental cost-effectiveness, and sustainability. Both screening and treatment have merits in achieving mortality reduction. It would be clever to recognize their mutual enhancing power and devote resources to a very appropriate topic for research: how early detection might or should change the treatment of breast cancer.

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_17

17.1.1 Introduction

Breast cancer (BC) has been a curse for women's health since historical records exist, back to the ancient civilizations thousands of years ago. Our generation has had the privilege to witness the first real breakthrough in a long-standing story of sufferance and defeats. It was only the final decades of the twentieth century that brought about decisive innovations, in both diagnosis and treatment of this ominous disease. New medical therapies were introduced, and radiation oncology was developed, both attaining a relevant role in treatment protocols, especially so in their adjuvant capacities.

However, the two major advances came (a) with the introduction of breast-conserving surgery and (b) with the prospective, randomized controlled trials (RCT) that demonstrated for the first time in history the possibility to reduce BC mortality through early diagnosis, by the systematic application of mammography screening (MS).

The therapeutic equivalence of quadrantectomy to mastectomy in the treatment of small cancers, originally suggested and then scientifically demonstrated by Veronesi and others [1, 2], presented women with an amazing chance to avoid the traditional, mutilating, standard treatment of the last century, namely, Halsted's radical mastectomy.

Almost at the same time, population-based radiological (mammographic) screening was proposed and validated as a major health achievement that made it possible to decrease BC mortality by treating the disease when it was still localized in the breast.

Indeed, these two major innovations enhanced each other's benefits, as early mammographic diagnosis provided surgeons with more and more small cancers, which could be a candidate for the new breast-sparing surgery. Early detection allowed also for the adjuvant therapies, both medical and radiation-based, to achieve extraordinary results in disease control. Through this mutual support, early diagnosis in conjunction with more effective treatment opened the way to a new era in the fight against BC.

It is ironic that in recent years, it was just this enhancing, synergic action that offered one of a series of spurious arguments to discount the value of early detection as a powerful measure to control BC mortality, in this epoch of developing new therapeutic regimens. Such argument has given support to a great deal of data misinterpretation and a long sequence of futile controversies.

The present pages shall try to summarize and highlight the clear, overwhelming scientific evidence on the efficacy of MS in reducing BC mortality and the importance of building and keeping up large population-based screening programs as a needful strategy in order to best capitalize all the treatment advances that have been and are being developed.

It will be shown how current estimates of benefits achievable through MS are substantially undervalued, and it will also be suggested that the future evolution of BC management should strive to include an innovative rethinking of some concepts that form the basis of pathological representation, description, and classification of breast diseases, taking into consideration many new pieces of knowledge derived from the screening experience. This new perspective could bring about a change in the fundamental concepts of BC treatment, at least when the tiny, screen-detected cancers are involved. New tailored treatment protocols, based on a full appreciation of different parameters of tumor characterization, should be developed. These in turn would make it negligible the concern that has been raised on the overdiagnosis at screening (and the ensuing overtreatment) of a proportion of indolent cancer cases.

In the near future, alongside some anticipated technology-based modifications of the protocols (the subject of subsequent chapters in this book), the evolution of MS will have to consider many different ways of customizing the screening intervention, according to various risk factors, in order to maximize the cost-effectiveness of the system.

17.1.2 The Evidence

Few medical procedures and interventions have been so extensively studied, proven effective, thoroughly evidence-based as MS, and yet discussed and subjected to persistent critiques and unrelenting, often specious attacks.

Since the pioneering New York Health Insurance Plan (HIP) project [3], a wealth of studies, trials, and service programs formed the basis for hundreds of publications that have been dedicated to MS, so that an exhaustive bibliography is practically impossible to collect and report. It is worthy of note and almost a paradox that the prospective, randomized controlled trials (RCTs) where we base the core of our knowledge have been subjected to far more analyses and meta-analyses than the original number of trials. Therefore, references at the end of this chapter should be considered as a very selective choice of relevant contributions. A comprehensive list of references (up to year 2012), as well as a very knowledgeable analysis of their contents, may be found in the special supplement issue of the *Journal of Medical Screening* edited by Paci and reporting the efforts of the Euroscreen Working Group in providing in-depth, expert discussion of the literature on MS, as well as precious, recent data from many European countries [4]. It is convenient to remark at this point that from the immense database accumulated through the screening experience, the best researchers have been able to draw illuminating concepts on the natural history of BC [5].

It was just this incredible number of publications, combined with the substantially variable quality among them and with the extreme complexity of the subject matter, that in the first place made it possible and then immensely contributed

to the diffusion of a still unending trail of largely futile controversies. However, a portion of the conflicting views on MS may in fact derive from different ways of expressing the same results, rather than from substantial disagreement on the data available.

It is still unfortunate that what has been opportunely defined as "an active anti-screening campaign […] based on erroneous interpretation of data from cancer registries and peer-reviewed articles" [6] has been kept alive over the last two decades to this day, with a disconcerting pattern of following waves. This process may be described as a "provocative sequence" of:

(a1) Main question
(a2) Scientific proof provided
(a3) Evidence questioned on poor or unsubstantiated terms
(a4) Evidence (to some extent) conceded, but then
(b1) New question set forward
(b2) Scientific proof provided - etc, through (d4)

According to this pattern, the subsequent questions and critical waves against MS can be summarized as follows (a discussion of these points and relevant references are given below):

(a) Can MS reduce BC mortality?—**the efficacy issue**: (a1) evidence provided by the big RCTs; (a2) evidence questioned, most pugnaciously by the Nordic Cochrane Centre; (a3) evidence eventually (to some extent) conceded in subsequent articles; and (a4) new issue set forward about effective reproducibility of trial results into public health practice.

(b) Can MS service programs reproduce the results of the RCTs and actually save lives in a sustainable way in the context of the health-care system?—**the effectiveness issue**: (b1) evidence provided by a large number of observational studies; (b2) evidence questioned, mostly on the basis of methodologically poor "ecological" studies, lacking information about actual exposure of women to MS; (b3) evidence eventually conceded in subsequent articles; and (b4) new issue set forward about "harms" of screening surpassing the possible benefits.

(c) Are the benefits provided by MS more substantial than any unwanted effect that it may produce?—**the harm/benefit balance** analysis of MS: (c1) evidence of a favorable balance provided by many researchers and prominently in the Euroscreen Working Group analysis; (c2) evidence questioned, especially on the basis of grossly inflated estimates of overdiagnosis; (c3) evidence conceded, most authoratively by the UK Independent Panel [7], the "Marmot report;" (c4) new issue set forward about any remaining significance of the role of early detection in the new age of effective cancer treatment.

(d) Even after MS was proved valid and effective by RCTs and even conceding that its side effects could be minor in respect to the potential benefits, does early detection through MS still hold its meaning in the new era where very effective new treatments for BC have become available? Is it not the case that most of the BC mortality reduction that has been recently observed should be credited to treatment rather than MS?—**the "expired validity" issue** of MS: (d1) evidence has been provided confirming a substantial net benefit of screening on top of the achievements of treatment and (d2) discussion on this point (d3–d4) will be commented in the following pages.

It might reasonably be argued that the above sequence respects the very basics of scientific debate. This would be certainly true, if such sequence was not undermined, as in this case, by an almost breathtaking, unrelenting introduction of methodologically weak or clearly erroneous arguments.

Then, for all these questions, is there any real room for genuine controversy?

The clear, plain answer has to be no.

It is soundly proved that MS substantially does reduce BC mortality and is effective in actual health-care practice; the benefits produced by MS are large and substantial, well above any negative effect.

MS does still substantially contribute to BC mortality reduction even in the age of modern treatment.

The exception where there is indeed space for further analysis is overdiagnosis which, although well compensated for by the mortality reduction benefit, is an extremely complex topic that deserves a more thorough discussion.

In the above series, one more argument has been purposely skipped that had at one point been raised to fuel the debate, namely, the lack of evidence about MS reducing general (all-cause) mortality in the population. This appears the most specious in a series of largely specious arguments. As clearly stated in the Marmot report, reducing BC deaths by 20% in ages 55–79 years would yield a 1.2% reduction in all-cause deaths. The RCTs were not designed for and "are not of sufficient size to allow such small reductions to be reliably estimated. Hence, a statistically non-significant effect for all-cancer or all-cause deaths in the trials cannot be interpreted as evidence against a reduction in BC deaths" [7].

Rather, two key points deserve to be highlighted already at this point, as central in the debate:

1. The quality evaluation of the studies considered has to be factual and circumstantial, i.e., their internal validity must be convincingly proven.
2. The importance of very long follow-up times. These are imperative as we aim at the precise estimate of the benefits involved with the early detection of a group of diseases like BC, which are characterized by a variable, often very long natural history.

Of the above sequence, **issue (a)** will be discussed at this point.

Issues (b–d) will be the subject of paragraph three (service screening).

17.1.2.1 The Efficacy Issue

MS involves an active intervention on large populations over extended times, i.e., huge numbers of study subjects, observed for very long study and follow-up periods, with many parameters to consider, subjected to a number of possible biases. The rationale for screening is advancing the time of diagnosis in order to improve prognosis through earlier treatment. Thus, the apparent incidence of BC has to increase at the start of the process. Also average time from diagnosis to death will increase, introducing a powerful bias (lead-time bias). This might induce erroneous estimates of benefits and harms of MS, when not judiciously taken into account. However, MS efficacy can be stated with great confidence, thanks to available scientific data of the best quality in order to overcome lead-time bias, as mortality data from RCTs are available to support it.

The wealth of evidence provided by a number of excellent, more recent observational studies will also be considered and highlighted in the next paragraph.

The story itself of MS was in fact born with a randomized study. It originated from a brilliant idea back in the 1950s–1960s, when the new technical tool of mammography was suggested [8] and then put to test in New York City in a prospective, randomized trial of annual invitation to mammography plus physical examination vs. current clinical practice in the HIP project. The statistically significant mortality reduction from BC in the study vs. control group [3, 9] was confirmed by further updates of the HIP data [10], as well as by a number of subsequent RCTs set up in the period 1976–1991.

Up to 14 RCTs [11] could be considered, the total number depending on counting trials with two parts (Malmoe, Swedish Two-County, Canada I and II) as separate studies or not and on exclusion criteria for one or more trials on different motivations, either of design or of their quality. As a consequence, meta-analyses and systematic reviews of RCTs, the most common gold reference for directing decisions on screening policies, may vary in their conclusions mainly due to the quality criteria for selection of trials to be included in the review process. More commonly, eight big RCTs are considered, and seven are actually included [7, 11], since all reviews agree to discard the Edinburgh trial on major unbalances in the randomization process [12].

The seven trials considered are the HIP study, started in 1963; the Malmoe trial I, started in 1976; the Swedish Two-County (STC) study (Kopparberg arm, started in 1977, and Ostergotland arm, started in 1978); the Canada I and II (CNBSS), started in 1980; the Stockholm trial, started in 1981; the Gothenburg trial, started in 1982; and the UK Age trial, started in 1991.

It is remarkable that, beyond all the many differences among the trials in design, technicalities (e.g., number of mammographic views), intervals between screening rounds, age groups involved, duration of follow-up, etc., meta-analyses tend to converge on an estimate of around 15–20% relative risk (RR) reduction in BC mortality for women invited to MS vs. the non-invited.

The Marmot report [7] may rightly be considered as the most balanced among the recent highest profile reviews, with regard to the MS debate, coming from a group of independent experts, selected and nominated by the UK authorities on the basis of their knowledge and on the absence of any personal involvement in the dispute. These authors recognize a 20% mortality reduction from BC associated with invitation to screening. They summarize their findings in a table that we reproduce in a simplified form as in Table 17.1, for ease of reference and discussion.

On the other hand, one might regard the series of meta-analyses from the Cochrane Collaboration, as the most pugnaciously critical of MS. Originated from a commission back in 1999, they were first published in 2001 and revised a number of times to the latest review in 2013, to which we now refer as the Nordic Cochrane review (NCR) [11]. These authors consider that the only three trials with "adequate randomization," i.e., Canada, Malmoe, and UK Age trials, did not show a significant reduction in BC mortality, with a RR of 0.90 (95% CI: 0.79–1.02). They recognize that the other four trials that they considered of "suboptimal randomization" showed a significant RR reduction of 0.75 (95% CI: 0.67–0.83). It must be remarked though that the quality evaluation as proposed by the NCR has been substantially subverted by the more balanced review of the UK Independent Panel [7]. The RR for all seven trials in the NCR was statisti-

Table 17.1 Breast cancer mortality reduction in RCTs of mammography screening

Study, date of start	Age group	RR	95% CI	Weight (%)
New York, 1963*	40–64	0.83	0.70–1.00	16.9
Malmoe I, 1976*	45–69	0.81	0.61–1.07	9.5
Kopparberg, 1977	38–75	0.58	0.45–0.76	10.7
Ostergotland, 1978	38–75	0.76	0.61–0.95	13.0
Canada I, 1980**	40–49	0.97	0.74–1.27	10.2
Canada II, 1980**	50–59	1.02	0.78–1.33	10.2
Stockholm, 1981*	39–65	0.73	0.50–1.06	6.0
Gothenburg, 1982	39–59	0.75	0.58–0.98	10.7
UK age trial, 1991*	39–49	0.83	0.66–1.04	12.8
Overall		0.80	0.73–0.89	

A meta-analyses after 13 years of follow-up, based on the Cochrane [11] and Marmot reviews [7] (modified)

RCT randomized controlled trial, *RR* relative risk, *CI* confidence interval

*Studies falling short of statistical significance and/or RRs between 0.80 and 0.90

**Studies with no statistical significance and RRs beyond 0.90

cally significant at 0.81 (95% CI: 0.74–0.87). The NCR concludes that assuming a 15% reduction in BC mortality with MS, one would need to invite 2000 women throughout 10 years to save one life.

Duffy et al. [13] argue that the number needed to invite is not the proper measure, since it will be heavily influenced by the attendance rate of the population; they recommend the number needed to screen (NNS) to prevent 1 BC death, as a more adequate measure of MS benefit. They work on this and make assumptions about a UK scenario. After correction for the actual participation rate to the UK screening program of 77%, starting from the Cochrane value of 15% mortality reduction in the invited women, they come to an estimate of 257 NNS in 10 years to prevent 1 BC death, as compared to the 2000 needed to invite in the Cochrane estimate. It is opportunely remarked that the very low estimate of absolute benefit in the Cochrane review derives from unduly restricting the benefit analysis to a 10-year period and from their selection of trials dominated by the younger (below 50) age group, which has considerably lower absolute mortality. Applying the same reasoning, corrections and NNS to another major recent review by the US Preventive Services Task Force (USPSTF) [14], Duffy et al. come to a similar result of 193 NNS to prevent 1 BC death. They insist that expressing results relative to the same denominator, with the same follow-up lenght, referring to absolute mortality rates, and applying them to different published reviews - we end up with absolute measures of benefit of the same, relevant order of magnitude. This supports the concept that the so-called controversy on BC screening is to a large extent an artificial one.

The NNS idea refers to the underlying problem of trials reporting benefits of invitation (intention to treat analysis), rather than an actual screening. Higher mortality reductions are expected in women actually attending screening; still it is difficult to say by how much, since different background risks may be involved due to selection bias. Women who attend screening are as such representative of a health-aware portion of the population that might gain extra benefits (beyond those conferred by MS) from the attitude that makes them keen to seek medical support, whenever needed.

One way to tackle this theme would be to consider the RCT evidence as the extremely reliable proof on which to base health policies and screening recommendations. It should be reminded though that the trials tested the impact of invitation to screening on BC mortality. As for the benefit expected for a woman actually attending screening, RRs should be best derived from service screening mortality estimates of attenders vs. nonattenders (see next paragraph).

It is also interesting to consider the USPSTF meta-analysis stratified on different age groups. The USPSTF estimates BC mortality reductions of 15% in the 39–49 age group, of 14% in the 50–59, and of 32% in the 60–69. One might consider that these differences could be determined by the well-known detection limitations of mammography in the denser breasts of younger women. Yet, it is worthy of note that the USPSTF estimates of the two younger age groups very closely resemble the Cochrane analysis of the so-called "adequately randomized" trials, among which only the smaller Malmoe trial includes a portion of women over 59 years old. In fact, it is the relative weight of the Canadian data that do not include the over 60 age group, to introduce a powerful bias.

At this point, some special remarks are warranted on the disgraceful impact of the Canadian National Breast Screening Studies (CNBSS) I and II on the screening debate.

The Canadian Contamination

The CNBSS was set up in 1990 as a thoroughly designed, ambitious project, into which enormous energy, resources, and good will were invested. It ended up as a huge amount of significantly flawed data that should not be considered any more in meta-analyses of screening trials. The fact that these data [15, 16] and one recent update of the same, based on a 25-year follow-up [17], have been widely considered in reviews and referred to contributed extensively to building up and maintaining the artificial controversy on MS. This process may be defined "the Canadian contamination." Instead, it has to be clearly stated that these Canadian results lack methodological value and should not be relied upon for evidence-based conclusions [18]. A quick glance at Table 17.1 suffices to show the CNBSS trials as the flagrant outlayers, showing no hint of benefit, as compared to the other seven studies, whose RRs range from 0.57 to 0.83. It is sadly ironic that the outlayer studies, with a flawed evidence base, should have cast their shadow on a wealth of scientifically sound data from so many other researchers.

It was immediately after their original publication in 1992 that a flourish of critics exploded in the scientific literature. These have obviously been resparkled after the Canadian follow-up article was published in 2014 [17]. In a recent paper by Heywang-Köbrunner et al. [18]—to which we refer the reader for an extremely detailed analysis of the debate and for punctual references—a systematic search on this topic yielded close to 300 articles, 70 of which were deemed of special interest. These articles split in two similar parts of 33 "defending" papers, mostly authored by the original directors of the study vs. 37 "critical" articles by a much wider, representative group of researchers.

The long series of critiques to the Canada trials fall in two main fields:

(a) Technical/clinical quality issues
(b) Methodological/management issues

Both are extensive; however, the methodological/management points are overwhelming.

Group (a) critiques were mainly on the quality of mammography. Quality of images (low contrast resolution, insufficient sharpness, and over- and underexposure) and of positioning was so heavily questioned that many external expert reviewers resigned from their position in the trial on claims of unacceptably poor standards and of their corrective measures not being taken into proper consideration. Also the interpretation of films was criticized as some readers had insufficient training and many obvious cancers were missed. Although quality issues must have played a role in the final results, the core reason why the CNBSS trials should not be considered eligible to be reckoned in meta-analyses of RCTs has to be found in the other group of arguments.

Group (b) issues (the methodological/management problems) are indeed conspicuous. The study design has often been described (most prominently by its authors) as ideal, due to randomization being carried out at the individual level. Conceding that, in principle, individual randomization would be preferable over cluster randomization, what in fact matters is the quality of the process. Most reviewers, among them the UK Independent Panel, recognized that cluster randomization produced significant biases in the Edinburgh trial, and on that basis, they excluded it from meta-analyses, but not in the STC trials, where cluster randomization did not result in relevant unbalances, so that the same reviewers agree to consider this study as soundly evidence based, eligible to be included in reviews.

On the other hand, the randomization process blatantly failed in the Canadian trials, as so apparently shown by the disproportionately large number of participants with late-stage cancer in the mammography arm at the first round [17–19]. Indeed, soon after the first CNBSS publication, the observation of the heavily unbalanced distribution of advanced cancers in young women was supported by a series of reports [20–23] on various contradictions to the initial study design. It was reported that randomization was performed at certain sites after a clinical breast examination, blinding was not consistently warranted, and various easy possibilities of subversion existed and could be done in practice. The motivation for this would have been—in good faith and with no fraudulent intention—to guarantee that significantly symptomatic women would be offered a mammogram. It is a recognized fact that at one time the coordinator of one unit was removed because of suspected subversion of the randomization.

The weak defense of the CNBSS investigators has eventually to face the striking fact that among the first round of younger women, 19 advanced cancers were allocated to the screening arm vs. five in the control arm. Also, eight women in the screening arm vs. one in the control arm had previous history of BC. It is clearly preposterous on the investigators' side to argue that a long list of other variables was perfectly balanced in the two study arms, when the most clinically significant variable, i.e., late-stage BC at first round, was so heavily unbalanced.

The Canadian update itself [17] that has been widely publicized to the scope of discrediting the benefits of MS does in fact supports the contrary view. In that paper, deaths from BC detected at year 1 of the study were double (52 vs. 26) in the mammography arm vs. control arm, a fact that is the obvious consequence of flawed randomization, as shown by the exceedingly unbalanced number of late-stage cancers.

It is telling to quote the authors' own words: "it has been suggested that women with a positive physical examination before randomization were preferentially assigned to the mammography arm. If this were so, the bias would only impact on the results from BC diagnosed during the first round of screening … However, after excluding the prevalent BC from the mortality analysis, the data do not support a benefit for MS (HR = 0.90, CI 0.69–1.16)."

This passage is so important as (1) it implicitly concedes that preferential assignations might indeed have happened within the trial organization and (2) recalculates HRs for only incident rounds of the trial demonstrating a clear drop in HRs. At this point, the authors, rather than expressing this as it should be, i.e., as a shocking 50% difference from the infamous HR value of 1.47 in the prevalent round of the trial (explainable only by subverted allocation) to a promising HR of 0.90 for incident rounds, prefer to highlight the fact that this value still shows a benefit of no statistical significance. The point is that it does suggest a benefit that might have been significant (a) in a high-quality screening service, as compared to the low mammography quality documented in the trial setting, and (b) in a more powerful study design or within a proper meta-analysis that should exclude the biased prevalent round data of CNBSS.

It is beyond the scope of this chapter to further discuss a number of questionable points in the CNBSS studies that contribute to make their results definitely not applicable to quality-assured screening programs. Just in passing, these other objections include the following: the studies included palpable, symptomatic cancers; these were in fact not blindly allocated to the two arms; long-term mortality reduction was calculated from a mixed trial participation of one to five rounds during up to 5 years, thus diluting enormously the benefit that would be possibly demonstrated; and recommended biopsies were not systematically performed.

The crucial point is that using these Canadian data, "evidence in the field of BC screening has systematically been omitted, distorted or inappropriately used over the last decades" [18]. Instead, CNBSS data are not applicable to evidence-based results of modern MS.

The Follow-Up Factor

One should regard BC as a group of many different diseases, with an average long natural history. Even back when MS and modern therapies were not available, median survival times for BC patients used to be several years. This explains the fact that no screening trials can show a mortality benefit in the first 2–3 years after their start and also that most benefit has to be reckoned only after many years of follow-up.

Screening could be then compared to an excellent mix of financial investment products. The investor may cash some short-term dividends, i.e., from lives saved after 3–5 years, due to the timely detection of very aggressive, Grade 3 cancers. Most profits will come in the middle term, these being lives saved 6–10 years after detection of Grade 2 cancers, while some long-term returns should be expected from lives saved 11–20 years after the detection of slowly growing cancers.

This consideration justifies the extra mortality reduction that is still evident in RCTs, after the moment when the control group is offered MS: a fact that puzzled many critics of MS, as in the original Cochrane reviews. This phenomenon is particularly well represented in the 29 years of follow-up publication of the Swedish Two-County trial [24] where most of the prevented BC deaths were those that would have occurred over 10 years after the start of screening, from cancers diagnosed in the first 7–8 years of the study, since after that time the control group was exposed to screening.

This supports the principle that in MS, as is the case with other primary and secondary prevention activities, considerable long-term follow-up is necessary for a full appreciation of the benefits involved. In a RCT setting, most benefit is to be expected more than 10 years after the trial starts, from cancers diagnosed in the first 5–10 years (recruitment period), depending if and when the control group is offered screening after the study recruitment phase.

Failure to fully appreciate this concept has led to many inconsistent or weak analyses and meta-analyses and to a substantial undervaluation of the merits of screening.

The importance of prolonged follow-up times will be shown for the observational studies, in the following paragraph. As to RCTs, implications are also important, e.g., when one considers the latest updates of the UK Age and Gothenburg trials [25, 26], both showing significant benefits from screening after follow-up times extended to 17 years, also in younger women (and provided one restricts the UK analysis to cases diagnosed in the intervention phase).

A similar pattern was demonstrated in an overview of the Swedish RCTs [27] that, restricting the analysis to women randomized when 40–44, demonstrated a 15% reduction in BC mortality at long-term (over 14 years) follow-up. In this overview, benefit increased up to 12 years after randomization and was then maintained.

Conclusive Remarks on the Efficacy Data from RCTs

When all the evidence in favor of MS is considered and duly recognized, screening opponents come up with another argument (issue d—in the above "provocative sequence"), namely, that RCT results are too old to maintain their validity in the modern setting. This is largely objectable, and we shall come back to this in paragraph three. However, this point could be considered more appropriate for trials where the quality of mammography technique was grossly antiquated with respect to modern standards. If this is probably true for the CNBSS studies that are to be excluded anyhow on other more weighty considerations, it is certainly the case with the HIP study conducted in the 1960s, where the quality of mammography (combined for that trial with clinical examination) did succeed in reducing cause-specific mortality mainly staging BCs down from the big lumps that were the usual case pattern of the time (often T3+ cancers), to some relatively "earlier" cases, but still typically in the T2+ TNM size category. These, as well as the average cancer size of close to 20 mm in the CNBSS studies, are not representative of the practice of modern MS, where a great majority of cases are below the 15 mm size threshold and many within the 10 mm limit.

What is difficult to perceive, and is thus totally unappreciated by non-radiologist, is that the amazing results of the Kopparberg arm in the STC trial gained one special contribution from the extremely high quality of mammography that the lead scientist of the trial, Laszlo Tabar, could achieve in the late 1970s. That is attested by the fact that the standard textbook on mammography remains to date the teaching atlas that Tabar published some 30 years ago and that in its latest edition of 2011 is still based on the original mammographic films of the late 1970s [28]. That quality was already representative of the good results that modern MS programs can attain.

To sum up the substantial evidence on MS efficacy as derivable from many sound RCTs, one could start from the table derived from the UK Independent Panel review (Table 17.1) and adapt it based on the above discussion (Table 17.2)—excluding the New York and the Canada trials and substituting the latest publications of the UK Age trial and of the Gothenburg trial [26, 27], since these capitalize on longer follow-up periods, which were not available at the time of the Marmot report.

In this updated Table 17.2, most trials show a consistent BC mortality benefit for women invited to screening, in the very narrow range of 0.70–0.76, the two slight outlayers being Malmoe (RR = 0.81) and Kopparberg at the other end (RR = 0.58). In this updated prospect, studies of borderline significance (marked with asterisk (*)—in Tables 17.1 and 17.2) account for only one quarter of the review material vs. two thirds in the Marmot meta-analysis.

Table 17.2 Breast cancer mortality reduction in RCTs of mammography screening, revised and updated

Study, date of start	Age group	RR	95% CI	Weight (%)
Malmoe I, 1976*	45–69	0.81	0.61–1.07	15.2
Kopparberg, 1977	38–75	0.58	0.45–0.76	17.1
Ostergotland, 1978	38–75	0.76	0.61–0.95	20.7
Stockholm, 1981*	39–65	0.73	0.50–1.06	9.6
Gothenburg, 1982	39–59	0.70	0.53–0.93	17.1
UK age trial, 1991	39–49	0.75§	0.58–0.97	20.4

Data derived from the Cochrane and Marmot reviews [7, 11], applying a restricted selection of trials (see text) and substituting the latest updates of the UK Age trial and of the Gothenburg trial [26, 27]
RCT randomized controlled trial, *RR* relative risk, *CI* confidence interval
*Studies approaching statistical significance and RRs between 0.80 and 0.90
§RR for cancers diagnosed during the recruitment period of trial (see text for discussion)
Weight was recalculated as a proportion from Table 17.1

In conclusion, the evidence from many RCTs supports a significant BC mortality reduction from invitation to MS consistently in the range of 20–30%, for women aged 39–75.

17.1.3 Service Screening

While well-conducted RCTs provide the most reliable information about the efficacy of MS (issue a), being subjected to fewer biases than observational studies, many questions have been and are still raised about a number of other points including the actual effectiveness of MS in real practice, the potential harms of screening, and a diminished role for MS in the age of modern treatment: these points (issues b–d) will be discussed in the present paragraph.

17.1.3.1 The Effectiveness Issue

Almost immediately after the initial publication of the HIP results in 1971 [3], not only other RCTs were launched in different countries, but also service programs were set up, and their number increased exponentially following the subsequent publications of the newer studies' results. This has led to the present situation where, in many countries, large screening programs have been implemented on a population base as a core component of systematic national health policies for cancer prevention. This is the case for many European nations [29]. Also outside Europe, more and more nations, from Canada to Australia, are already managing, while others are in the phase of starting organized MS projects. In many other places, like the USA, screening mammography is extensively employed outside the organized setting, in a form that has been defined "spontaneous" or "opportunistic" screening.

The diffusion of large population-based MS programs provided researchers with the incredible opportunity to produce observational studies that, when thoroughly conducted, i.e., with a special attention to a long series of methodological traps, brought a wealth of new evidence to support the validity of MS in practice. Observational studies are generally more recent than RCTs and can thus reinforce estimates of the effects of screening, offering a robust sense of closer comparability to actual practice, in the present era of continuing developments in diagnostic imaging and clinical care.

If this is certainly the case, one has to be warned that especially the harsher critics of MS suggest to consider observational studies as more relevant than the RCTs. Such assumption allows them to allege biases and problems of interpretation as a polemists' weapon and offers a chance to come up with unfocused analyses of population data, in order to diminish the rigorous efforts of many other researchers. The fine details of methodology are beyond the scope of these pages, and we again refer the reader to the References for comprehensive discussions and especially to the very knowledgeable, large reviews of pertinent literature as may be found in the Euroscreen supplement publication of 2012 [4, 30–32] and in the Marmot report of 2013 [7].

Yet it is crucial to remark that with observational studies, it is fundamental to stick to the polar star that helps to identify the immensely useful, valid publications, namely, the availability of sufficient longitudinal, individual data, i.e., very long follow-ups (ideally beyond 10–15 years) with the possibility to link a woman's screening history to her cause of death. Articles falling short of these requisites should be considered with the utmost caution, if not discarded altogether, even when published in highly regarded scientific journals. A firm warning has to be made about this continuous flow of articles where all the basic methodological prerequisites are not met. Whenever reading observational/ecological/trend publications that lack individual data and/or long-term follow-up, one should be aware that these papers actually use invalid material to fuel the artificial debate on MS [33–36]. Based on conjectures and extrapolations rather than facts, there is obviously not much chance that the benefit of MS can be fully appreciated. In Broeder's words [30]: "Much of the current controversy on breast cancer screening is due to the use of inappropriate methodological approaches that are unable to capture the true effect of mammographic screening."

In brief, we may consider among the observational studies:

1. Trend Studies

This would be the weakest group [7, 31], comparing BC mortality trends with regard to the availability of MS on a population as a whole rather than on an individual basis. Methodological difficulties are overwhelming with these studies. Problems include the impossibility to attribute BC

deaths to cases diagnosed before or after the screening activity started, to the possible relevant contamination from opportunistic screening even prior to the introduction of screening [37]. Some studies attempted to include more detailed analyses, fine corrections for various confounding factors, and extended follow-up [38, 39] and still estimate MS mortality benefits in a relatively wide range. In general, these methods should be considered of limited value for assessment of screening activities and have in fact been considered not reliable by the UK Independent Panel.

2. Case-Control (CC) Studies

This is the best known methodology, apart from RCTs, comparing the history of screening exposure between women dying of BC and live controls. Such a design yields estimates of relative mortality in compliers to screening invitation vs. non-compliers. This produces the main, well-known problem of self-selection bias, since compliers and non-compliers may differ a priori in their risk of dying from BC [7]. Therefore, researchers typically have to introduce a correction for this bias, whose adequacy may be questioned by critics. The Euroscreen review and selection of the best European CC studies, with exclusion of overlapping data, confirm a reduced mortality benefit of 31% in invited women (OR = 0.69; 95% CI 0.57–0.93) and 48% in women screened (OR = 0.52; 95% CI 0.57–0.83), after adjustment for self-selection.

3. Incidence-Based Mortality (IBM) Studies

In IBM studies all BC deaths in a population are considered if the corresponding BC diagnosis occurred in a time window when the woman had the opportunity to be screened, due to eligibility and invitation [7]. These BC deaths are then compared with corresponding BC deaths from women not having the chance to be invited on geographical (region with no screening program) or chronological (historical, pre-screening data) basis. A meticulous selection of the studies with the strongest design [30, 32] and excluding overlapping publications demonstrated a mortality reduction for women invited to screening of 25% (RR = 0.75; 95% CI 0.68–0.91). When women actually attending screening were considered, the benefit estimate was 38% (RR = 0.62; 95% CI 0.56–0.69). The huge amount of valuable data involved should be emphasized, as well as the substantial homogeneity of the results across the studies under review.

The Euroscreen estimates, as derived from the detailed analysis of a wealth of evidence-based data of service screening studies and on the most scrupulous methods [30–32], show a BC mortality reduction of 25–31% for women invited to MS and 38–48% for women actually screened. These figures reaffirm the large benefit demonstrated by the "old" RCTs also in the more recent, real-life situations of service screening.

To further stress the extreme importance of these service screening studies and the powerfully distracting capacity of those studies that do not comply with the basic methodological prerequisites (individual data/long-term follow-up), we shall now analyze a few instances in some more detail.

As a paradigmatic example, let us consider the Norwegian Breast Cancer Screening Programme (NBCSP) that was launched in 1996 and what different studies have published about its impact on BC mortality.

Kalager et al. [34] in 2010 on the basis of aggregated screening data, and a maximum follow-up time of only 8.9 years, with an IBM approach, conclude that in Norway the availability of MS was associated with a 28% reduction in BC mortality in the screening group as compared with the historical preceding 10-year period. Since a similar, although lower, reduction of 18% in BC mortality was observed also in the non-screening group vs. the historical comparison group, they conclude that only a third of the total reduction could be attributed to screening, the remaining benefit being interpreted as a result of improved treatment within an interdisciplinary team. As is commonly the case, the role of the organized MS experience of the 1980s–1990s in building up the concept of the specialized interdisciplinary, collaborative management of BC that has recently led to the institution of the Breast Units system as an international standard of care is not remarked.

In 2013 Olsen et al. [40] still based on aggregated data and an IBM approach, with a maximum follow-up of 13 years, try to improve on some aspects of Kalager's work, in order to correct possible underlying temporal changes in BC mortality. They conclude that the implementation of the Norwegian-organized screening program was associated with a nonsignificant decrease in BC mortality of 11%. There is again a misleading message in this apparently disappointing summary conclusion. In the first place, it should be emphasized that this result does not represent the impact of MS on BC mortality, i.e., this is not a comparison of screening vs. no screening. Rather, it depicts the impact of building an organized MS program on top of existing widespread spontaneous mammography. In Norway, this was estimated by the authors at around 40% prior to the program. Eventually, one might read the conclusions of this study either in an erroneously diminishing fashion as a "nonsignificant effect of MS" or—more opportunely—as a coherent, promising observation of an "extra effect on mortality from organized screening," as compared to a similar, widespread, non-organized mammography coverage of the population, and this extra effect is perceivable even at relatively short follow-up, still in the recent era of modern treatment. This makes altogether a different picture.

Conversely, the first report of the Norwegian program, which was based on the access to individual screening data

[41] with a maximum follow-up of 15 years, shows a significant, conspicuous 43% mortality reduction from BC (RR = 0.57; 95% CI 0.51–0.64) associated with attendance, after adjusting for several factors, most notably for self-selection bias.

After the previous discussion of the serious perturbation of scientific evidence associated with the publicity of the Canadian trials, it seems relevant at this point to emphasize the results of an excellent analysis of BC mortality in a service MS situation published in 2006 by Coldman et al. [42] on data of the Screening Mammography Program of British Columbia (SMPBC) established in 1988 in Canada. The authors show that MS significantly reduced BC mortality at all ages between 40 and 79. Mortality reduction was 40% for all ages combined (RR = 0.60; 95% IC 0.55–0.65). In women entering screening at age 40–49, the reduction was 37%, after exclusion of mortality associated with cancers diagnosed after age 50. Even after correction for self-selection bias, the mortality reduction was 24% for all ages.

In Italy, a series of valuable publications have been produced over the years by the IMPACT study project, a national research task force based on an extensive database linking BC cases in areas covered by cancer registries to individual screening files. In the IMPACT project, all cases are classified by cause of death and detection method (screen detected, interval cases, never respondent, diagnosed before invitation). From this material, a case-control study [43] assessed BC mortality reduction associated with MS exposure at 45% (OR = 0.55; 95% CI 0.36–0.85), over and above the background access to mammography, thus confirming the important impact of service screening in the Italian health situation. The OR associated with invitation was also significant at 0.75 (95% CI: 0.62–0.92).

In 2013, the IMPACT Working Group produced another study of outstanding importance demonstrating a significant decrease of advanced-stage cancers after the introduction of organized screening in Italy [44]. This represents a central issue in the ongoing evaluations of screening programs in practice and is based on an early indicator derived by the data of the STC trial. As back as in 1989–1992, Tabar et al. [45] showed that the incidence of stage II and greater cancers started to decrease 5 years after randomization and this decrease paralleled quite neatly the decreasing mortality curves in the study, with a substantially stable 30% reduction from 8 years onward. This proves that early diagnosis does interrupt the natural history of BC, and this has led to the proposal of the incidence of late-stage BC as one powerful surrogate indicator of a MS program effectiveness.

Many studies have aimed at assessing this parameter, with conflicting results, some confirming the reduction in advanced cancers [46–50], while others showing stable rates over time [51–54]. The IMPACT Working Group study of 2013 [44] adopts a sophisticated approach in order to tackle the subtle methodological traps that are hidden in a service situation, especially from subgroups of the dynamic target population. In this, at any point in time, there are always subgroups of women whose screening exposure is so short as to have no measurable impact, thus causing a dilution of the screening benefit (in part again a consequence of working with insufficient follow-up times). Among the solutions adopted in this study, there was the exclusion from analysis of women aged 50 to 54 because of screening exposure necessarily below 5 years and reference to pathological tumor size (beyond 2 cm) to define advanced cases, rather than the pN data, in consideration of the substantial stage migrations observed in recent years after the introduction of sentinel node biopsy and improvements in the pathological study of lymph nodes. This study, based on a total of 14,447 incident cancers, was able to show a significant and stable decrease in the incidence of late-stage BC from the third year of screening onward. Incidence rate ratio was 0.81 at years 3–4, 0.79 at years 5–6, and 0.71 at years 7–8. This result is consistent with an effect of MS in reducing advanced cases (which anticipates the effect on mortality) around 20% in the first 3–4 years after the screening starts, increasing to some 30% in the medium term (5–8 years), showing a consistent effect in a real-life situation with data of a screening population of 700,000 women, 55–74 years old, from 700 Italian municipalities.

To further stress the importance of extended follow-up times, one cannot leave unmentioned one large Swedish experience of service screening, where an earlier assessment based on mean follow-up of 8 years [55] yielded a nonsignificant impact of MS on BC mortality of younger women (40–49 years old) with a RR of 0.91 (95% CI: 0.72–0.95), while a subsequent publication on the same material [56], but with follow-up extended to 16 years, gave a strong, significant 38% mortality reduction in the same age group (RR = 0.62, 95% CI: 0.42–0.91).

Another study that deserves a special mention was published in 2011 [57] and represents one among many outstanding contributions from a research group based at the Dutch National Reference Centre for Screening in Nijmegen (in this case, as a joint effort with UK experts). This study investigates the impact of screening from the start of the Nijmegen service screening program in 1975 up to 2008. With a case-referent approach [58], BC death rate was 35% lower in the screened women, in the complete period. What is new to this study is the demonstration of a favorable trend of increasingly strong reduction in mortality over time, attributable to MS, from 28% in the period 1975–1991 to 65% in the years 1992–2008 (OR =0.35; 95% CI = 0.19–0.64). The authors consider the probable role of improvements in the quality of service screening in achieving these results, not only from a technical point of view (i.e., availability of more modern technologies) but also from progressions in quality assurance and special training of dedicated

personnel. Also, the multidisciplinary management of BC and a greater combined effect of modern treatment and early detection are highlighted, as possible causes of this progressively increasing benefit.

17.1.3.2 The Overdiagnosis Issue and the Balance Sheet

Given the massive high-quality data in favor of a relevant positive effect of MS on BC mortality, such as to be eventually conceded even by the harsher opponents, the last decade has seen a new outburst of objections, focused on the alleged harms of screening potentially surpassing the possible benefits. In other words, the question is whether the benefits provided by MS are more substantial than any unwanted effect that it may produce.

This debate has often taken the form of a "balance sheet" of screening benefits vs. the potential side effects of the organized intervention. The major potential harms that are taken into account are false-positive recalls and overdiagnosis.

Other negative effects are generally agreed to carry a negligible weight. These would include the risk of X-ray-induced cancer, estimated at 1–10 per 100,000 in a recent review [59], and the false reassurance, which might entail a delay in BC diagnosis after a negative screening result; this is also considered to have minimal effects [60]. When performing the balance sheet exercise, depending on a series of assumptions and on the reference value considered, as apparent from the simple comparison of Tables 17.1 and 17.2, the final picture can be very different. All in all, the Euroscreen publication of 2012 [61] provides the best reference demonstration to date of a well-devised scenario based on a reasonably weighted evidence base.

Overdiagnosis

Central to this field of dispute, the argument of overdiagnosis has been fueled by many in these last years and has in fact been at the basis of the institution of the special panel of experts in the UK that eventually produced the "Marmot report" [7]. To this, the reader is once more referred for an extensive, knowledgeable coverage of this particular argument, and its many methodological implications, although some caveats, will be discussed in this paragraph.

Overdiagnosis is indeed a momentous subject in screening research and evaluation. It refers to the possibility that anticipating the time of diagnosis before clinical symptoms are apparent will result in a number of cancers diagnosed, which would not have provoked harms in the woman's lifetime, if not detected by screening. The two crucial aspects are the quantification of overdiagnosis and the impact on the woman's well-being of an overdiagnosed cancer.

The major methodological difficulty in estimating overdiagnosis lies in the ability of recognizing the excess incidence due to lead time and separates this from that due to overdiagnosis. The excess "lead time" incidence is in fact a requisite of MS, necessary to allow for early diagnosis and effective treatment. In the absence of overdiagnosis, this increase in BC incidence as women enter the screening program would be balanced by a similar decrease in cancers among older women exiting the program at the upper age limit: this phenomenon has been defined as the "compensatory drop" [62]. Again, this requires either a very long follow-up time in order to be fully accounted for or some well-devised statistical adjustment. The UK Independent Panel, recognizing the utter difficulty of the estimate, takes a conservative position, based on data from only a few RCTs (Malmoe plus the Canadian trials), and considers overdiagnosis at about 5–15% from the population perspective and 15–25% from the individual woman's perspective.

The Euroscreen Working Group [61] starting from a focused review of the literature [63–67] concludes on a more substantiated estimate of overdiagnosis in the range from 1 to 10%.

A recent work by Duffy and Parmar [68] reinforces the need for observations up to 10 years beyond the upper age limit for screening (which means up to 30 years of complete follow-up) in order to compensate for lead time and nullify the pseudo-excess of overdiagnosed cases. This represents one further and very strong caveat against all studies that fail to take into account the very long natural history of BC and the related lead time required in order to cash the screening benefit: such studies would produce inconsistent conclusions if based on nonindividual data and/or too short observation times. Also the need for correcting for underlying incidence trends independent of screening requires estimates and extrapolations. This adds to the difficulties and has been taken by some as an excuse to ignore a problematic issue, in fact ending up with even less reliable estimates. Duffy and Parmar convincingly conclude that previous measures of overdiagnosis are likely to be overestimates. They point to further empirical evidence that overdiagnosis is a smaller problem than generally thought, as can be derived from the TCS, where at 29 years the cumulative incidence was identical between study and control groups [69].

However, they also admit that their estimates include only the invasive cancers, while a substantial part of the overdiagnosis debate involves the possibility that MS could detect a vast number of preinvasive lesions that might never evolve into clinically significant cancers. One very recent study [70] shows that this assumption—and the idea that large numbers of invasive BC would never progress in the absence of treatment—might have no actual evidence base. In this paper, an analysis of data from over 5 million women in the UK screening program showed an inverse correlation between invasive interval cancers and DCIS detected at screening. This association suggests that detection and treatment of DCIS at MS effectively prevent invasive disease.

The balance sheet

The Euroscreen Working Group [61] has created a decision-making scenario where the essential components of the harm/benefit balance could be fitted and discussed in a way that could be effectively communicated to the population involved [71]. Such a setting would also allow for the possibility that updated figures could be inserted and worked up as new evidence should be made available. This scenario considers 1000 women entering MS aged 50–51 and screened biennially until 69 and followed until 79 years (a substantial observation time of 30 years). Based on evidence from European service screening programs, results are expressed as a number of women that need to be screened (NNS) in order to achieve any specific outcome. With this framework, estimates are of 125 NNS to save one life (benefit) vs. 250 NNS to have one overdiagnosed BC and 33 NNS to have one invasive assessment (harms). These results represent a brilliant, honest, scientifically sound collection of data that are intended as a tool that will help a woman who is invited to screening to make an informed personal choice about the implications of participating. To such scope, a narrative was also created to help explain a complex situation, like screening actually entails [61]. Two small European cities are described, with 1000 female residents aged 50–51, where only one city invites women to an organized MS. This results in the outcomes outlined in Table 17.3: over 20 years, there will be eight fewer deaths from BC at the cost of four overdiagnosed cases and a considerable number of false-positive assessments. In this narrative, it is stated that "most of the women participating in screening will have only negative mammograms and, therefore, will have no benefits other than a reassurance about their health status, and only short-term harms from service screening (discomfort, anxiety)."

Arguably, this last point may be considered as a diminishing appreciation of the importance of regular, true reassurance about individual women's health status, with regard to such a high incidence disease as BC. At a closer survey, the picture delineated in the Euroscreen narrative shows some weakness in its aiming at a faithful representation of the health-care scenario in the absence of organized MS. Indeed, BC expected in the population with no organized MS should not be considered to come at no cost, be it financial or from side effects. In the absence of an organized program, women still have breast symptoms; besides that, some of them do have tests in a "spontaneous" screening fashion.

Organized MS involves setting up multidisciplinary specialized units, staffed by dedicated personnel, with special training. It also requires regular quality assurance procedures, monitoring, and evaluation of ongoing activities. Screening guidelines and protocols pay close attention to specificity and require that screening cases come to a definite conclusion after each episode, discouraging short-term repeat examinations, as is common practice in many clinical settings.On the other hand, areas not covered by organized screening tend to be served by non-breast dedicated clinicians, resulting in a higher number of unnecessary examinations, inconclusive test, and less straightforward protocols. This is represented in the comparison of the UK organized screening vs. the performance of spontaneous screening mammography in the USA, as detailed in a study by Smith-Bindman et al. in 2005 [72]. This showed that a slightly higher cancer detection rate in the USA was obtained at the expense of more than double recall rates and surgical biopsy rates. These results are fitted in a scenario similar to the one in the Euroscreen balance sheet. A face-to-face comparison (see Table 17.4) immediately shows that it is totally unfair to suggest that the city with organized MS produces 200 false-positive recalls, thus causing more psychological harms than in a neighboring city with no such program.

A possibly more faithful narrative—to accompany and illustrate a revised form (Table 17.5) of the balance sheet—may be the following:

Consider two small towns where an important group of diseases, namely, breast cancers, because of their clinical implications and very high incidence, cause per se a large burden of anxiety in the female population. In one city an organized, controlled, specialized program offers women the continuing reassurance of well-managed periodic tests, significantly cutting back the mortality rate from the disease, at the cost of a limited number of overdiagnosed cases. Participating in such program would also confer these women a reduced burden in terms of false-positive assessments, less psychological harms from too frequently repeated examinations with no conclusive diagnosis, as compared to the neighboring city where such program and all the related skills, organization, protocols, and

Table 17.3 Harm/benefit balance sheet for organized mammography screening of 1000 women[a] from the Euroscreen Working Group 2012 [61], modified and expanded

Outcome	For every 1000 women screened for 20 years	NNS
Number of BC diagnosed	71	14
BC mortality reduction	8	125
Over-diagnosed BC	4	250
False-positive (FP) tests, of which:	200	5
– FP recalls, with non-invasive assessment	170	6
– FP recalls, with invasive assessment (biopsies)	30	33
Reassurance of true negative cases (all rounds)[b]	729	1.4
Equity of access to high quality health care[b]	1000	1

BC breast cancer, *NNS* number needed to screen
[a]Women entering screening at age 50, screened biennially until 69 and followed until 79
Mortality reduction was adjusted for self-selection bias

Mortality reduction adjusted for self-selection bias

quality assurance are not available. The point suggested in the present pages is that the false positives of organized MS should in fact be considered as a protection conferred by screening, being largely inferior in number when compared to a setting of spontaneous, low-specificity clinical and preventive medicine. Hence, balance sheets of harm/benefits of organized screening should not register the false-positive recalls as screening harms. Instead, the true reassurance conferred to the majority of the population, again and again over many years, by an organized program and the equity of access to highly specialized medical care that service screening provide, should stand out among the major benefits of MS alongside the topmost target achievement of reduced BC mortality (Table 17.5). So, the above-quoted statement might be reworded as most of the women participating in screening will have only negative mammograms and, therefore, will have the continuing, long-term benefits of a reassurance about their health status and only short-term harms from service screening (discomfort, anxiety). A valuable communication of benefits and harms of screening to decision-makers, to women, and to the scientific community itself [71] should consider alongside the effectiveness and the limitations of the procedure and the relevance of such factors as trust, gratitude, and convenience that may play an important role in the informed choice to participate. It should be explicit that balance sheets (Tables 17.3 and 17.5) are the product of dedicated professionals. They are bound to set up effective health initiatives and on this basis produce communication tools that can be transparent and honest, but that cannot be neutral. There are other historical merits to be credited to MS. The leading role of the organized MS experience of the 1970s–1990s in building up the idea that there was a need for dedicated professionals with specific education, training, and expertise in BC diagnosis and treatment is rarely, if ever, remembered. The importance of interdisciplinary, collaborative management of BC by experts in senology has been advocated by the screening guidelines, at a time where senology was hardly recognized by most physicians as a field of specialization in its own right. This awareness has greatly contributed to the institution of the Breast Units system as an international standard of care. An important concluding recommendation would then be, when reminding potential harms of attending screening, to give a proportionate emphasis also to harms entailed by not attending the program: larger tumors, worse stage at diagnosis, more systemic treatment, and worse survival.

17.1.3.3 Inconsistency of the "Expired Validity" Issue

It has been shown that RCTs and service screening data proved that MS is valid and effective and that its side effects would be minor with respect to the potential benefits. At this point, the question has been arisen whether early detection through MS still holds its meaning in the new era where very effective treatments have become available and if most of the mortality reduction from BC that has been recently observed should be credited to treatment, rather than screening. This is a reasonable question in itself, but once again the answer is clear: there is substantial evidence that MS still plays an important role in BC management and cause-specific mortality reduction.

Some of this evidence has been already discussed in the above paragraphs. Of special relevance to this point are the service screening studies performed in the last 15 years [30–32, 40–43, 56, 57]. These do show net benefits for women attending MS compared to nonattenders, who still have potentially access to all the advanced treatments available in the regional health-care system. One publication [57] has brilliantly shown that screening not only retains its effectiveness in the recent years of sophisticated oncological

treatment, but in fact it contributes a favorable trend of increasingly strong reduction in mortality over time. This reminds that alongside advancements in therapy, improvement of radiological techniques also come into the picture, enhanced by the virtuous setting of quality assurance, dedicated training, and interdisciplinary collaboration in a new Breast Unit arrangement that organized MS contributes to develop.

The intuitive concept that even in an epoch when sophisticated systemic therapies are available, small, node-negative BC as those detected at screening still carry a significant survival advantage, has been confirmed by many.

Of special interest, and largely unappreciated by many physicians, is the demonstration [5] that screening detection of small tumors not only reduces the incidence of lymph node metastases but also prevents the worsening of their malignancy grade.

An Italian service screening study [73] showed an improvement in survival rates by before-after invitation period in an intention to treat analysis addressing the fact that screening changed the pattern of tumor characteristics in the population. Within the same tumor characteristic subgroups, survival was comparable, supporting the hypothesis that the difference in prognosis observed was due to early diagnosis rather than differential treatment or access to treatment.

Other experiences [42] support the idea that notwithstanding the advances of modern systemic therapy, large differences persist in prognosis by extent of disease at diagnosis. One paramount confirmation is from the Swedish experience, where individual counties had the possibility to choose 40 or 50 years as the lower age of screening. This gave the chance to measure the impact of screening in a population aged 40–49 including over 16 million women-years with 16 years of follow-up. The significant 29% decrease in BC mortality that was demonstrated for women who attended screening (RR 0.71; 95% CI 0.62–0.80) occurred in a country with uniform treatment guidelines. This proves that this mortality reduction was achieved in addition to the benefits of modern therapeutic advances [74].

It is clear that both early detection and modern treatment have merits in achieving the long-awaited for reduction in BC mortality: it would then probably be a much better way to look into the future to recognize the mutual enhancing power of the two, as early detection allows for more refined treatment options and for the adjuvant therapies, both medical and radiation based, to achieve extraordinary results in disease control. In other words, rather than keeping up a long sequence of futile controversies, it could be more advantageous to devote resources to a very appropriate topic for research: how early detection might or should change the treatment of some subgroups of BC.

17.1.4 Evolution

A positive evolution of BC screening has to build on the clear appreciation of what can already be achieved through the "classical" population-based programs. Physicians, healthcare providers, and the population alike have to understand that MS contributes a significant reduction in BC mortality and represent a major achievement and a public health intervention of demonstrated feasibility and cost-effectiveness. Future developments of screening should prove not only their absolute efficacy but also their feasibility and sustainability in terms of incremental cost-effectiveness, in order to guarantee that the new policy should not put at risk the regular management of the existing MS programs.

To date, screening has been implemented on the two strongest risk factors for BC, i.e., sex and age. However, in this epoch of personalized medicine, the concept of tailoring BC screening to different levels of risk has gained increasing interest. Mammography has been regarded as the most suitable test for screening, due to the evidence available, its reasonably high sensitivity and specificity, and low cost. It is important though to be aware of the limitations that a single screening tool entails and that while alternative breast imaging techniques have been around for decades, recent advances in digital-based diagnostic devices and information technology (IT) have widened the spectrum of imaging possibilities.

Keeping in mind the big caveats regarding (1) evidence of efficacy, (2) incremental cost-effectiveness, and (3) sustainability, one might think about screening evolution, apart from the special policies already envisaged for the population at the highest risk (the theme of the following chapter) according to the three main pathways:

(a) Tailoring the screening process on the basis of different levels of risk (low to intermediate)
(b) Introducing new screening tools (technological evolution)
(c) Increasing the effectiveness through improvements in the overall quality of the process

17.1.4.1 Tailored (Risk-Based) Screening

This involves the idea of offering customized screening policies on factors influencing the risk and/or the performance of the intervention, such as (1) age, (2) breast density, and (3) other personal risk factors. The assumption is that benefits and harms/limitations of screening vary according to BC risk, so that such tailoring of interventions may optimize their balance.

(1) Age—Besides sex, age has always been identified as the main risk factor for BC. All MS projects have been tar-

geted to those age groups where the general consensus recognized the optimal cost-effectiveness balance; these are most commonly the 50–69 years old women.

Younger and older women have always represented a subject for discussion, and in the past, there was a major debate over the appropriateness of offering MS to women in their 40s.

Arguments against screening the 40–49 years old included the lower incidence (and mortality) and the predictable lower efficiency of the screening test due to the limitations of mammography in denser breasts, both of which contributed to the lower mortality reduction observed in the RCTs. Recent data have clearly demonstrated a relevant impact on mortality also in these younger women, when offered MS. This is unequivocal in studies that can provide extended follow-up [56, 74, 75]. As to incidence, the major, abrupt increase in most western countries is obviously at the 40–44 age group, when incidence exceeds 100 cases per 100,000 women per year. Women diagnosed with BC when 40–49 account for a significant proportion of the BC mortality, in fact similar to that attributable to 50–59 and 60–69 years old women [76]. This leads to the conclusion that there is no scientific reason to exclude this age group from a screening program, beyond issues related to resources and feasibility.

Another important point to consider is that life expectancy at birth has in many countries surpassed 80 years for the female population, and for women aged 69 (the upper age target for most programs), life expectancy may exceed 15 years. This implies that stopping invitation after 69 is no longer adequate. Since diagnostic capabilities of mammography in older women are particularly good, and screening efficacy up to age 74 was proven by RCTs, also the optimal upper age limit for screening should be carefully discussed. In 2007, the Italian Society for Breast Cancer Screening (GISMa) produced a consensus document [77] that envisaged the possibility to extend screening to age groups 40–49 and 70–74, where sufficient resources were available. This has in fact been implemented in some Italian regions. A similar strategy of extended screening beyond age 70, based on self-referral of women interested, is in practice in the UK. Sweden, the home to most of the historical RCTs, has been and probably still is the country with the widest age span covered by screening: women aged 40–74 years are offered screening in many Swedish counties as opposed to 50–69 years of age in most other nations.

Another aspect strictly connected to age is the interval between screening rounds. The evidence base for current protocols lies mainly in the results of the RCTs. Considering the high proportional incidence of interval cancers in the second year after screening in the age subgroup 50–54, the Swedish option of screening ages 40–54 every 12–18 months and switching to the 18–24 months interval for ages 55–74 is arguably a better solution than the 24 months interval, starting at age 50 that is adopted by most screening guidelines worldwide. Availability of financial resources still remains one background decisive factor in determining these policies.

(2) Breast density—Breast density, being both a risk factor and a determinant of lower performance for mammography, has been the most discussed criteria to develop customized screening strategies. Many studies and proposals have been produced on this subject, actually resulting in very limited practical achievements until very recently. The subject remains extremely complex, and some issues are still to be clearly defined. Different patterns and composition of breast densities exist; the relation between density and cancer risk needs to be further understood, although it is clear that high mammographic density decreases sensitivity and the positive predictive value (PPV) of mammography, resulting in more interval cancers.

The introduction of digital mammography has already modified this situation to some extent, although the major advances are expected from the introduction in screening protocols of more modern, tomographic imaging techniques, like digital breast tomosynthesis (DBT) and automated whole-breast ultrasound (AWBU).

In recent years, modern digital technology has also made available softwares that can automatically calculate breast density values; these softwares may contribute to higher reproducibility in the classification of density levels. These measures are then used alongside personal risk factors in the definition of statistical models of BC risk. However, a precise definition and a consensus on optimal thresholds and statistical models are still lacking. In the USA, a specific legislation has made it mandatory to inform women about their breast density and the limitations of mammography in dense cases, so that women may decide to have additional examinations. From an organized screening perspective, before additional diagnostic techniques or modified protocols do not prove cost-effective, it would be questionable to stress communication on this issue, which is also generally exaggerated by the use of relative rather than absolute risks.

(3) Other risk factors—Other personal risk factors have been considered, including personal history (previous BC diagnosis or atypical hyperplasias), family history of BC, socioeconomic status (SES), comorbidities, etc. More recently, milder degrees of hereditary susceptibility to BC have been considered, as those related to the study of single nucleotide polymorphism (SNP) [78, 79].

As the overall risk cannot be calculated as a mere sum of different risk factors, it will be essential to develop and validate efficient prediction models. The availability of more sophisticated IT support will probably provide powerful tools and play a decisive role in the advancement of this line of clinical research, also through sophisticated modeling that may con-

tribute to the design of risk-stratified forms of screening, where a better balance between costs, harms, and benefit could be achieved offering adapted programs to different groups of women [80, 81]. In this framework, costs and harms may be contained also reducing screening offer to women at lower risk.

In summary, risk-based tailored evolutions of MS are at hand where revision of the age limits and frequency (1) of screening are concerned. As for factors in points (2) and (3), the general situation is that offering more intensive (or also less intensive) screening, based on one or a combination of the above factors, might indeed result in a qualified improvement in the risk/benefit balance. However, more research and clear data are warranted, as the underlying concept states that marginal gains in effectiveness have to be proven, and the big caveat remains about creating increasing motives of complexity that could eventually detract from the practical management of the screening system.

One major challenge for the future would be to devise strategies where risk-stratified screening would be offered in combination with primary prevention measures, targeting modifiable risk factors, like obesity, through interventions on diet, lifestyle, etc.

17.1.4.2 Introducing New Screening Tools (Technological Evolution)

This is the most promising pathway for BC screening evolution, given the development over the last decade of very promising, new imaging tools, sharing two common denominators: digital framework and tomographic technology. Indeed, tomography-based imaging ideally represents the optimal solution to overcome limitations of mammography in dense breasts. These techniques are (1) magnetic resonance (MR), (2) digital breast tomosynthesis (DBT), and (3) automated whole-breast ultrasound (AWBU). Since these are the subjects of the following chapters in this textbook, to these the reader is referred for extensive discussion and relevant references. At this point, only a very essential-focused comment will be given.

1. MR is by far the most powerful instrument in this series, combining excellent morphologic, three-dimensional representation with functional data. At this moment, however, its use in screening has to be limited to the very high-risk patients, mainly on cost considerations.
2. DBT has the widest literature as a potential new screening instrument. Being in fact a modified version of mammography, its introduction in the screening organization is relatively simple, and a number of studies have proven its ability to increase cancer detection rates in screening settings [82, 83]. Data on specificity are less uniform, yet promising as well. Concerns about the higher radiation dose delivered to the population will be probably overcome by technical developments and especially by the introduction of synthetic 2D images. These should dispense with the need to obtain a double exposure in order to have 2D and 3D images available for the same woman. The main research topic for DBT in MS remains the demonstration of a significant impact on the interval cancer rate. Cost issues are mainly related to the prolonged reading times of the tomographic sequence, rather than to significant modifications in the patient workflow. In fact, the extremely promising diagnostic data and its minor impact on the screening organization have led to DBT being already introduced in some screening programs, within randomized trials or pilot demonstration studies.
3. Automated whole-breast ultrasound (AWBU) takes into the diagnostic field a brilliant combination of the superior ability of sonography to read through the denser portions of the breast with the advantages of an automated procedure that is able to guarantee a more standardized coverage of the breast volume. Due to the superior sonographic potential in dense tissues (at no radiation costs) and hence also a powerful integration with mammography, this technique carries the potential for a more relevant diagnostic contribution than DBT. However, a few studies available to date in the screening setting, while confirming the expected very promising detection gain, show a substantial increase in false-positive values [84]. Moreover, the introduction of this technique in the screening context appears to be more demanding, not only for the extended radiological reading times but mainly in terms of radiographers' working time.

Another important contribution to be expected in the near future is the development of dedicated CAD (computer-assisted diagnosis) systems that will reduce the costs involved with the reading times of long series of tomographic images, be it DBT or AWBU.

17.1.4.3 Optimizing Existing Programs

It has been strongly represented how MS produces substantial benefits to the population in terms of cause-specific mortality reduction, and it has been discussed in the harm/benefit paragraph that an organized screening program provides significant advantages in terms of cost-effectiveness as compared to a spontaneous setting [72]. This reinforces the idea that optimization of the available system would be a rewarding field of evolution. Also in this field, the digital revolution of the past decades offers a number of new, interesting possibilities.

A recent, extremely detailed comparison of the costs involved by an organized service screening system [85] demonstrated significant savings both for the health system as a whole and from the women's point of view. The cost of mammography in a non-organized setting was more than

double compared to the organized program. Outside organized MS, social costs would also be higher, as those related to time lost from work, travel to the screening unit, telephone calls, administration costs, etc.

Moreover, the practical support provided to the female population by the organized setting, from the letter of invitation onward, contributes to its capacity to reach women in the lower socioeconomic categories, thus reducing inequalities in breast cancer survival. In one study [86] the lower survival rates in less-educated women before the launch of the organized MS disappeared completely in the age group invited to screening. The current design of MS has one major strength in the availability of a complex organization that embraces such aspects as detailed shared protocols and guidelines, quality assurance and audit systems, continuous evaluation, and feedback on the results to stakeholders. This is typically represented in the European Guidelines for Breast Cancer Screening [87] and in similar documents produced at the national or regional level in many countries.

Some crucial points that might be developed (and greatly gain from the introduction of digital mammography and the IT support) include:

1. Expanding the monitoring system, from the general program/unit level to the level of the individual operator, with regular personalized feedback on professional screening performance (e.g., recall rates, cancer detection rates), in order to allow for timely educational refreshments where needed. It is important that among the many performance indicators [87, 88] the most relevant will be selected for their special value. Interval cancers, representing a failure of the procedure, should be fully monitored to evaluate screening performance. The radiological revision of pertinent mammograms is a valuable tool of internal audit and a valuable occasion for training and continuing education of the screening radiologists. However, complete data on interval cancers may be difficult to collect. Large cancers (20 mm or more, i.e., T2+) that are screen detected at subsequent rounds represent an equally strong indicator of screening performance and (when combined with the T2+ interval cases) are the best early surrogate indicator of screening impact [5]. Screen-detected T2+ cancers are immediately available at the screening unit, so that their radiological revision would be more easily feasible than reviewing interval cancers—while also their educational value would be substantially similar [89]. As to the evaluation of screening performance and impact, analysis of the pathological size distribution of all BC in the population exposed to screening, expressed as absolute rates rather than percentages, should be regarded as a cornerstone.
2. Recognizing an enhanced role for dedicated education, investing on specialized courses and practical training of all the professional figures involved in the screening process, with a special emphasis on radiographers, radiologists, and pathologists. Specialized education is in many countries largely neglected, while it may probably result in the most rewarding field of investment in order to optimize screening cost-effectiveness. This process should routinely envisage the funding of National or Regional Reference Centres for Quality Assurance and Training for Breast Cancer Screening. The importance of having access to Expert Screening Training Centres is confirmed by the long-lasting experience of the Dutch National Training Centre in Nijmegen, as well as by the Swedish experience. This is effectively represented in one service screening study [90], where organized programs conducted in dedicated centers could consistently achieve mortality reductions at least as high as those observed in the RCTs. This achievement was built on the cooperation of screening centers in seven counties across Sweden, with the expert support of the leading researcher of the STC trial. Expert Reference Centres would represent the ideal site to set up and coordinate relevant research, as the Nijmegen (NL) and Falun (Sweden) experiences confirm.
3. Promoting innovative research taking advantage of the multidisciplinary context of screening. Research should be focused on the key issues of screening evaluation and risk customization. Besides that, it would be most appropriate to exploit the screening setting to foster research based on a radio-pathological cooperation. Improved standard pathologic techniques are to be implemented in order to create a better mutual understanding of the clinical significance of screen-detected lesions. Large-format histologic sections have already proven their value [91, 92] and supported the need for improved pathologic terminology that should reflect the site of origin of the lesions [93]. The integration of imaging morphology into the TNM classification of the in situ and 1–14 mm invasive tumor size range would represent a major advance. There is a considerable potential of mammographic tumor features alongside classical pathological and modern molecular prognostic factors to improve the outcome prediction of BC subgroups [94, 95]. Such radio-pathological synergy could enable the multidisciplinary team to better distinguish the less frequent subgroups with the highest fatality [94] among the small invasive cancers, thus allowing for setting up clinical trials that may identify the more successful, targeted treatment. For the majority of screen-detected, monofocal, small invasive cases that belong to the better mammographic and pathological prognostic groups [96, 97], the current use of adjuvant treatment might be reevaluated through more pertinently designed trials. This research cooperation may

eventually enable many women to forego some of the current adjuvant therapeutic regimens, without compromising their survival and avoiding the hazards of overtreatment. Finely tailored treatment protocols, based on a fuller appreciation of different parameters of tumor characterization, should make negligible any concern over the overdiagnosis of the more indolent cancer cases.

17.1.5 Discussion

The clear scientific evidence on the efficacy of MS as derivable from RCTs and its effectiveness in reducing BC mortality as confirmed by more recent studies conducted in the routine service screening situation have been reviewed and highlighted.

It has been shown how benefits achievable through MS are substantially undervalued.

This is not only the case with a number of skeptical authors, often on the basis of methodological flaws in their arguments. Also some screening advocates appear at times not to fully appreciate the size of the benefits entailed by organized screening. This can derive from:

1. The unjustified consideration paid by many to some large yet scientifically unsound studies.
2. The incomplete appreciation of many experts of the clinical peculiarities of breast tumors: especially their wide inter- and intra-tumor heterogeneity, extremely long natural history of many cases, and the concept of progressive dedifferentiation of BCs. Hence, it is not fully appreciated how MS benefits cumulate over very long times. Some screening dividends of lives saved are cashed as soon as 3–4 years after the timely detection at screening of aggressive cancers, while dividends of lives saved from more indolent cancers might still be cashed 10–15 years after screening detection. The most recent updates of the well-conducted observational studies of screening service, with the longest follow-up times, are wanted to gauge the full effect of MS on mortality (the screening dividend) and should be given prominent attention in the scientific debate. The same applies to the long-term follow-up of the best RCTs.
3. Screening harms related to false-positive recalls are unduly emphasized. It has been illustrated that the limited rate of false-positive recalls in population-based, organized screening is in fact a protection vs. the much higher rates observed in non-organized settings.
4. Neglect of the immense human and social value of MS and the diffuse, continuing real psychological reassurance it provides to the vast majority of true negative women.
5. Insufficient appreciation of the value of equity in the high-quality health-care access provided by organized MS.

It is important to state at this point one rarely, if ever remembered merit of screening. This is the leading role of the organized MS experience of the 1970s–1990s in building up the idea of a need for dedicated professionals, with specific education, training, and expertise in BC diagnosis and treatment. The importance of interdisciplinary, collaborative management of BC by experts in senology has been advocated by the screening guidelines at a time when senology was hardly recognized by most physicians as a field of specialization in its own right. This awareness has greatly contributed to the institution of the Breast Units system as an international standard of care.

There are also important, well-known limitations of cancer screening with mammography.

The lower sensitivity of mammography in dense breasts and—more generally—the traditional use of a single diagnostic tool for the early detection of a complex variety of clinical entities are obvious weaknesses. Although the use of a single test is motivated by evidence of impact, practical feasibility, and competitive cost-effectiveness, intelligent research has to be promoted to open the way to new protocols that take advantage of complementary imaging methods. The recent availability of such sophisticated technologies as DBT, AWBU, and MR will definitely accelerate this evolutionary process. The combination of the newest imaging methods with the powerful support provided by the modern IT systems is due to create a winning environment. Specially developed new CAD systems will help tackle problems related to the longer interpretation times implied by the tomographic techniques. The digital support will also play a role in the form of improved monitoring, evaluation, and educational tools, e.g., mammography test sets for training. Given the limitations of its current format, MS will have also to consider risk-based, customized screening policies, in order to maximize the cost-effectiveness of the system and the harm/benefit balance of the procedure.

So, future evolution of screening should be built on the organized setting of MS: introducing new diagnostic technologies, improving on the stratification of women and the way screening is offered (tailoring), making the most profit from modern IT technology support (simulation models, CAD, etc.), and threading along the main road of the specialized multidisciplinary units, where different specialties work together to optimize the synergies of diagnosis and treatment. Evaluation could be optimized, working on the most significant early indicators of performance (as T2+ cancer rates), refined to the individual operator level, and combined

to a more efficient system of feedback. Optimization should also be pursued of the information provided to physicians and the population and the communication tools.

The prominent importance of dedicated, specialized education, training, and research should be recognized and adequate resources provided. The organized screening framework represents an exceptional resource for producing applied research of the utmost scientific level, at competitive costs. One foremost topic of integrated research would be the innovative rethinking of the pathological classification of breast diseases, to be built on a strict collaboration of breast pathologists and screening radiologists. This new perspective could bring about a change in the fundamental concepts of BC treatment, making it negligible the concerns about screening overdiagnosis.

Conclusion

Implementing, expanding, and keeping up large, high-quality, population-based screening programs should be considered a needful strategy in order to best capitalize on modern treatment advances. In the future context of preventive medicine, innovative strategies may be devised aimed at combining risk-stratified screening with actions of primary intervention targeting modifiable risk factors. Futile controversies on the respective roles played by early detection vs. modern treatment should be abandoned, in favor of a shared awareness that these two major innovations enhance each other's benefits and of research projects on the theme of how early detection through screening might and should change the treatment of breast cancer.

17.2 High-Risk Population

Francesco Sardanelli, Franca Podo

Abstract Although breast cancer (BC) is mainly a sporadic disease, about 15% of cases are clustered in families at increased incidence. Gene mutations with autosomal dominant inheritance confer a 50–85% cumulative lifetime risk (LTR) and account for about 5% of BCs; about 50% of hereditary BCs are associated with BRCA1/2 mutations. In high-risk (HR) women, mammography has a too low sensitivity (29–50%) to be used alone as a screening tool. Nonrandomized studies showed that contrast-enhanced magnetic resonance imaging (CE-MRI) largely outperforms mammography and/or ultrasound in detecting asymptomatic BCs in HR women, reaching a sensitivity higher than 90% and a positive predictive value higher than 60%. In 2007, the American Cancer Society issued recommendations in favor of *MRI as an adjunct to mammography* for screening women with 20–25% or greater LTR, including those with a strong family history of BC or ovarian cancer or previously treated with chest radiation therapy (CRT). Recommendations in favor of MRI screening for HR women were also issued by other institutions and medical bodies. Studies suggested that MRI screening of BRCA1/2 mutation carriers should not be discontinued over 50 and that an *MRI alone* strategy could be adopted, also considering the higher sensitivity of these mutation carriers to ionizing radiation. Although randomized controlled trials are not allowed for ethical issues, evidence exists in favor of MRI screening to improve patient outcome. In cases of previous CRT, *mammography as an adjunct to MRI* is recommended, because a high incidence of ductal carcinoma in situ with microcalcifications and low neoangiogenesis limits MRI sensitivity.

17.2.1 Introduction

Exactly 30 years ago, in 1986, Sylvia H. Heywang and coworkers reported the first experience about contrast-enhanced magnetic resonance imaging (CE-MRI) of the breast [98]. Notably, only some months before, in 1985, the same author concluded a paper about unenhanced (*non-contrast*) MRI [99] saying that "possible future indications are suggested for selected cases," an elegant way to state that non-contrast breast MRI had no real clinical perspective. Conversely, when, for the first time, a gadolinium-based contrast material had been intravenously injected, "all carcinomas enhanced" and the authors concluded that "preliminary results indicate that MR imaging of breast using Gd-DTPA may be helpful for the evaluation of dense breasts and the differentiation of dysplasia and scar tissue from carcinoma" [98].

This was a turning point which opened a window for breast MRI to enter the clinical practice. At the beginning, even after the introduction of contrast injection, radiologists who pioneered the use of this technology (a name for all, Werner A. Kaiser, who firstly showed the value of dynamic scan for CE-MRI [100]) faced difficulties and distrusts from the established medical community working on breast cancer (BC). Even breast radiologists, who were in those days highly confident with the so-called triple assessment composed by mammography, ultrasound (US), and needle sampling, were not so favorable to MRI. Although mammography was still in the era of film-screen, US B-mode images were distant from today's quality, and needle sampling was mainly fine-needle aspiration, surprisingly breast CE-MRI did not receive a good acceptance.

Breast MRI investigators highlighted that the new method allowed BC identification thanks to its ability to visualize *neoangiogenesis* associated with tumor progression, a completely

new functional imaging approach intrinsically different from the only morphologic evaluation of mammography and US. Physically speaking, two completely different pieces of theory are involved: differences in photon attenuation as an effect of *electronic density* on the X-ray side and differences in nuclear magnetic relaxation times due to the local uptake of the paramagnetic contrast material on the CE-MRI side. Unfortunately, the reference to tumor-associated neoangiogenesis was reminiscent of the old thermography, an approach leading to a false hope for BC diagnosis as it was burdened by a high rate of false negatives and positives,[1] although it is still sometimes represented as a new method [101].

The main criticisms against breast MRI were based on high cost, need of contrast injection, and, above all, an alleged high rate of false positives. A *mantra* arose very soon: *breast MRI has a high sensitivity but a low specificity*. This was due to some papers reporting results of CE-MRI of the breast when descriptors and methods for interpreting breast MRI were still in their infancy. In fact, MRI was firstly considered in the Breast Imaging-Reporting and Data System by the American College of Radiology only in 2003 [102]. Thus, every contrast-enhancing breast finding could at that early stage be considered as suspicious, with the result that small studies often reported low specificity values. Unfortunately, those small studies became the reference against breast MRI.

One clear example of this misleading use of published data is given by the comparison of two papers published in 1993–1994.[2] In 1993, a small breast MRI study from the USA [103], conducted on 30 breasts with 47 malignant and 27 benign lesions, reported a 94% sensitivity and a 37% (!) specificity; these data were included in the Abstract. A year after (1994), a group from Germany, guided by Werner A. Kaiser, reported 2053 cases, 766 with histopathological verification within 2 weeks ($n = 766$) or follow-up control up to 7 years [104]. The title was "False-Positive Results in Dynamic MR Mammography: Causes, Frequency, and Methods to Avoid." Sensitivity was 98%, specificity 97.4%, and PPV 81%. Unfortunately, these results were not reported in the Abstract, thus leading to a strong underestimation of the value of the paper [105]. Looking at the number of citations through Scopus® [106], up to April 26, 2016, the small US study [103] had 580 citations, while the huge German study [104] had only 56 citations. For decades, when researchers reported a range for breast MRI, specificity values, this notorious 37%, the lowest range limit, drew the reader's attention. *Bad news have better legs than good news*.

However, 1993 was also the year of the first report on tumor suppressor BRCA1 gene conferring a high BC risk to women carriers of a deleterious mutation [107]; the identification of a similar role for BRCA2 followed very soon [108]. This relevant new knowledge created the possibility to identify not negligible populations of women having a clearly higher risk of developing BC during their lifetime.

As a consequence, teams of breast radiologists, mostly in cooperation with geneticists, physicists, and other professionals, initiated studies in order to compare the diagnostic performance of CE-MRI with that of conventional imaging (mammography and/or US) for screening high-risk populations. In Italy, we started the discussion in the late 1990s under the coordination of the Istituto Superiore di Sanità, organ of the Italian Ministry of Health, in Rome. For more than 10 years, we guided the High Breast Cancer Risk Italian (HIBCRIT) study for the comparative evaluation of CE-MRI vs. mammography and US for early BC diagnosis among women at high genetic/familial risk. The initial results of this study were published in 2002 [109] and contributed to the initial body of evidence considered by the American Cancer Society for the first recommendation in favor of *MRI as an adjunct to mammography* for screening women with 20–25% or greater lifetime risk [110]. Interim [111] and final [112] results of the HIBCRIT study further contributed to support the use of CE-MRI for screening women with hereditary BC predisposition.

In this chapter, the *high-risk* screening issue is placed in the larger context of the screening debate, and then the evidence in favor of MRI screening protocols for women at hereditary high risk is summarized in terms of superior diagnostic value, including the *MRI alone* concept, and in terms of patient outcome. Thereafter, the special case of high risk from previous chest radiation therapy (CRT) will be considered.

17.2.2 The Context: Population-Based Screening Programs

Mammography, notwithstanding its intrinsic limitations in terms of sensitivity and specificity, remains the basic tool for population-based mass screening, being demonstrated to be effective in reducing mortality and allowing for conservative therapy [113]. The stage of BC at diagnosis significantly impacts on overall survival even in recent years, when effective systemic therapies are applied. In other words, *early diagnosis remains crucial*. This concept has been recently confirmed by a population-based study from the Netherlands Cancer Registry evaluating more than 170,000 patients: although the rate of those receiving neoadjuvant/adjuvant therapy from 1995–2005 to 2006–2012 increased from 53 to 60%, in 2006–2012, mortality still increased with progress-

[1]Notably, some new currently emerging technologies such as *optical imaging* and *opto-acustic imaging* should not be confused with the old *thermographic* methods. Interesting research on these new approaches is ongoing, and good results may be possible. See, for example, Sella T, Sklair-Levy M, et al. (2013) A novel functional infrared imaging system coupled with multiparametric computerised analysis for risk assessment of breast cancer. Eur Radiol 23:1191–1198.

[2]This comparison was firstly reported in Amsterdam by Pascal Baltzer during the ceremony for the EUSOBI (European Society of Breast Imaging) 2014 Gold Medal to the memory of Prof. Werner A. Kaiser (*05.10.1949, † 27.12.2013).

ing tumor stage, significantly for T1c vs. T1a and independently from nodal status [114].

The International Agency for Research on Cancer (IARC) recently summarized the evidence in favor of screening mammography [59, 115]. The estimated reduction in BC mortality is 40% for those women aged 50–69 who take up the invitation and 23% when also including those not accepting the invitation. A mortality reduction has been also estimated for women aged 40–49 and 70–74, though with "limited evidence" [59]. In addition, we must note that screening mammography allows for both downscaling of the clinicopathological features of invasive BCs and reducing locoregional and adjuvant treatments [51, 116–118].

A good news of the last years is the *end of confusion*, as appropriately stated by the Society of Breast Imaging about harms from screening mammography [119]. This is a hot topic, in particular for *false-positive rate* and *overdiagnosis*. In Europe, the average risk for a false-positive recall is limited to 20% for women aged 50–69 who have ten screens in 20 years; the probability of false-positive needle biopsy is <1% per round [59]. A low rate of overdiagnosis has been calculated by the IARC working group [59], from 1 to 10% or from 4 to 11%, according to different estimation methods. Notably, *overdetection* (a radiological issue) has to be distinguished from *overdiagnosis* (which implies also an essential role of pathologists) [120], while more efforts should be dedicated to the reduction of *overtreatment*.

However, one weak point of current population-based screening programs remains the *one-size-fits-all* rule: in Europe, mammography every 2 years (every 3 years in the United Kingdom) from 49 to 69 years. Some change has been introduced when also women from 40 to 49 (mostly from 45 to 49) are invited: the periodicity is commonly reduced to 1 year only. During the last three decades, organizational issues and other factors worked against the idea to stratify the screening strategy according to the risk level and breast density. The latter factor is relevant: even though density as an independent risk factor is commonly overestimated [121], its masking effect results in a relevant reduction in mammography sensitivity [122]. An organized screening strategy tailored for the woman's individual risk, also considering breast density, is a hope for the future.

Coming to the crucial point, it was clear that the diagnostic performance of mammography in high-risk women was inadequate. The sensitivity ranged 29–50%, the interval cancer rate 35–50%, and the metastatic nodal involvement at diagnosis 20–56% [123]. Something different had to be proposed. A new screening strategy to be implemented had to consider four elements:

1. The need to start very early in the high-risk woman's life, accounting for the early disease onset
2. The need for closer screening events, accounting for the fast BC growth in these women
3. Independence of the screening tool from breast density, accounting for the woman's young age and for the higher breast density in high-risk women
4. Possible avoidance of ionizing radiation exposure, accounting for the higher sensitivity to radiation of BRCA mutation carriers (as explained in detail below)

This was the scenario when the first studies on MRI-including screening programs were initiated. The only change in those years and during the first decade of 2000 was the slow but progressive transition from film-screen to digital mammography, without any substantial impact for high-risk women.

17.2.3 High-Risk Screening with MRI: From a *Mission Impossible* to a Large Body of Evidence

To explore the diagnostic power of CE-MRI in a screening setting was initially a *mission impossible*. The typical objection was the following: *MRI specificity is too low, and you will be flooded by a deluge of false positives*. However, as stated by Thomas Kuhn [124], scientific research is attractive also due to "the excitement of exploring new territory, the hope of finding order, and the drive to test established knowledge".

Thus, different groups started to verify the hypothesis that CE-MRI could be useful for BC screening. For epidemiological reasoning, women at increased BC risk, especially those with hereditary predisposition, were the natural candidates for these projects. A greater expected incidence would have resulted into a higher positive predictive value (PPV) of screening modalities and a smaller sample size needed to evaluate the differences in diagnostic performance among the modalities [125]. This was also a way to begin to dismount, from the side of high risk, the *one-size-fits-all* rule.

In fact, breast radiologists had to get at least a basic information about familial/genetic predisposition to BC [126]:

- Autosomal dominant inherited BCs are only 5% of all cancers (one third of all familial BCs).
- BRCA1/2 mutations explain only about 40% of autosomal dominant inherited BCs (other genes such as TP53, STK11, PTEN, NF1, CHEK2, ATM, BRIP1, and PALP2 explain about 10%), while the remaining 50% has no gene mutation clearly identified. BRCA1/2 deleterious mutations confer a 50–85% LTR.
- Most BCs in very young women are associated with a BRCA1 mutation, a condition which may also show association with ovarian cancer.
- In women carrying a BRCA2 mutation, the risk profile is shifted to a slightly more advanced age, while BCs in males are commonly associated with this type of mutation.

This body of knowledge allows radiologists, who have the possibility to deal with a large number of women on the occasion of screening and diagnostic imaging, to identify those women whose family history indicates the possible presence of an inherited BC predisposition. Software can be used for a preliminary risk evaluation, such as that based on the Tyrer-Cuzick model [127, 128]. Anyway, *radiologists (or other professionals who suspect a BC genetic predisposition) have to refer the woman suspected to be at high risk to a specialized department/center for genetic counseling to define the possibility of genetic testing.* Importantly, in the case of strong family history of BC and/or ovarian cancer without identification of known gene mutations in the family, genetic testing is defined as *inconclusive* and the case is labeled as *BRCAX* [129]. Finally, for different reasons, including unsuitable psycho-oncologic condition, many women with strong family history prefer not to perform any genetic testing.

Thus, since the mid-1990s, the context has been enriched to comprise three basic concepts:

1. Mammography, the only established method for BC screening in general, was not working properly for screening women at high genetic/familial risk.
2. Identification of high-risk populations could be based on clearly established criteria to assess/estimate a BC genetic predisposition.
3. There was a need for several years of clinical experience with CE-MRI of the breast in the diagnostic setting, acquired in academic centers and great hospitals, to participate in suitably designed screening programs.

The first report was published by Christiane K. Kuhl in 2000 [130]. Fifteen cancers were detected in 192 women proven or suspected to be carriers of a BC susceptibility gene. Sensitivity was 33% for mammography, 33% for US, 44% for mammography and US combined, and 100% for CE-MRI; PPV 30%, 12%, and 64%, respectively. A number of studies were followed, and the body of evidence grew up in the last 15 years. When the sample size of high-risk women, the number of screening events, and the number of centers involved increased, the sensitivity of MRI slightly decreased, as expected, but the general trend for a huge difference in diagnostic power, especially in sensitivity, between MRI and the other imaging modalities was confirmed not only in terms of efficacy but also in terms of large-scale effectiveness.

High-risk screening has been the prominent application for breast MRI multicenter studies in the last 15 years, involving 7690 women who performed 18,307 MRI examinations (Table 17.6).

The evidence from prospective studies about MRI including screening protocols was summarized in 2014 [131]. Overall, nine studies [111, 132–139] enrolled more than 5500 women. A total of 392 BCs were diagnosed. Of them, 45% had a diameter ≤ 10 mm (95%; confidence interval [CI], 39–51%), 77% were invasive (95% CI 73–81%), and 52% were G3 invasive (95% CI 46–58%). Of the invasive cases with explorable axilla (not previously treated for BC), 23% had nodal metastatic involvement (95% CI 18–28%). Study-by-study details are reported in Table 17.7.

All these studies contributed to build the body of evidence in favor of the use of CE-MRI for screening women at high BC risk. National and international recommendations and guidelines accepted this indication on the basis of the superior sensitivity of breast MRI, including not only professional and scientific societies such as the American Cancer Society (already mentioned) [109], the American

College of Radiology [140], the European Society of Breast Imaging [141, 142], or the multidisciplinary European Society of Breast Cancer Specialists (EUSOMA) [143] but also governmental bodies such as the National Comprehensive Cancer Network [144] in the USA and the National Institute for Health and Care Excellence [145] in the United Kingdom.

Differences exist among guidelines, especially for the threshold of LTR to define the indication to MRI, lower (20–25%) in guidelines from the USA and higher (30% or more) in some European guidelines. However, in all guidelines MRI is proposed for screening high-risk women. Key recommendations issued by EUSOMA in 2010 [143] are summarized in Table 17.8.

Table 17.8 Ten key points on screening women with an increased BC risk from EUSOMA recommendations

1.	Women with a family history suspicious for inherited BC predisposition should have their risk assessed by an appropriately trained professional group (genetic counseling); LTR thresholds for including women in surveillance programs with annual MRI may be selected on the basis of regional or national considerations
2.	High-risk screening including MRI should be conducted only at a nationally/regionally approved and audited service or as part of an ethically approved research study. Periodical audit should be undertaken to ensure that high sensitivity is achieved and recall rate (MRI more frequently than annual) is less than 10% and to monitor detection rate, needle biopsy rate, and interval cancers
3.	Annual MRI screening should be available starting from the age of 30. Starting screening before 30 may be possible for BRCA1/2 mutation carriers (from 25 to 29) and TP53 (from 20)
4.	Annual MRI screening should be offered to BRCA1, BRCA2, and TP53 mutation carriers; women at 50% risk for BRCA1, BRCA2, or TP53 mutation in their family (first-degree relatives of mutation carriers); and women from families not tested or inconclusively tested for BRCA mutation with a 20–30% LTR or greater
5.	MRI including screening should be offered also to high-risk women previously treated for BC
6.	Screening mammography should not be performed in high-risk women below 35. In TP53 mutation carriers of any age annual mammography can be avoided based on discussion on risks and benefits from radiation exposure
7.	Annual mammography may be considered for high-risk women from age 35
8.	If annual MRI is performed, screening the whole breast using US and clinical breast examination are not necessary. They are recommended in women under 35 who do not tolerate or have contraindication to MRI or to Gd-based contrast material administration
9.	Cases requiring workup after MRI should be initially assessed with conventional imaging (reevaluation of mammograms, targeted US). In case of only MRI-detected suspicious findings, MR-guided biopsy/localization should be performed
10.	Risk factors such as heterogeneously or extremely dense breasts, previous diagnosis of breast invasive cancer or ductal carcinoma in situ, atypical ductal hyperplasia, and lobular intraepithelial neoplasia, when not associated with other risk factors, do not confer an increased risk that justifies MRI screening

BC breast cancer, *LTR* lifetime risk, *MRI* contrast-enhanced magnetic resonance imaging, *US* ultrasound. From Sardanelli et al. [142], modified. Notably, the EUSOMA recommendations include also women who underwent chest radiation therapy, here discussed in the section 17.2.6.

Secondary evidence in terms of systematic reviews were published, generally confirming the introduction of annual CE-MRI for high-risk screening in terms of both diagnostic performance [146–148] and cost-effectiveness [149].

One relevant contribution came from an individual patient data meta-analysis [150], authored by a team including authors of six original studies. It was demonstrated that the addition of MRI to mammography for screening BRCA1/2 mutation carriers aged ≥50 improves screening sensitivity by a similar magnitude to that observed in younger women. This means that those guidelines which limit screening MRI in BRCA1/2 mutation carriers only up to 50 years of age should be updated to this new evidence.

17.2.4 Radioprotection Issues and the *MRI Alone* Approach

The idea of avoiding mammography in carriers of gene mutations conferring an increased BC risk is not new. It was related to the well-known role of oncosuppressor genes such as BRCA1 and BRCA2. Studies on animal model had shown that BRCA2 protein interacts with the DNA repair protein Rad51, explaining a higher radiation sensitivity [151]. Thus, also from our side [152], we suggested the possibility to abstain from doing mammography at least up to age 35, taking into consideration that, on the basis of available studies, the rate of undetected BCs was only 4%, limited to only ductal carcinoma in situ (DCIS).

This view was subsequently confirmed by statistical modeling of the risk of radiation-induced BC from mammographic screening for young BRCA mutation carriers [153] and by the empiric demonstration of more DNA double-strand breaks induced by mammographic exposure in human mammary epithelial cells sampled from patients with high than with low family BC risk, with a dose-effect exacerbated in cells from high-risk women [154].

Moreover, mammography could be avoided also from the viewpoint of a limited diagnostic performance. This was very clear especially after the results of the EVA study conducted in Germany [138] and of the HIBCRIT study conducted in Italy [111]. The EVA study, based in four academic institutions, included 687 asymptomatic women with familial high risk (LTR ≥20%) who underwent 1679 annual screening rounds composed by clinical breast examination (CBE), mammography, US, and MRI; in a subgroup of 371 women, additional half-yearly ultrasound and CBE were performed in more than 869 rounds. Of 27 BCs diagnosed (11 DCIS and 16 invasive), 3 (11%) were node positive. After a mean follow-up of 29 months, no interval cancers occurred; no cancer was identified by half-yearly ultrasound examinations. No significant difference in detection rate was observed between US (6.0%) and mammography (5.4%), with a not significant increase to 7.7% for both modalities combined. MRI alone had a significantly higher detection rate (14.9%), unchanged by adding US and not significantly increased by adding mammography (MRI plus mammography, 16.0%) , and not changed by adding ultrasound (MRI plus ultrasound, 14.9%). The PPV was 39% for mammography, 36% for US, and 48% for MRI.

Similar results were obtained by the HIBCRIT study [111], based in 18 cancer centers, universities, and general hospitals. We enrolled 501 asymptomatic women aged ≥25 who were BRCA mutation carriers, who were first-degree relatives of BRCA mutation carriers, or women with strong family history of BC or ovarian cancer, including those with previous personal BC. A total of 1,592 rounds were performed; 49 screen-detected and 3 interval cancers were diagnosed: 44 invasive and 8 DCIS; and 4 being pT2 stage, 32 G3 grade. Of 39 patients explored for nodal status, 28 (72%) were negative. Incidence per year-woman resulted significantly higher at ≥50 years of age (5.4%) than at <50 years of age (2.1%), 3.3% overall, significantly higher (4.3%) in women with previous personal BC than in those without (2.5%). The diagnostic performance of CBE, mammography, US, and their combinations is reported in Table 17.9.

At receiver-operating characteristic analysis, MRI showed a superior diagnostic performance than mammography or US (0.82), while MRI combined with mammography and/or US did not overrun MRI alone (Fig. 17.1). Of 52 cancers, 16 (31%) were diagnosed only by MRI. An example of the superior sensitivity of MRI is shown in Fig. 17.2.

Both the German and the Italian studies showed that MRI largely outperforms mammography, US, and their combination. While the EVA trial added the relevant information that US, even when performed every 6 months, does not add sensitivity, the HIBCRIT study demonstrated the effectiveness of an MRI including screening protocol on the large scale of 18 centers. The PPV values were about 50 and 60% for the two studies, respectively, a certainly good metrics in a screening setting. Of note, specificity of MRI was obviously very high in both studies, as of course expected when the probability of the true negative is overwhelming. However, only very recently the *mantra* about the low specificity of breast MRI has begun to reduce its credibility.

The key point of the superior sensitivity of MRI is due to the high detection of small cancers. In the HIBCRIT study, the sensitivity for pT1a–b BCs was 10/20 (50%) for mammography plus US vs. 95% for MRI. Moreover, in an explorative analysis, we also showed no gain in sensitivity as an effect of the transition from film-screen (17/31, 55%) to digital mammography (8/19, 42%) [112].

This new *MRI alone* paradigm, i.e., the absence of additional diagnostic power by adding other imaging modalities after a negative MRI, is due to the very high sensitivity and specificity of the method. For statistical reasons, it is quite

Table 17.9 Diagnostic performance of the different modalities in the HIBCRIT study

Modality	Sensitivity (%)	Specificity (%)	PPV2 (%)	NPV (%)	LR+	LR−

Mammography + ultrasound	62.5	98.4	65.2	98.2	39.0	0.38
MRI + mammography	93.2	97.0	58.6	99.7	31.5	0.07
MRI + ultrasound	93.3	97.1	60.0	99.7	32.0	0.07

PPV2 positive predictive value 2 (needle biopsy prompted), *NPV* negative predictive value, *LR+* positive likelihood ratio, *LR−* negative likelihood ratio, *MRI* contrast-enhanced magnetic resonance imaging. * indicates that the MRI value is signficantly better than each of the the other modality or their combinations.

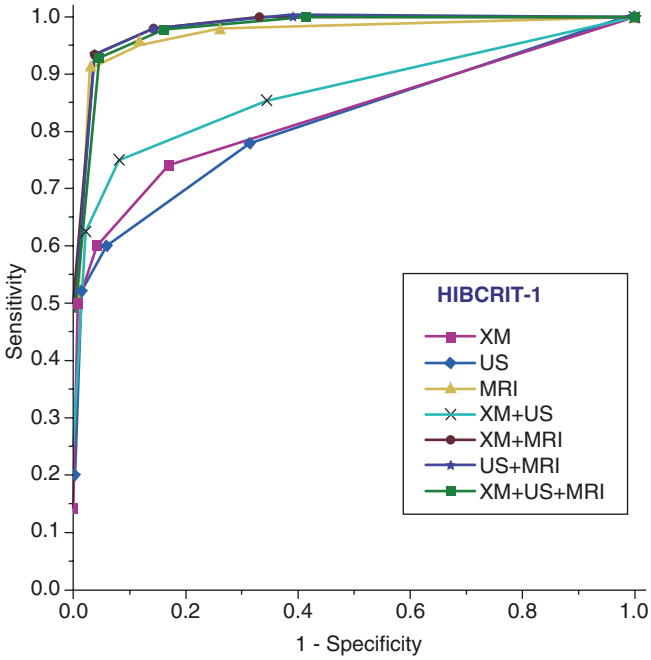

Fig. 17.1 Receiver-operating characteristic analysis of diagnostic performance of mammography (XM), ultrasound (US), MRI, and their combination for screening high-risk women. The AUC of MRI (0.97) was significantly higher than that of mammography (0.83) or US (0.82) and not significantly increased when MRI was combined with mammography and/or US. HIBCRIT study [111]

unlikely that any other technique can add significant diagnostic gain, unless a huge sample size is considered.

This approach has been reinforced by the results of a number of subsequent studies. A study from Ontario, Canada, reported on the initial evaluation of 2207 high-risk women [156]: of 35 BCs detected, none was identified by mammography alone. A study from the Netherlands considering only BRCA1 mutation carriers [157] reported on 82 invasive BCs and 12 DCIS during the study. They had four interval cancers (all invasive): MRI missed only 2 DCIS that were detected by mammography (2/94, 2%). An update from the Austrian study [158] showed that of 40 BCs 18 (45%) were detected by MRI alone and only two by mammography alone (a DCIS with microinvasion and a DCIS with <10 mm invasive areas), without leading to a significant increase in sensitivity vs. MRI alone; no cancers were detected by US alone.

Finally, an individual patient data meta-analysis including six high-risk studies [159] recently showed that in BRCA1/2 mutation carriers, adding mammography to MRI did not significantly increase sensitivity. However, the increase was 3.9% in BRCA1 but reached 12.6% in BRCA2 mutation carriers. In women with BRCA2 mutation younger than 40 years, one third of BCs were detected by mammography only. We should consider here that the inclusion of only six studies, based on the voluntary contribution of the individual patient data by the authors of the original researches, did not allow for including data from some other studies which could have reduced the rate of BCs detected on mammography only.

At any rate, due to the very low, if any, contribution of US and the low contribution of mammography when compared to MRI for screening a high-risk population, we can propose the following simple recommendations:

1. MRI alone up to 35 years of age for all high-risk women
2. MRI alone for BRCA1 and p53 mutation carriers without age limitations
3. *Mammography as an adjunct to MRI* for BRCA2 mutation carriers after 35 years of age

Thus, the paradigm *MRI as an adjunct to mammography* has been reverted into its contrary. When *mammography as an adjunct to MRI* is under consideration for high-risk women, a good conservative approach has been suggested, consisting of performing only one projection, the mediolateral oblique one [160].

17.2.5 Impact on Patient Outcome

If the principles of evidence-based medicine [161] are applied to screening programs, a high detection rate or a very good diagnostic performance of a screening tool should not

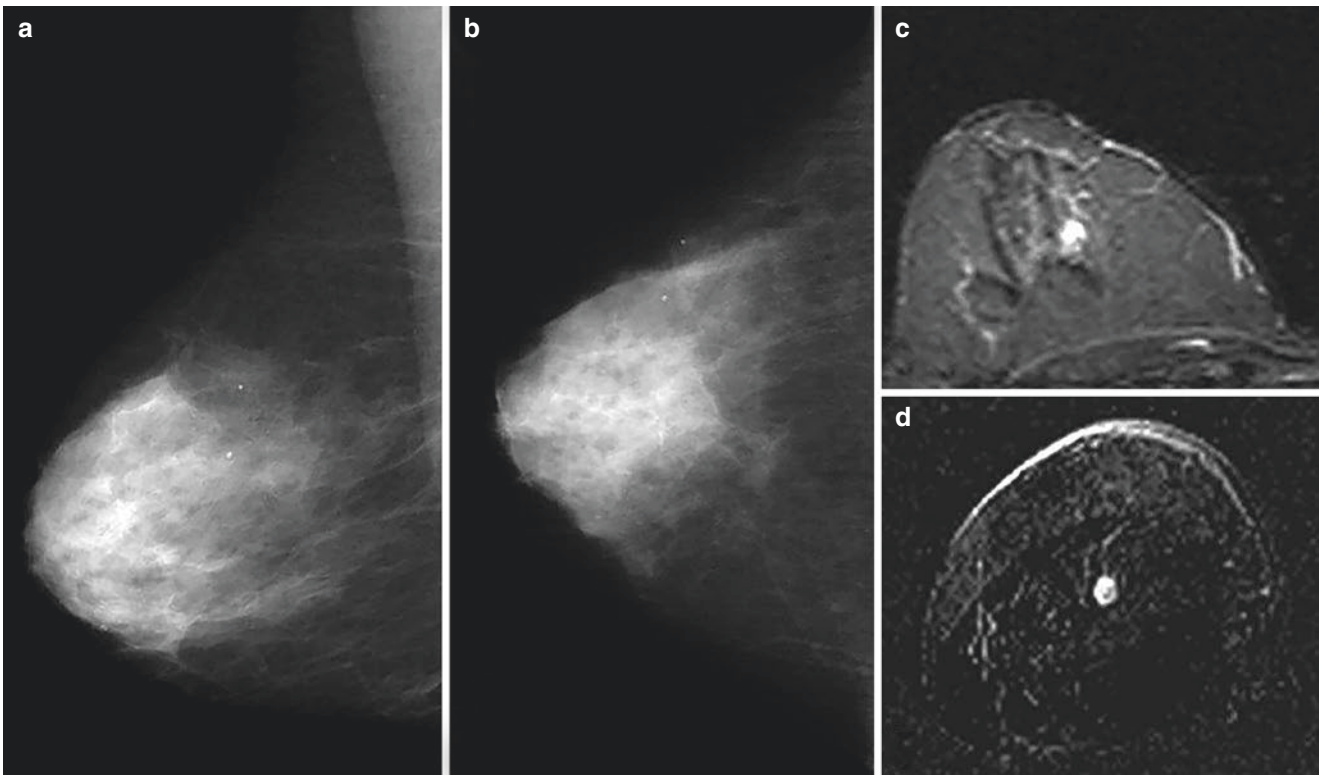

Fig. 17.2 Case from the HIBCRIT study. A 53-year-old BRCA1 mutation carrier, already treated for an invasive ductal cancer of the left breast at 33 years of age, underwent multimodal screening including clinical breast examination (CBE), mammography, US, and MRI. The left breast only showed minimal signs of the previous treatment at each screening modality (not shown). Mammography of the right breast showed a negative dense breast (**a**) and (**b**). Also CBE and US (not shown) were negative; at MRI the unenhanced T2-weighted axial short-tau inversion-recovery sequence (**c**) showed a small hyperintense mass, confirmed at the subtracted (contrast-enhanced minus unenhanced T1-weighted gradient echo) coronal image (**d**). Final diagnosis: node-negative invasive ductal carcinoma (6 mm in diameter) (From Podo et al. 2016 [155], with permission)

be considered *per se* as a sufficient reason to implement this screening tool in practice. Randomized controlled trials should be performed to take into account lead time bias, length bias, and overdiagnosis, finally evaluating whether the screening under consideration has a significant impact on mortality and patient outcome overall.

This rule should be theoretically also applied to high-risk population. However, ethical issues make this approach (i.e., to obtain information from randomized controlled trials) no longer possible for what we are considering in this chapter. The demonstrated gap in sensitivity between MRI and mammography and/or US is too high to propose a randomization to a BRCA or p53 mutation carrier. We are convinced that no ethics committee would approve such a protocol.

Therefore, we had to refer to an indirect evidence. On the one side, an impact of the anticipated diagnosis obtained with MRI in a high-risk population can be inferred considering the impact of screening mammography on the general female population [114]. On the other side, relevant information began to come from the cohorts included in the above-mentioned high-risk studies.

Rijnsburger et al. [137] reported a 5-year cumulative overall survival higher in the prospective MRI screening patient series of the Dutch MRISC study (93%) than in institutional historical unselected controls, as well as in 26 published series. This result was associated with a more favorable tumor stage, particularly in a moderate-risk group.

Møller et al. [162] reported on survival of patients with BRCA1-associated BCs diagnosed in an MRI-including screening program. The 5-year BC-specific survival for women with cancer was 75%, and the 10-year survival was 69%. The 5-year survival for women with stage 1 BC was 82% compared to 98% in the general population. The authors commented that these survival rates were *less than anticipated* and *the benefit of annual MRI surveillance on reducing BC mortality in BRCA1 mutation carriers remains to be proven.*

We argue that one key point is the historical context of the cohorts of screened women, i.e., the associated effect of early diagnosis combined with that of modern treatment protocols to better exploit the advantage of an early MRI detection. When Evans et al. [139] compared three cohorts

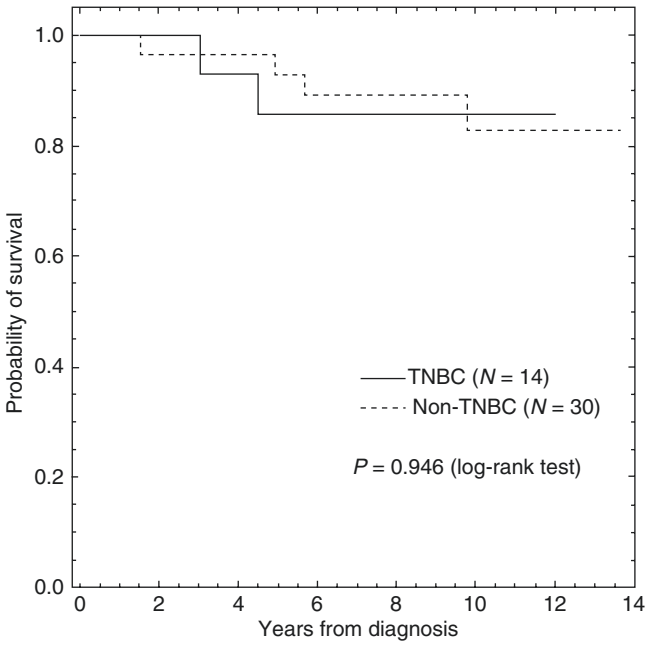

Fig. 17.3 Kaplan-Mayer analysis of overall survival of high-risk women affected with triple-negative breast cancers (TNBC) or non-TNBC during the HIBCRIT study [111] (with permission)

of high-risk women who had no screening, mammography or an MRI including program, a clear advantage of mammography vs. no screening and MRI vs. mammography or no screening is visible. However, these three cohorts are not concurrent, but subsequent and their survival should have been influenced by the progressive improvement of therapies [131].

Our contribution has been to compare phenotype features and survival of triple-negative BCs (TNBCs) vs. non-TNBCs detected during the HIBCRIT study [155], on the basis of a median of 9.7-year follow-up. The 44 invasive BCs (41 screen-detected and 3 BRCA1-associated interval TNBCs) comprised 14 TNBCs (32%) and 30 non-TNBCs (68%), without significant differences for age at diagnosis, menopausal status, prophylactic oophorectomy, or previous BC. Of 14 TNBC patients, 11 (79%) were BRCA1; of the 20 BRCA1 patients, 11 (55%) had TNBC; and of 15 patients enrolled for family history only, 14 (93%) had non-TNBCs. TNBC patients had more frequent ipsilateral mastectomy, contralateral prophylactic mastectomy, and adjuvant therapy. The 5-year overall survival was 86% ± 9% for TNBCs vs. 93% ± 5% for non-TNBCs; 5-year disease-free survival was 77% ± 12% vs. 76% ± 8%, respectively, without significant differences (Fig. 17.3). We are aware that the detection of TNBCs in BRCA (especially BRCA1) mutation carriers could have been responsible for the selection of more drastic therapies vs. those decided for noncarriers, so that the relative contribution of MRI and systemic therapies is not easily discernible [163]. At any rate, the relevant clinical message here is that, in high-risk women, by combining an MRI-including annual screening with adequate treatment, the usual reported gap in outcome between TNBCs and non-TNBCs could be reduced.

17.2.6 The Special Case of Previous Chest Radiation Therapy

Women who underwent chest radiation therapy (CRT) during pediatric/young-adult age (typically those treated for Hodgkin's lymphoma) have an increased BC risk, in particular those who received mantle CRT with high doses. The cumulative BC incidence from 40 to 45 years of age in these women is 13–20%, higher than that observed in the young female general population and similar to that of BRCA mutation carriers. The risk is higher for high doses delivered between 10 and 16 years of age. The BC is diagnosed on average about 15 years after CRT at about 40, to be compared with a mean age of about 61 in the general female non-exposed population [164, 165]. These BCs are similar to those encountered in the general female population in regard to histopathologic subtype, receptor status, lymphatic invasion, and nodal involvement. Of note, BCs in women who underwent CRT exhibit a preferential localization at upper external quadrants more extreme than that observed in women with hereditary predisposition (67% vs. 48%, respectively); moreover, in these women the possibilities of treatment of BC mostly exclude radiation therapy and chemotherapy with doxorubicin [166].

For women who underwent CRT, guidelines [109, 143, 167] recommend annual mammography and CE-MRI, starting from 25 years of age or, for those women who had CRT before 30, 8 years after the end of treatment. The rationale is the similar BC incidence in the young age for women who had CRT and women with hereditary predisposition associated with relatively lower sensitivity of mammography, also related to the need to start at a young age, and higher sensitivity of MRI.

In the USA, a study published in 2009 [168] reported that, of 551 women with previous CRT, 47% of those with 25–39 years of age never had a mammogram and only 37% had biannual screening mammography, the same percentages being 8 and 53% between 40 and 50 years of age. Importantly, the screening rate was higher in the presence of a specific medical recommendation.

Before the MRI introduction, the breast surveillance of women with previous CRT included annual physical examination and mammography [169]. This protocol allowed for detecting 60% of BC in the preinvasive phase or at T1 stage [170–174]. Two prospective [175, 176] and two retrospective studies [177, 178] compared mammography and MRI. Sensitivity ranged from 67 to 70% for mammogra-

phy, from 63 to 80% for MRI, with a 92% sensitivity reached only in one retrospective study, with a very small sample size for MRI [178]. Importantly, in women who underwent CRT, MRI sensitivity is relatively lower (63–80%) and that of mammography is relatively higher (67–70%) than those observed in women with hereditary predisposition, due to a higher incidence of DCIS with microcalcifications [179] and low neoangiogenesis. A sensitivity close to 95% can be obtained only using mammography as an adjunct to MRI.

An expert panel [180] recently compared the recommendations proposed by the following working groups: North American Children's Oncology Group (COG), Dutch Childhood Oncology Group (DCOG), Scottish Intercollegiate Guidelines Network (SIGN), and UK Children's Cancer and Leukaemia Group (UKCCLG). As a result of this comparison, a series of "harmonized recommendations" were provided: physicians, health-care providers, and women who had CRT should be informed on the treatment-related BC risk (strong recommendation); the surveillance is recommended for doses ≥20 Gy (strong recommendation); the surveillance is reasonable for doses between 10 and 19 Gy, taking into account the clinical context and further risk factors (moderate recommendation); the surveillance may be reasonable for doses between 1 and 9 Gy, taking into account the clinical context and further risk factors (weak recommendation); the surveillance implies annual check from 25 years of age or, at least, 8 years after CRT up to 50 years of age using mammography, MRI, or both of them (strong recommendation); and physical examination may be reasonable in countries where only clinical surveillance is available (weak recommendation).

Considering the available evidence, women who underwent CRT before 30 receiving a cumulative dose ≥10 Gy should be invited after 25 (or, at least, 8 years after CRT) to attend the following program [181]:

1. Dedicated interview about individual risk profile in order to define the potential of different breast imaging modalities in this specific setting
2. Annual CE-MRI using the same protocol recommended for women with hereditary predisposition
3. Annual bilateral two-view full-field digital mammography or digital breast tomosynthesis (DBT) with synthetic two-dimensional reconstructions

When reaching the age for entering population screening program, the individual risk profile should be discussed with the woman to opt for the only mammography/DBT screening or for continuing the intensive protocol including MRI.

Conclusions

More than 20 years after the identification of BRCA gene mutations and 20 years after the introduction of CE-MRI, evidence has been accumulated in favor of MRI-including screening programs for high-risk women. In some conditions, especially for BRCA1 mutation carriers, *MRI alone* can be proposed. Importantly, in the case of previous CRT, *mammography as an adjunct to MRI* is always recommended as a high incidence of DCIS with microcalcifications and low neoangiogenesis limits MRI sensitivity.

The challenge for public health programs is to integrate these protocols for high-risk women into the general screening organization as models for a future stratification of BC screening protocols on the basis of different risk classes, up until a modulation based on the individual risk estimate will be possible, including a possible reduction of screening invitation to very low-risk women.

18.1 Mammography and Tomosynthesis

Rumana Rahim and Michael J. Michell

Abstract X-ray mammography remains the most effective technique for routine breast cancer screening and plays a key role in imaging the breast in symptomatic patients aged from 40 years. The quality of mammography images has improved significantly during the last decade with the introduction of full-field digital mammography. However, although it is the most acceptable and effective technique used for population-based screening with reported breast cancer mortality reductions of up to 20%, the sensitivity and specificity of mammography are limited particularly in younger women and in those with dense glandular breasts.

In modern practice, mammography is complimented by other imaging modalities to improve lesion detectability and characterisation and establish disease extent. These techniques include ultrasound and contrast-enhanced MRI as well as newer mammographic techniques including digital breast tomosynthesis and contrast mammography.

In this chapter, we discuss the strengths and limitations of mammography in the diagnosis of breast disease and the role of advanced techniques in both diagnosis and screening practice.

18.1.1 Mammographic Technique

Full-field digital mammography is now the standard of care, and the optimisation of technical factors including automatic exposure control, contrast to noise ratio, detail detection, and radiation dose is required for the detection of subtle signs seen with early breast cancer. Breast composition can vary significantly between normal individuals with differing proportions of fat, glandular, and stromal tissue. The correct equipment and technique should allow for the wide variation of patient build, breast size, as well as variations in anatomy.

Careful and skilled positioning of the breast including keeping the patient at ease is essential. Firm and even compression of the breast improves contrast by reducing radiation scatter, improves resolution by reducing tissue overlap; allows for reduced dose, uniform density and minimises both geometric and movement unsharpness. This is essential for the detection of both fine microcalcification and subtle soft tissue signs, for example, distortion.

Standard mammography includes two views of each breast. These are the medio-lateral oblique view and the craniocaudal view (Fig. 18.1). The medio-lateral oblique (MLO) view is performed by angulating the X-ray tube between 30 and 60° depending on patient build, often 45°. The nipple should be in profile, and the anterior surface of the pectoralis major should be visible to the level of the nipple. The inframammary skinfold should be visible with no superimposed skinfolds on the breast. This projection demonstrates more breast tissue than any other projection. The aim of this view is the complete visualisation of breast parenchyma and the retromammary fat as well as low axillary nodes. Review of the area anterior to the pectoralis

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_18

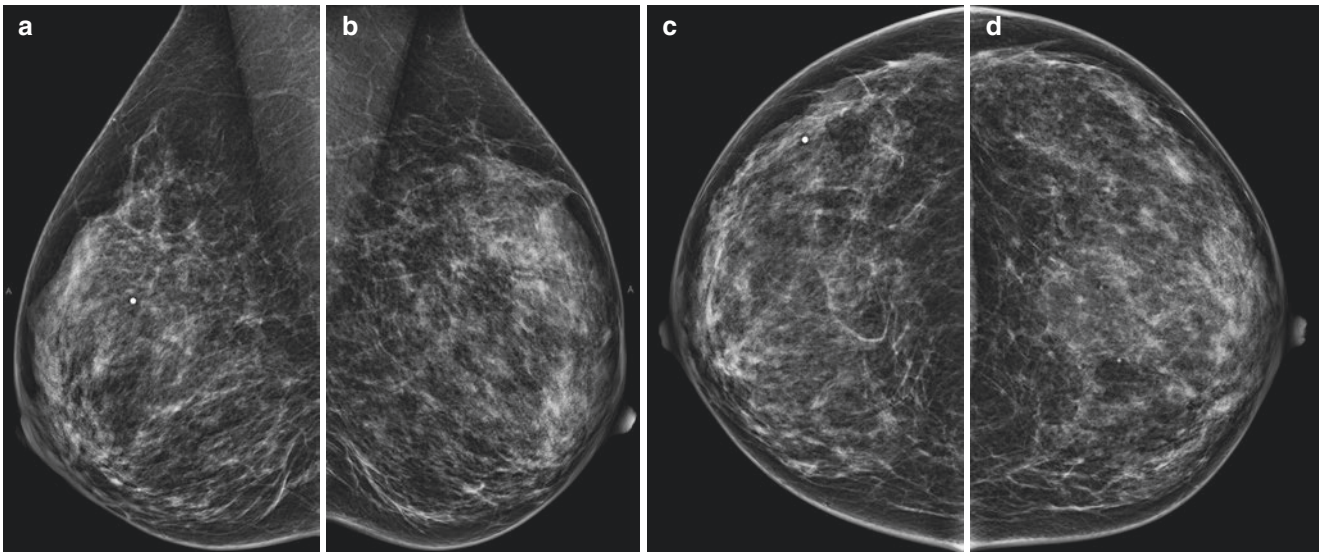

Fig. 18.1 (**a**–**d**) Normal two-view mammograms. (**a**) RMLO, (**b**) LMLO, (**c**) RCC, (**d**) LCC

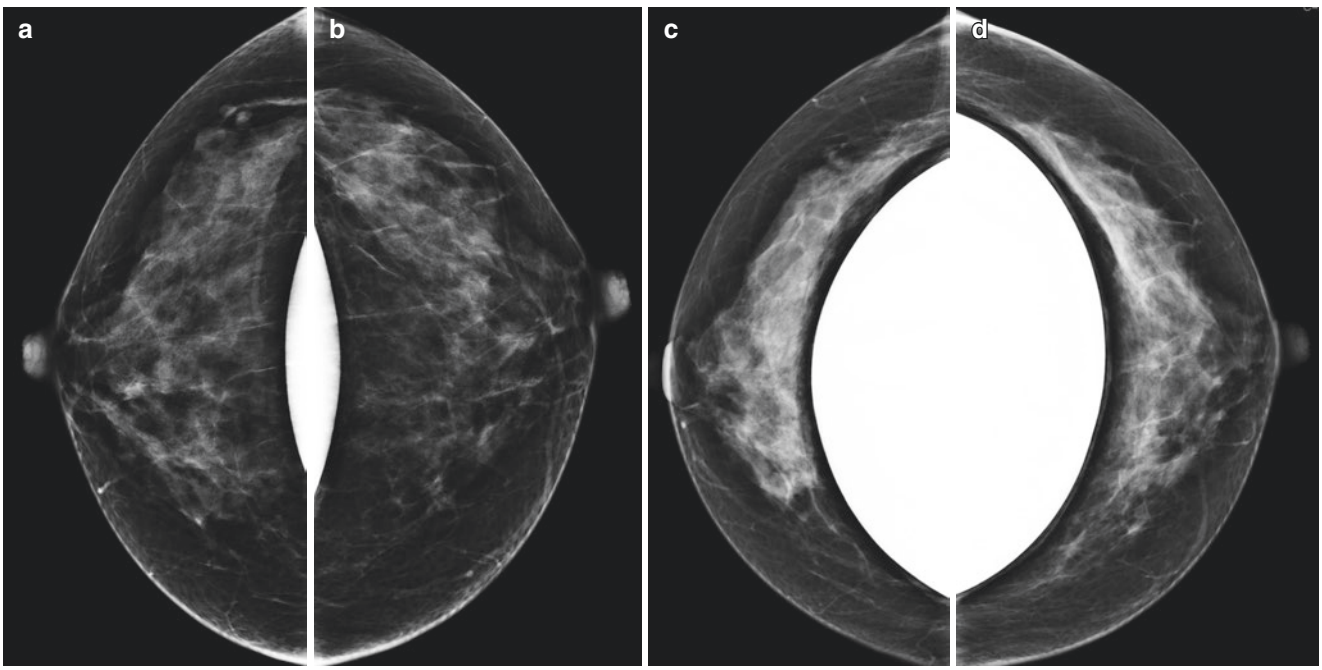

Fig. 18.2 (**a**) and (**b**) are Eklund projections which improve the visualisation of breast tissue in women with implants. (**c**) and (**d**) are standard cc projection mammograms in a woman with implants

muscle and in the immediate retroareolar region is important for the detection of small breast cancers. An important area of the breast not consistently well demonstrated on the MLO projection is the upper inner quadrant which is better demonstrated on craniocaudal (CC) view. The craniocaudal view is performed with a vertical X-ray beam. The nipple again should be in profile with as much breast parenchyma as possible visualised, particularly that in the retroareolar, medial and lateral aspects of the breast as well as the retromammary fat.

In addition to the standard views, supplementary views can be used to improve the visualisation of abnormalities or areas of the breast. Medially or laterally extended craniocaudal views can be performed by rotation of the patient. Fine-focus magnification views increase resolution and are used for the improved visualisation and characterisation of microcalcification. Focal compression views can be used to improve the characterisation of soft tissue densities, asymmetrical densities as well as distortions by displacing the overlying tissues. The Eklund technique is a modified compression view for patients with breast augmentation (Fig. 18.2). The implant is displaced toward the chest wall with anterior traction of the breast tissue to improve visualisation.

18.1.2 Anatomy

The female breast typically has 12–15 lobes which contain terminal ductal lobular units (TDLU). The TDLU consists of acini and lobules which are constantly changing in size and number according to hormonal status. The lobes are variable in size, and the anatomical boundaries of these lobes are not restricted by the quadrants often used to describe disease location in radiology. The shape and contour of the breast are also influenced by supportive fascia and Cooper's ligaments. The wide spectrum of appearances seen on a normal mammogram is reflective of the heterogeneity in breast composition. The parenchymal subtypes were described in the original classification system by Wolfe [1] to enable the recognition of normal mammographic structures.

Breast density is an important descriptor in the interpretation of mammograms. It has significant effects, both on sensitivity and specificity. The mammographically dense breast is an independent risk factor for breast cancer. Breast density is determined by genetic factors and is influenced by age, weight, pregnancy/lactation, medication including exogenous hormones (inhibitors) and breast disease, for example, inflammation. Breast density can be assessed subjectively by the radiologist, but quantitative systems, for example, Volpara and Qantra, provide more accurate, reproducible data. The most widely used classification system in current practice is the BI-RADS (Breast Imaging-Reporting and Data System).

BI-RADS 1: The breast(s) is almost entirely adipose with <25% glandular tissue (Fig. 18.3).

BI-RADS 2: The breast(s) has scattered fibro-glandular tissue occupying 25–50% of the breast (Fig. 18.4).

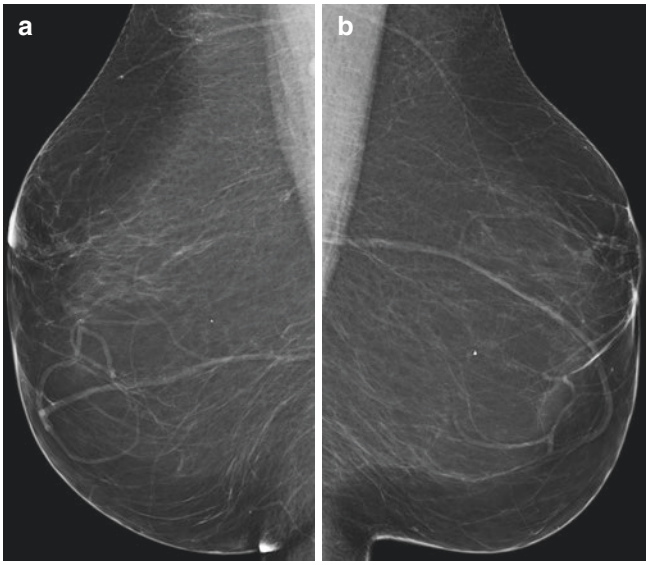

Fig. 18.3 (**a–b**) MLO projection mammograms demonstrate the BI-RADS classification of mammographic breast density. BI-RADS 1

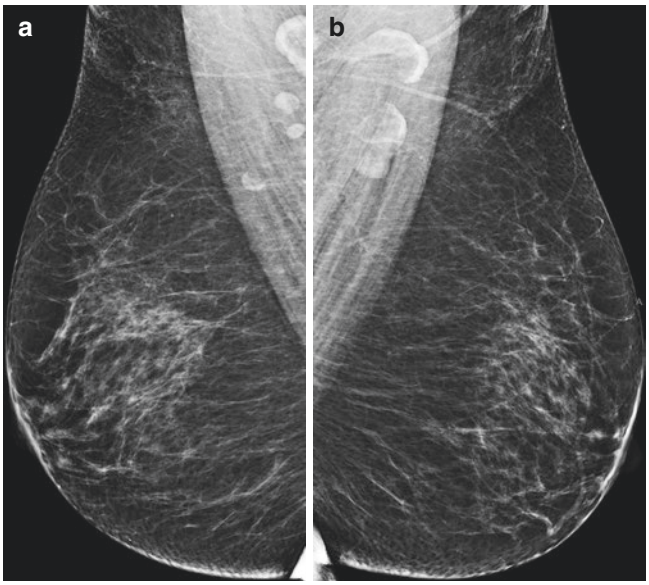

Fig. 18.4 (**a–b**) MLO projection mammograms demonstrate the BI-RADS classification of mammographic breast density. BI-RADS 2

BI-RADS 3: The breast(s) has heterogeneously dense fibro-glandular tissue ranging between 50 and 75% (Fig. 18.5).

BI-RADS 4: The breast(s) has extremely dense 75–100% glandular tissue (Fig. 18.6).

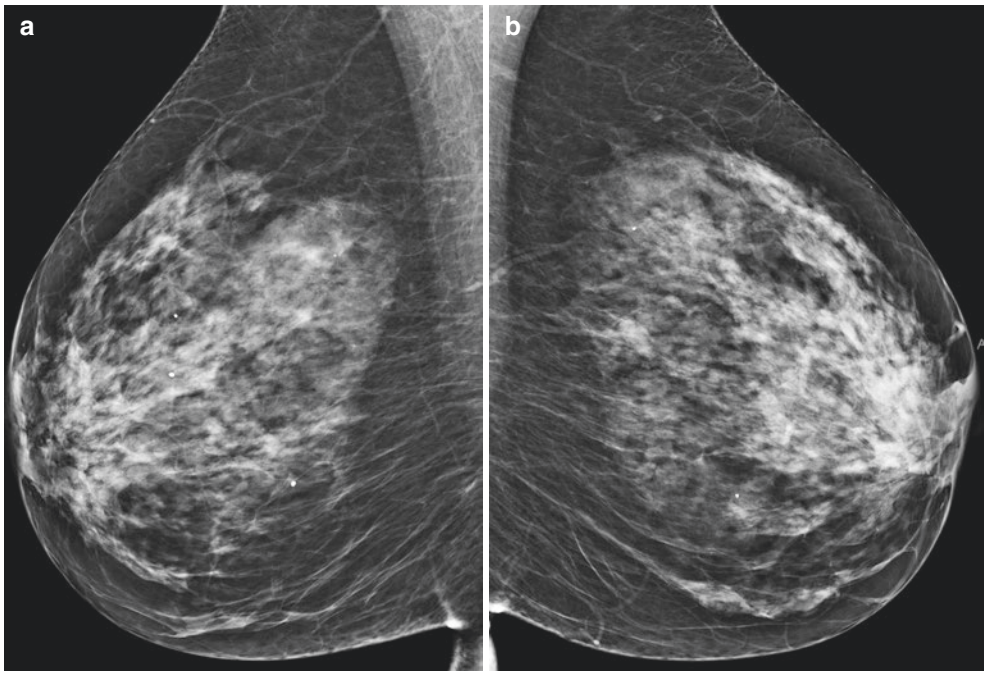

Fig. 18.5 (**a–b**) MLO projection mammograms demonstrate the BI-RADS classification of mammographic breast density. BI-RADS 3

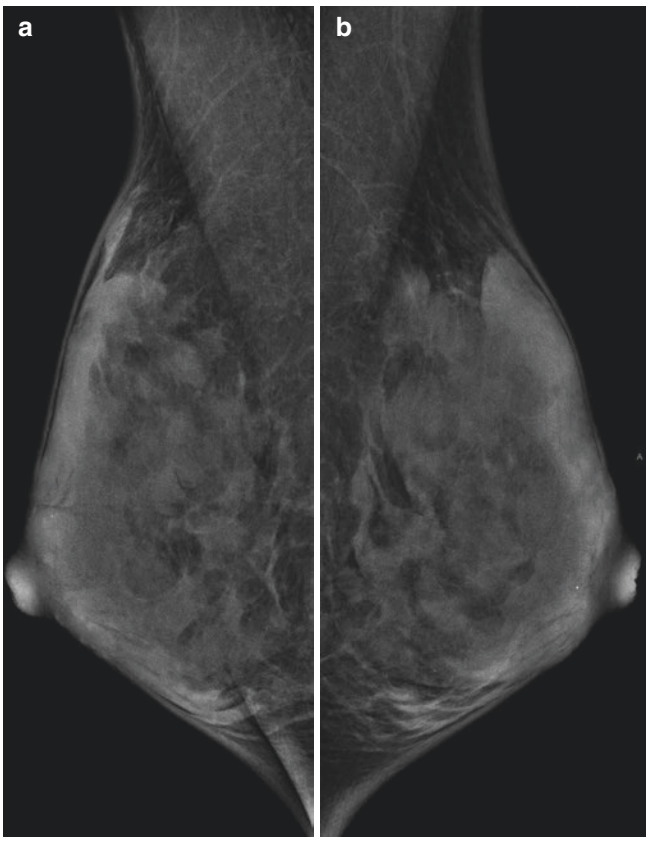

Fig. 18.6 (**a–b**) MLO projection mammograms demonstrate the BI-RADS classification of mammographic breast density. BI-RADS 4

18.1.3 Indications

18.1.3.1 Symptomatic Patients

The triple assessment approach to patients in diagnostic clinics includes clinical breast examination, imaging and biopsy, if required. This ensures an efficient diagnostic process which results in a definitive diagnosis of normal physiological change, benign or malignant disease. Mammography is routinely used in symptomatic patients who present to the breast clinic and are aged 40 years or over. Mammography should also be considered in those below 40 years presenting with signs and symptoms suspicious for breast cancer and in the investigation of male patients over 50 years with a unilateral firm subareolar mass. Standard two-view mammography in symptomatic patients may be complimented with supplementary mammographic views or digital breast tomosynthesis for further characterisation of mammographic features. Ultrasound should be carried out for any patients with breast lumps, persistent focal lumpiness, change in breast size with signs of oedema, change in breast contour, skin tethering or skin dimpling and women with implant-related symptoms as described by Willet et al. [2].

18.1.3.2 Population Screening

Screening mammography is the modality of choice for routine population screening and has been shown to reduce the mortality rate in those invited to breast screening by approximately 15–20%. A meta-analysis of screening trials by Tabar et al. [3]

demonstrated an overall reduction in breast cancer mortality of 22% with an invitation to breast cancer screening. The paper showed a strong relationship between decreased rates of advanced stage (stage II and higher) tumours and lower breast cancer-specific mortality. The mortality benefit from mammographic screening continues following screening as shown on follow-up data from the Swedish randomised control trials published by Tabar et al. [4].

A screening programme must be underpinned by robust quality assurance and measurements of performance to ensure high quality. Mammographic screening should include MLO and CC projections of each breast. The most common age range for routine screening is 50–70 years. The UK age extension trial is a multicentre trial examining the effect of screening in women aged 47–50 and 70–73 and is to report in 2022–2026. Over 2 million women have been recruited with over 200,000 screens to date. Moser et al. [5] reported the age extension pilot results which showed a 0.5% cancer detection rate in those 47–49 years and 1.1% in those 71–73 years with recall rates 2.5 times higher in those 47–49 years compared with the 71–73 years group. The US Preventive Services Task Force published recommendations in 2009 [6] of biennial screening for women 50–74 years for general population breast screening and no screening for those aged 40–49 years except on an individual case basis. The effectiveness of mammographic screening of women aged 40–49 is less certain than for those over 50 years.

The frequency of mammography is variable dependent on individual risk and the screening programme. Intervals vary from 1 to 3 years. The UK programme invites women triannually. However, Dibden et al. [7] demonstrated 44% of interval cancers in this programme to be in the third year following negative screen, suggesting that 3 years is too long an interval for screening. Biennial screening has been suggested as optimal for normal population screening.

Women of greater than average population risk of breast cancer can be categorised as moderate or high risk. The UK categorises women at high risk if they have a lifetime risk of 30% and moderate risk between 17 and 29%. The European Society of Breast Cancer Specialists recommends high-risk screening for women with a lifetime risk greater than 20–30%, and the American College of Radiology recommends high-risk screening for those with a lifetime risk of >20%. Moderate risk is classified in Europe and the USA as a lifetime risk of >15%. There are a number of risk calculation tools including the Claus model, Gail model and BOADICEA (Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm). The BRCAPRO and Manchester scoring system are used specifically for the assessment of BRCA mutations.

Mammographic screening is the mainstay in women with a moderate lifetime risk with annual mammograms. Moderate-risk women may have a family history without known genetic mutations. Other risk factors include women with a personal history of breast cancer; benign conditions like atypical ductal hyperplasia (ADH), atypical lobular hyperplasia (ALH), and lobular carcinoma in situ (LCIS); and dense breasts. Women with a previous personal diagnosis of breast cancer have a 5–10% risk of recurrence in the first 10 years. The mammographic sensitivity is compromised in women who have had breast conservation therapies. Houssami et al. [8] reported sensitivities of 65% vs 76% in those with a personal history of breast cancer vs. those without, with only 25–45% of recurrences detected on mammogram overall. Distortion from surgery and increased density from radiation therapies can affect the detectability of an early breast cancer.

Women of higher risk develop cancers at an earlier age, perhaps in denser breasts with tumours with atypical morphological mammographic features and a faster tumour growth rate. Mammographic screening is often performed annually from a younger age and is enhanced with magnetic resonance imaging in higher-risk women due to the reduced mammographic sensitivity reported in these women. MRI screening studies report sensitivities of 77–100% vs. mammographic sensitivities of 23–50% (Kuhl et al. [9], Kriege et al. [10], Leach et al. [11], Sardanelli et al. [12] and Warner et al. [13]). Women who have a high breast cancer risk due to TP53 mutations or Li-Fraumeni or A-T homozygotes should not undergo routine mammographic surveillance due to increased radiation sensitivity.

18.1.4 Limitations

2D mammography has limitations. The advent of digital mammography and full-field digital mammography has improved the visualisation of breast disease in comparison to film screen, especially in denser breasts; however, there has not been the improvement in cancer detection as had initially been hoped. In the DMIST study, Pisano [14] studied cancer detection in digital vs. film-screen mammography in 49,528 women in a multicentre, multivendor trial and found digital mammography to be more accurate in women <50 years with dense breasts or who were pre-/perimenopausal. The superimposition of structures can lead to the under-detection of breast malignancy. Fifteen to thirty percent of cancers may not be detected by screening mammography and present as interval cancers, between screens.

Interval cancer rates can be used as a measure of the effectiveness of a screening programme. It is not only a key

quality indicator of a screening programme but allows for the surveillance of individual radiologist performance and education. Interval cancers tend to be larger in size at presentation compared to screen-detected tumours and are more likely to have nodal metastasis. They tend to be invasive tumours with less than 5% of interval cancers being due to ductal carcinoma in situ (DCIS) in a study by Bennett et al. [15]. In a review, Housammi et al. [16] report that interval cancers have a prognosis similar to that of other symptomatic cancers. The review found approximately 25–45% of interval cancers were due to a false-negative read, i.e. a perception or misinterpretation error. These errors are usually minimal signs, where perception errors may be improved with double reading or CAD. In those cases clinically assessed, the errors may possibly be reduced by assessment guidelines and improved clinical decision making. True intervals, with no findings on the screening mammogram, account for 18–63% of cases. These cancers are hard to minimise except for the consideration of enhanced screening techniques or shorter screening intervals where feasible. Mammographically occult tumours at diagnosis account for 8–12%.

Studies have reviewed the characteristics of undetected and missed cancers (Table 18.1). Birdwell et al. [22] reviewed the data used in the Warren Burhenne et al. [20] study above to demonstrate 30% of the missed cancers were microcalcifications and 70% were masses (28% were spiculate or irregular). They reported breast density to be the second most common cause for missing a breast cancer (34% of cases) following a distracting lesion as the most common cause (44%). Bird et al. [18] also demonstrated missed cancers were less likely to have microcalcifications and more likely to be an increasing opacity in denser breasts.

Elmore et al. [23] report the overall sensitivity for screening mammography to be 75% with a specificity of 92.3%. The accuracy of mammography is variable, being limited by breast density and symptoms. Sensitivity and specificity in fatty breasts are as high as 87% and 97%, respectively.

The sensitivity of mammography is reduced in situations where the breast tissue may be obscured or distorted including cosmetic techniques as well as following breast-conserving treatments (Fig. 18.7). Heterogeneously and extremely dense breasts are an independent risk factor for breast cancer. Boyd et al. [24] discussed the increased risk of breast cancer in women with dense breasts to be four- to sixfold. The reasons for this are likely multifactorial, not only due to the reduced sensitivity of mammography which is only a "masking effect" but the increased volume of tissue

Table 18.1 Table of interval cancer studies with undetected and missed cancer analysis

Author	Year	Interval cancers reviewed	% with (actionable) signs on previous mammogram
Ikeda et al. [17]	1992	96	32
Bird et al. [18]	1992	320	24
van Dijck et al. [19]	1993	84	38
Warren Burhenne et al. [20]	2000	427	27
Brem et al. [21]	2003	377	32

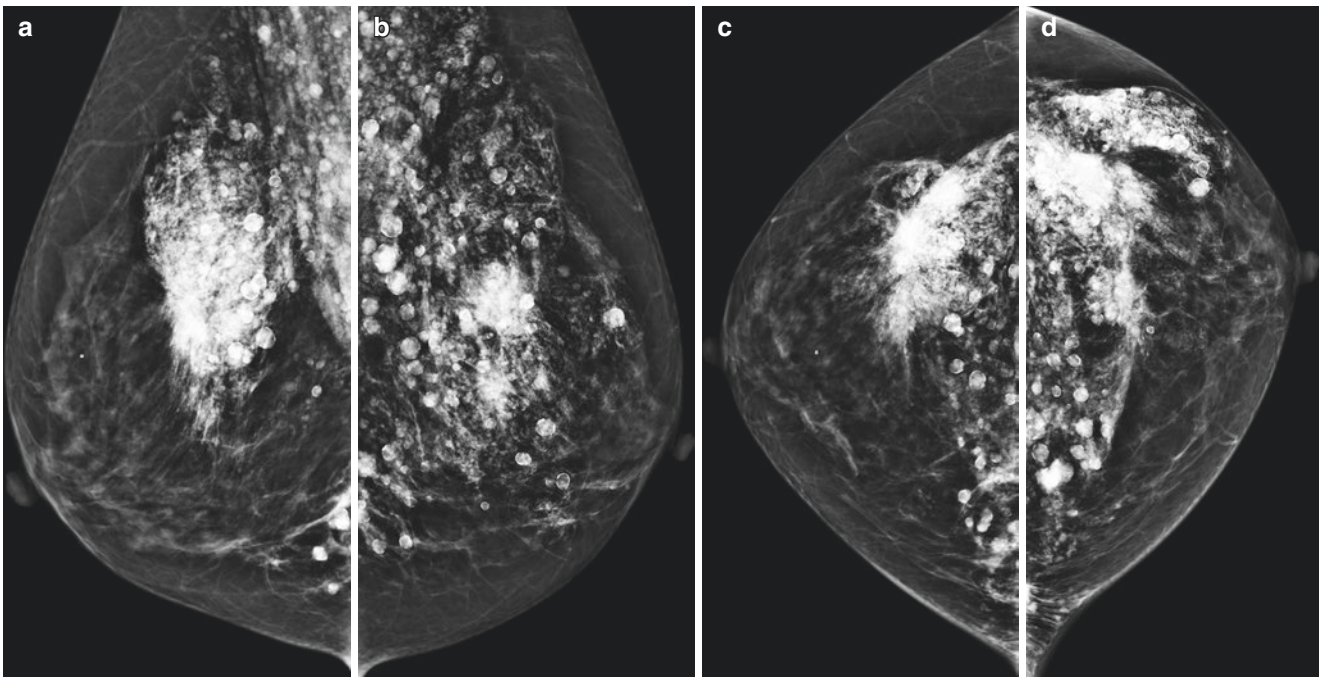

Fig. 18.7 (**a–d**) Silicone prevents the optimal visualisation of breast tissue reducing the sensitivity of the mammogram in the detection of early breast cancers

that may potentially undergo malignant change and possible underlying genetic predisposition. Dense breasts are associated with epithelial proliferation and stromal fibrosis. The review also looked at the effect of age, family history, diet, alcohol consumption, exercise and race on breast density and suggested age to have the strongest effect. Berg et al. [25] reported a sensitivity of 45% for the detection of malignant lesions in patients with extremely dense breasts. The study also examined cancer detection by tumour type. The sensitivity for invasive ductal cancer was 81% but 34% for invasive lobular cancer.

Mammographic sensitivity can be affected by a number of factors. The mammographic breast density and lifestyle factors affecting this, patient age, and reader experience affect the sensitivity (Banks et al. [26], Britton et al. [27]). Patient age has been shown to be a significant factor in mammographic sensitivity by multiple study groups. Kolb et al. [28] showed the sensitivity in younger women with dense breasts (<49 years) to be significantly lower than in older women with dense breasts. The mammographic accuracy may be affected by the context in which it is performed, as the reader may look for an abnormality on mammography to explain a presenting clinical symptom. Kavanagh et al. [29] reviewed 106,826 women presenting for routine screening and compared asymptomatic women to those with symptoms. The sensitivity in those with breast-specific symptoms was 80.8% vs. 75.6% in those asymptomatic but with significantly lower specificities of 73.7% and 94.9%, respectively.

The sensitivity of mammography is improved by double reading which may be carried out by two readers independently or together. This is common practice in the UK and other European countries. A systematic review by Taylor and Potts [30] has shown a significant increase of approximately 10% in cancer detection rate with double reading. Published data shows a variable effect on recall rate. In most studies specificity is not compromised. In cases where there is discordance between reader 1 and reader 2, the process of arbitration or consensus is used. Arbitration is performed by a single reader and consensus is by a panel. Duijm et al. [31] have shown the process of consensus and arbitration to be effective in recalling the majority of cases with cancer while minimising the recall rate.

Increasing the recall rate reduces the positive predictive value and the cost-effectiveness of mass screening. Schell et al. [32] performed a study of 1,872,687 mammograms in the USA and concluded recall rates between 6.7 and 10% (incident and prevalent screens) were optimal. Europe recall rates are between 3 and 10%. Smith-Bindman et al. [33] reported the average recall rate in the USA to be double that of the UK with no difference in cancer detection rates. This was explained in the study by multiple variations in screening practice between the UK and the USA. The UK national programme has robust radiology quality assurance in place including a minimum reading volume of 5000 mammograms per year per radiologist. The balance of sensitivity vs. specificity depends on multiple factors. It may be affected by litigation concerns; if the aim is to detect all cancers, i.e. maximise sensitivity, this will increase recall rates and reduce specificity.

The use of computer-aided detection (CAD) may optimise cancer detection by one reader where double reading is not available. The Computer-Aided Detection Evaluation Trial II (CADET II) compared single reader with CAD with double reading to show cancer detection/sensitivity between the two arms was similar, 87.2% and 87.7%, respectively (James et al. [34]). The specificity of double reading was higher at 97.4% in comparison to 96.9% with CAD which also resulted in a higher recall rate. There was no statistical difference between cancer subtypes although the CAD arm detected more in situ disease and smaller, higher-grade invasive disease. Pooled estimates from two meta-analyses of 27 studies with CAD by Taylor and Potts [30] concluded with the same results for cancer detection rates between CAD and double reading but a lower recall rate with double reading. It is reported that radiologist productivity was unaffected by CAD, perhaps due to radiologist experience in the final decision as to whether or not to recall (Brem et al. [21]). In addition to this, Freer and Ullissey [35] reported CAD not to affect the positive predictive value for biopsy.

CAD has been shown to be particularly effective in the detection of microcalcification clusters. The detection of microcalcification does not appear to be affected by breast density (Brem et al. [36], Birdwell et al. [22]). Distortions are the third most common mammographic sign for breast cancer and can be very subtle with appearances often mimicking overlapping tissues. Baker et al. [37] reviewed the performance of CAD on benign and malignant architectural distortions. In this study, CAD was not sensitive to subtle signs, detecting <50% of the cases. Among the cancers not detected by CAD, studies have shown a posterior location is more common; however, quadrants are equal.

CAD is a sensitive system; however, mammographic reading also requires the expertise of an experienced radiologist who is able to distinguish correctly between true-positive and false-positive prompts, ensuring that the correct areas are recalled without compromising specificity (Azavedo et al. [38]).

The positive predictive value (PPV) of mammography for malignancy and that for biopsy varies widely according to the mammographic sign, between 15 and 75%. The mammographic signs with the highest predictive value for malignancy are masses with a spiculated margin or irregular shape and linear microcalcifications in a segmental or linear distribution (Liberman et al. [39]). Lazarus et al. [40] reviewed the PPV by BI-RADS category with BI-RADS 4 and above recommended for biopsy and reported a PPV between 6% for BI-RADS 4a and 91% for BI-RADS 5 lesions.

The recall rate following screening reflects the specificity of mammography. The UK National Health Service Breast Screening Programme (NHSBSP) screened 2.08 million women in 2013–2014, detecting 8.6 cancers per 1000 screened of which 39.9% were 15 mm or less. The prevalent and incident screen recall rates were 7.9% and 3%, respectively. The false-positive rate in mammographic screening is a limitation which has significant morbidities related to anxiety and biopsy.

Screening is performed in otherwise (breast) healthy women; the harm vs. benefit must therefore be addressed. The Marmot review [41] of the benefits and harms in population mammographic screening reported for every life saved with breast screening, 180 women are screened or 235 women are invited to screening for 20 years. Screen-detected disease that may not otherwise have resulted in harm to the patient in her lifetime is known as overdiagnosis. The review estimated that 19% of screen-detected cancers are due to overdiagnosis or for each breast cancer death prevented, three women are overdiagnosed.

Overdiagnosis may include the detection of small low-grade invasive tumours and DCIS. The detection of DCIS has significantly increased with the advent of screening accounting for approximately 20% of screen-detected malignancy. The benefit of detecting DCIS against harm has been questioned. This is partly related to the very different natural history of low-grade DCIS in comparison to high-grade DCIS within the same disease category and the uncertainty about the progression of disease. A review of over 5.2 million screened women by Duffy et al. [42] provided evidence that the diagnosis and treatment of DCIS in screening are worthwhile and suggested that one less invasive interval cancer occurred for every three cases of DCIS detected.

The recognition of the variable sensitivity and specificity of mammography dependent on patient factors has led to the development of new techniques which enhance lesion detection compared with conventional mammograms. We discuss digital breast tomosynthesis and contrast-enhanced digital mammography.

18.1.5 Digital Breast Tomosynthesis (DBT)

DBT, sometimes called 3D mammography, provides the reader with images of the breast in thin slices and overcomes many of the interpretation problems of 2D DM due to overlapping normal tissue, sometimes referred to as "anatomical noise". The mammographic signs of breast cancer may be obscured, particularly in women with dense fibro-glandular breast tissue (Al Mousa et al. [43]), resulting in delay in the diagnosis of cancer. The UK national interval cancer data shows that up to 4000 women per annum (2.88 per 1000 screened) are diagnosed with breast cancer in the interval between screens (Offman and Duffy [44]). Conversely, superimposition of normal tissues may produce features on mammography which are suspicious for cancer and lead to unnecessary recall for further diagnostic tests. UK national screening data for 2012/2013 show that of 2.3 million women screened, 79000 (3.4%) without breast cancer were recalled to specialist diagnostic assessment clinics for further tests (Centre for Cancer Prevention [45]). DBT has been incorporated into the routine for further mammographic investigation of breast lesions in many centres replacing conventional spot compression views. Some centres in North America and Europe are already using DBT in addition to conventional 2D mammography to screen asymptomatic patients.

18.1.5.1 Technique

Tomosynthesis involves the movement of the X-ray tube in an arc during which data from multiple low-dose projection images are acquired. Between 9 and 25, low-dose projections are taken over an angular range of 15–50 degrees depending on the manufacturer. Images for viewing are reconstructed using either a filtered back projection or iterative method from the low-dose projection image data and are typically displayed as 1 mm thickness in-focus planes. The images may be viewed singly or as a series, similar to viewing a CT scan. The total dose is comparable to that of conventional full-field 2D digital mammography but depends on the manufacturer. Certain systems can also produce a reconstructed or synthetic 2D image from the tomosynthesis images which can reduce the total dose further by avoiding the need for conventional FFDM (Fig. 18.8).

18.1.5.2 Indications

This technique has been demonstrated to show increased accuracy in comparison to film-screen and full-field digital mammography (FFDM). This is particularly the case in the characterisation of soft tissue abnormalities. There does not, however, appear to be an advantage of DBT in the assessment of microcalcification (Spangler et al. [46]). The TOMMY trial (TOMosynthesis with digital MammographY) reported DBT specificity was highest for distortions and lower for microcalcifications (Gilbert et al. [47]). Michell et al. [48] demonstrated an accuracy of 97% when interpreting using DBT in comparison with 90% with 2D FFDM. Cancer visibility has been shown to be superior with DBT. Studies have shown single-view MLO projection DBT to be more accurate in the detection of tumours than two-view DM (Andersson et al. [49], Svahn et al. [50]).

The improved visibility of the margins of circumscribed soft tissue lesions may enable readers to predict the likelihood of malignancy as presented by Wasan et al. [51]. The addition of DBT improves lesion conspicuity, margin analysis and the detection of additional abnormalities.

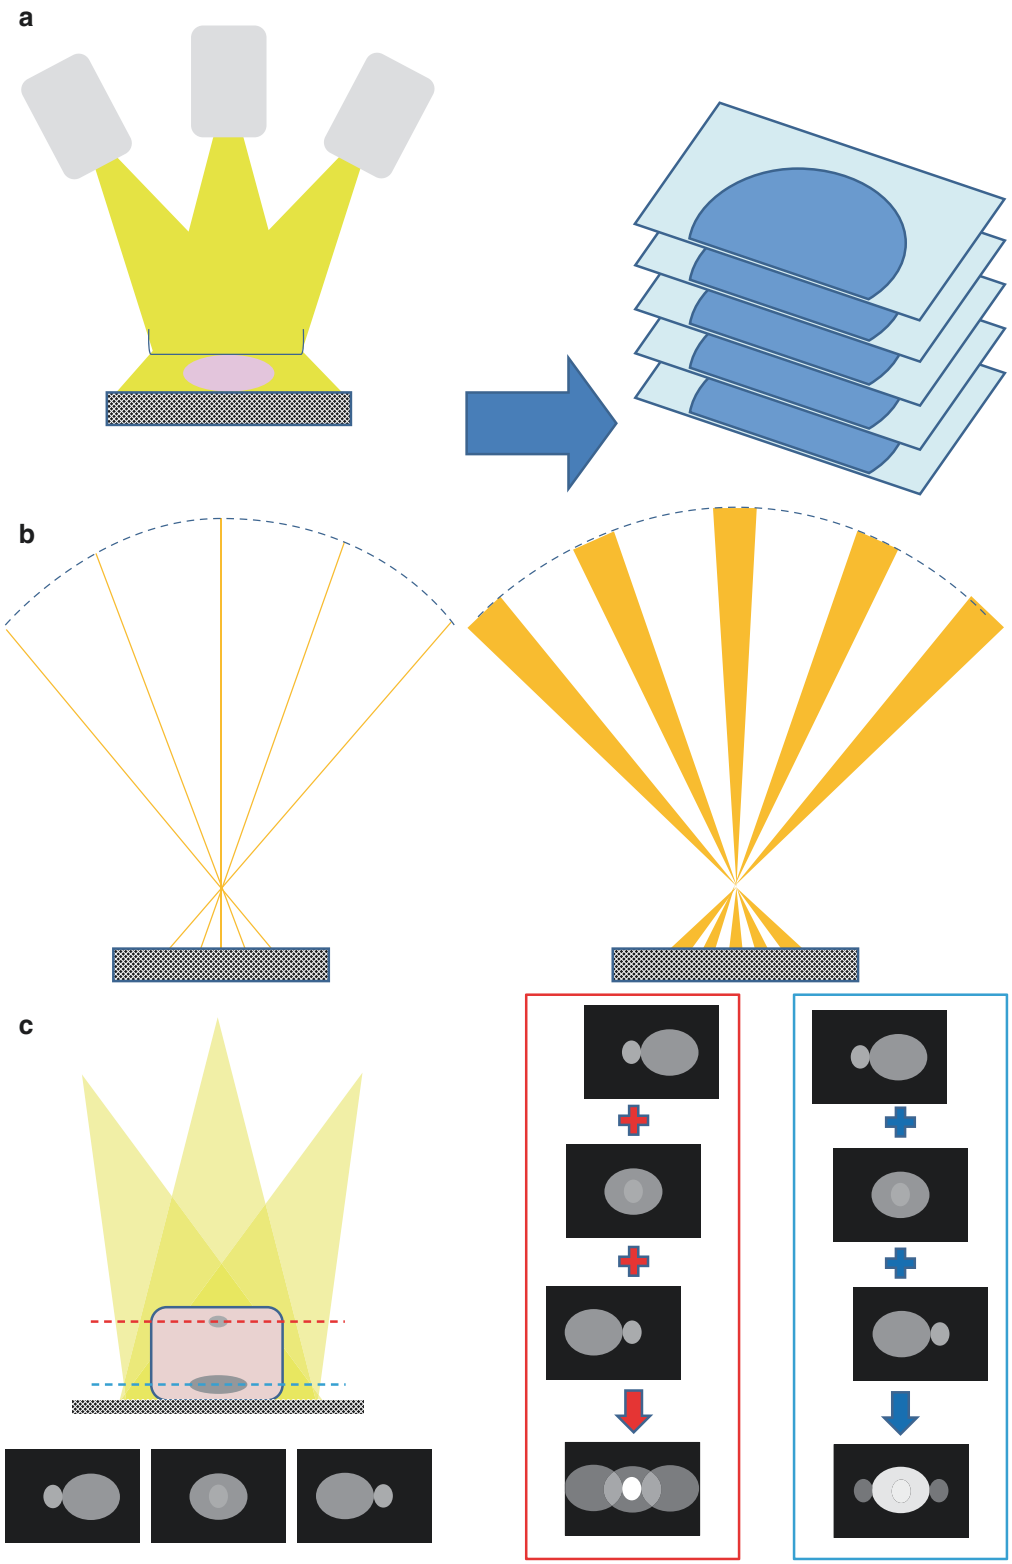

Fig. 18.8 (**a**–**c**) Illustrations courtesy of Dr. Celia Strudley, The Royal Marsden Hospital, London. (**a**) Illustrates how DBT acquires multiple images through an arc. The focal planes taken from sequential depths are then stacked approximately 1 mm apart. (**b**) These images demonstrate tube motion. The step and shoot tube movement has a small focal spot and produces sharp images but is slower to acquire images. The continuous tube movement elongates the focal spot causing blurring in the direction of the motion but is faster and has smoother motion. (**c**) This illustrates the simple back projection reconstruction method used by some DBT systems

The role of DBT in the diagnostic workup of soft tissue masses, distortions and asymmetrical densities is established. The reported advantage is the improved ability to predict malignant lesions without increasing the false-positive rate (Morel et al. [52] and Zuley et al. [53]). Studies have shown fewer benign biopsies and short-term follow-up are recommended with the use of DBT. This results in a significant improvement in the accuracy of diagnostic assessment. There

are further advantages to using this technique over coned compression views as visualisation of the whole breast improves detection of multifocal disease.

Gur et al. [54] demonstrated an improved performance with DBT including demonstrating lesion location and multifocal lesions; however, this was at the cost of an increased false-positive rate which was justified by the increased true positives (Figs. 18.9, 18.10, 18.11, 18.12, 18.13).

18.1.5.3 Potential Use in Screening

A topic which is of interest in research at the time of writing this chapter is the possible use of DBT in the routine

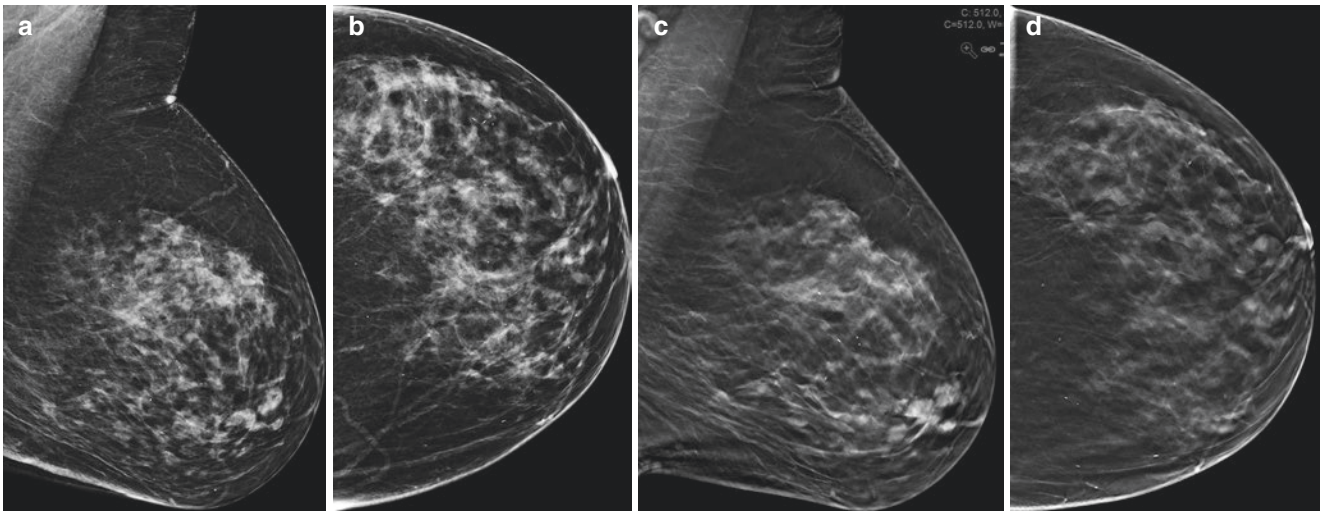

Fig. 18.9 (**a**–**d**) DBT increases the conspicuity of a lesion enabling a sign change in this case from a circumscribed mass to a spiculate mass. This case is a screen-detected lymph node negative 12 mm grade 2 invasive lobular carcinoma recalled to assessment on the (**a**) LMLO and (**b**) LCC 2D FFDM, which demonstrated a circumscribed mass in the lower outer breast. (**c**) LMLO (**d**) LCC DBT demonstrates a spiculate lesion improving reader confidence and BI-RADS 5 score from the initial BI-RADs 4a based on the 2D images

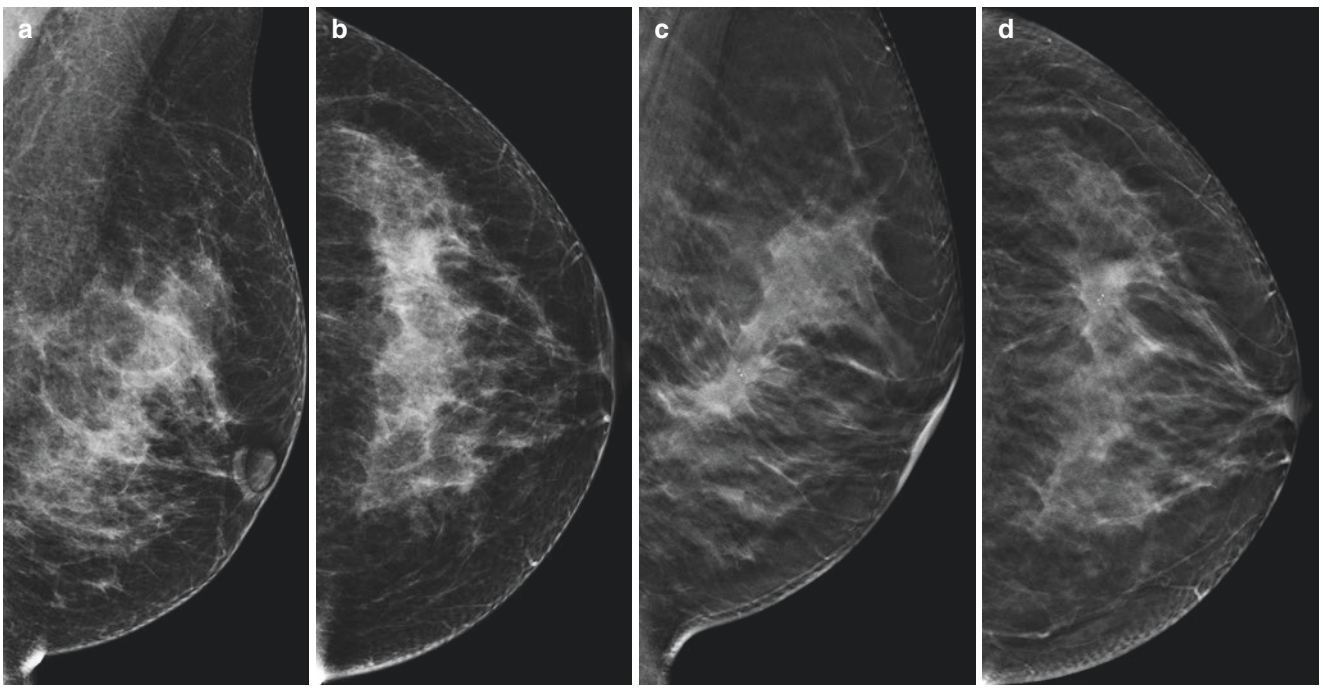

Fig. 18.10 (**a**) LMLO 2D FFDM, (**b**) LCC 2D FFDM, (**c**) LMLO DBT, (**d**) LCC DBT, (**e**) left lat magnification view and (**f**) left CC magnification view. The 2D FFDM screening mammograms (**a**, **b**) demonstrate microcalcification which underwent supplementary views. DBT (**c**, **d**) demonstrates a spiculate mass which is occult on the 2D. The magnification views (**e**, **f**) demonstrate the microcalcification and subtle increased density. Final pathology demonstrated a grade 2 invasive ductal carcinoma with axillary lymph node involvement

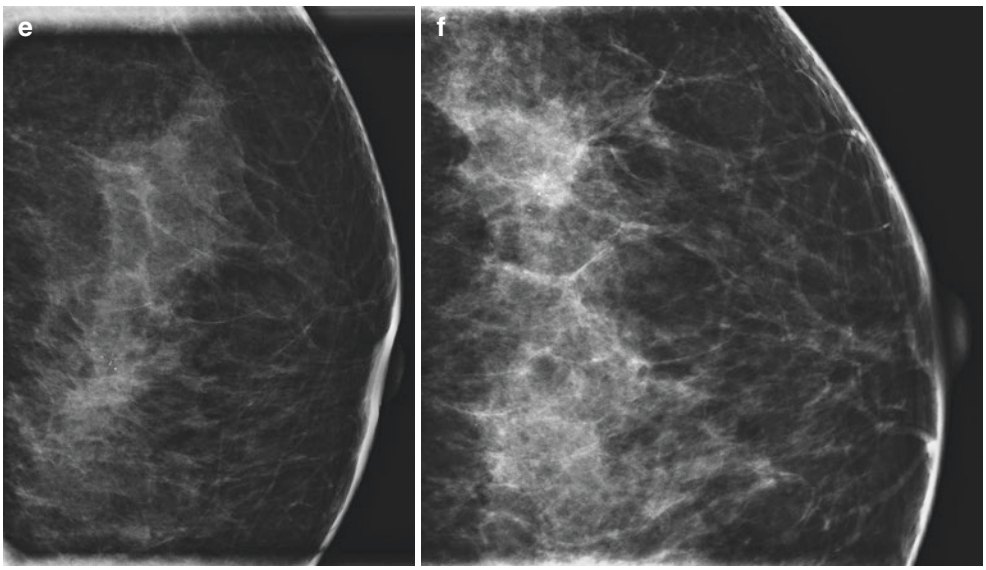
Fig. 18.10 (continued)



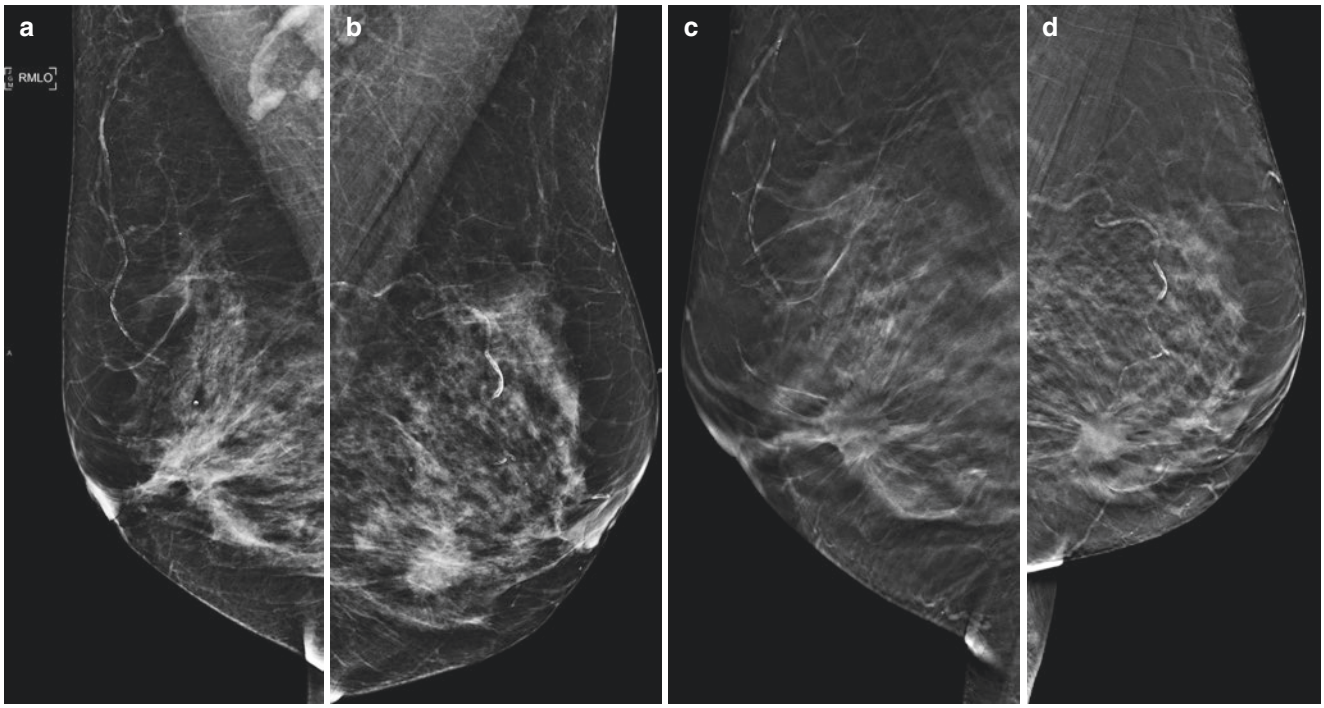


Fig. 18.11 (**a**) RMLO 2D FFDM, (**b**) LMLO 2D FFDM, (**c**) LMLO DBT and (**d**) RMLO DBT. The 2D FFDM demonstrates bilateral breast cancers. The *left breast cancer* was a grade 2 invasive ductal carcinoma with spread into the axillary lymph nodes. The *right breast cancer* was a grade 2 invasive lobular carcinoma. However, the extent of the breast tumour is more clearly appreciated with the DBT especially the *right breast tumour*

screening of women for breast cancer. The radiation dose of DBT is similar to that of established 2D DM which invites the possibility of this technique being used for population screening. Studies of DBT used in addition to 2D DM have shown a significant increase in invasive cancer detection rates with no significant effect on DCIS. Further prospective trials are underway in North America (TMIST), Norway (Oslo trial), Italy (Storm trial), Sweden (Malmo trial) and the UK (PROSPECTS).

The Malmö Breast Tomosynthesis Screening Trial (MBTST) showed an increase in sensitivity in cancer detection with single-view DBT vs. two-view mammography. This

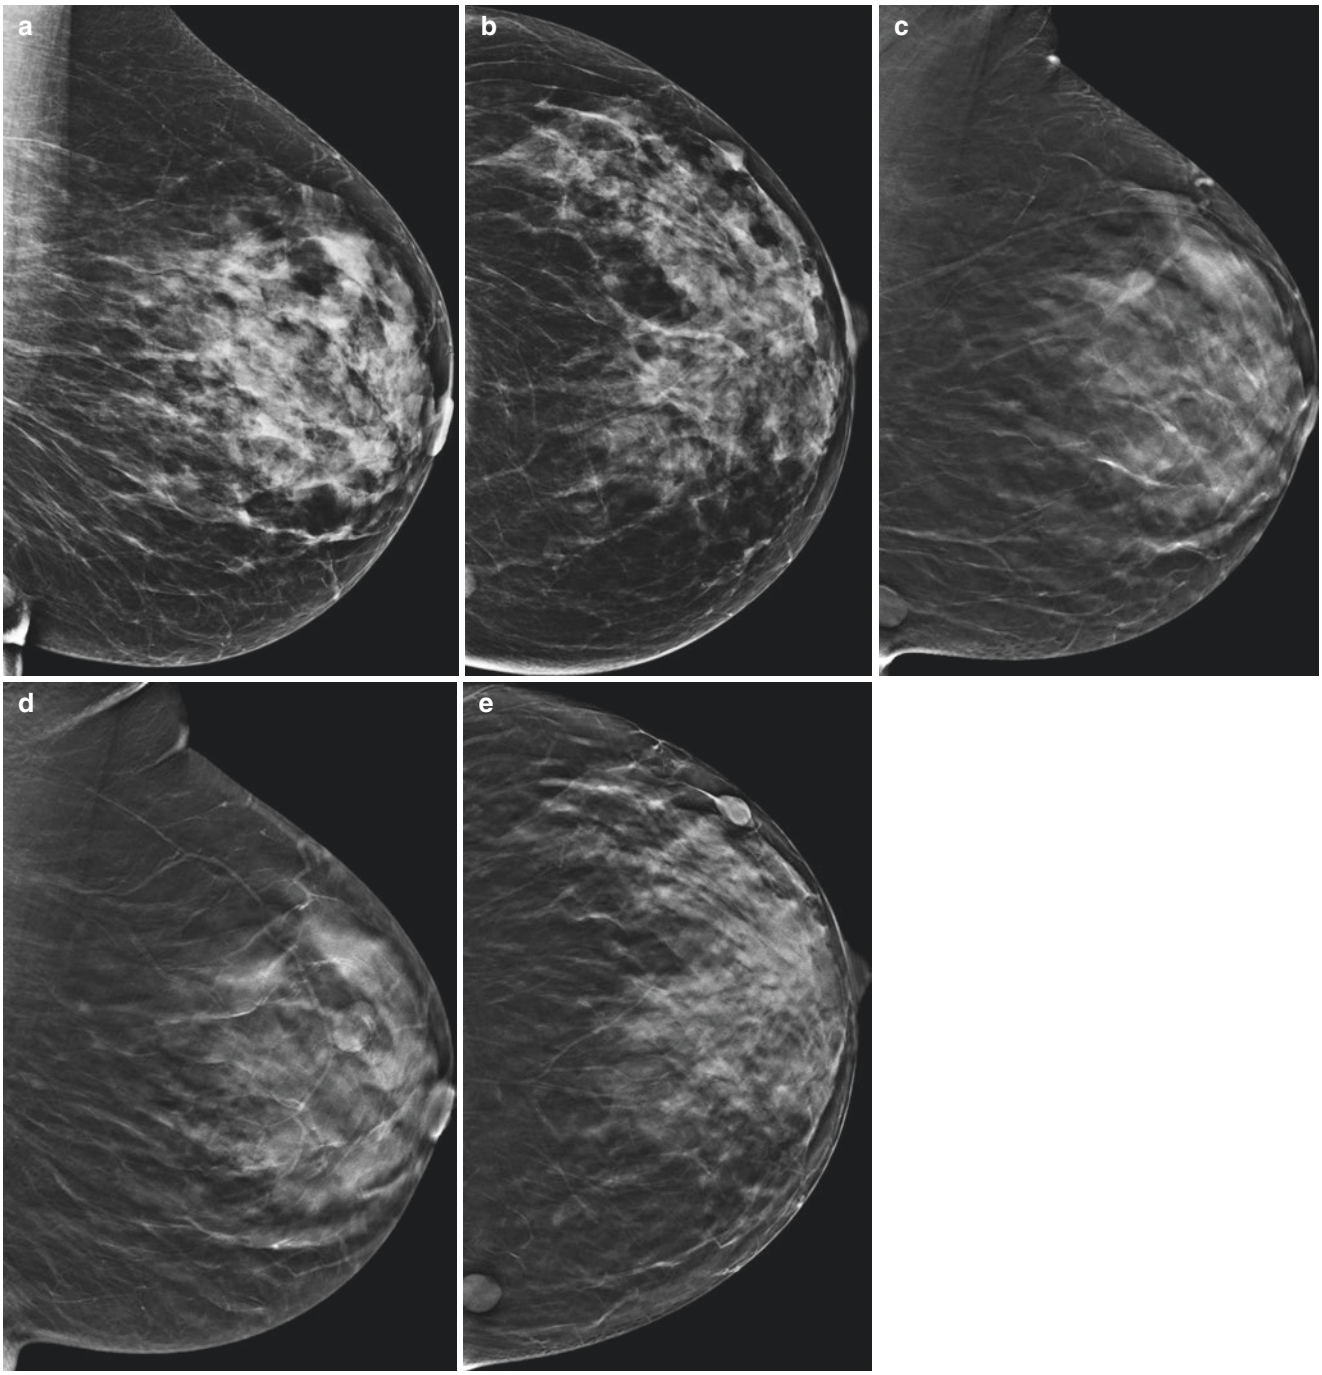

Fig. 18.12 (**a**) LMLO 2D FFDM, (**b**) LCC 2D FFDM, (**c**) LMLO DBT, (**d**) LMLO DBT and (**e**) LCC DBT. (**a**–**b**) 2D FFDM images of the left breast demonstrate BI-RADS 3 breast density with a nodular parenchymal pattern and multiple densities with partial visualisation of the margins. (**c**–**e**) DBT images enable clear visualisation of 100% of the margins of these multiple lesions which were biopsy-proven fibroadenomas. The DBT images enable confident diagnosis of benign lesions which would require no further investigation

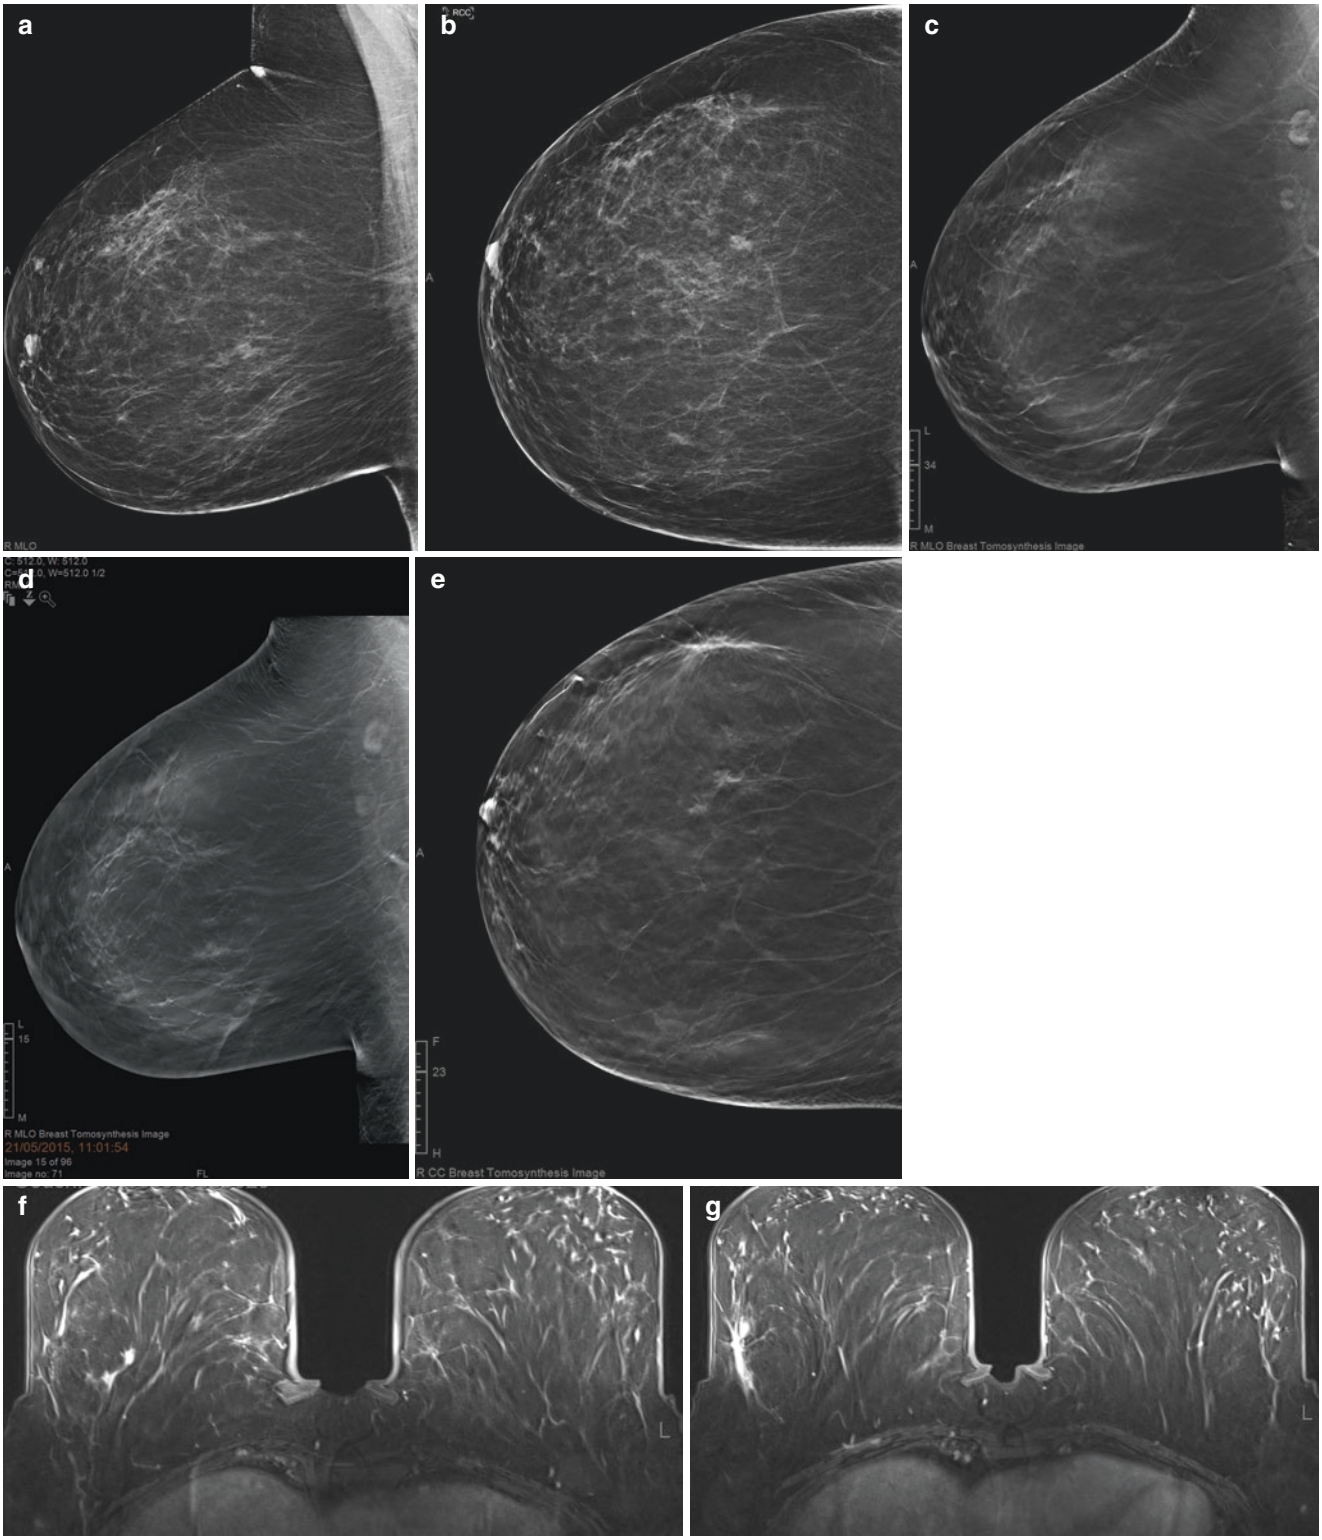

Fig. 18.13 (**a**) RMLO 2D FFDM, (**b**) RMLO 2D FFDM, (**c**) RMLO DBT, (**d**) RMLO DBT, (**e**) RCC DBT, (**f**) axial 1 min post-contrast MRI and (**g**) axial 1 min post-contrast MRI. This case illustrates the detection of multifocal disease in a screen-detected multifocal grade 2 invasive lobular carcinoma. The asymptomatic woman was recalled for a new central irregular-shaped mass on routine 2D screening mammogram (**a**–**b**). DBT at the time of assessment demonstrated the central mass as two spiculate lesions on (**c**) RMLO DBT and (**e**) RCC DBT. Further to the recalled lesions is a distortion in the *right upper outer breast* not appreciated on 2D FFDM but detected on the (**d**) RMLO DBT and (**e**) RCC DBT. Post-contrast MRI images (**f**–**g**) illustrate the three tumours

study design takes into account the practical issues of increased radiation dose and radiologist reading time, increased costs and increased data storage by the use of a single MLO DBT view as opposed to two-view DBT. This may enable DBT to be more feasible in the context of mass screening (Table 18.2).

A further area of interest is the reconstruction of tomosynthesis images into a synthetic 2D mammogram which may be comparable to conventional 2D FFDM (Fig. 18.14). The clear advantage is the dose reduction as a result of not needing to perform conventional 2D digital mammography. Skaane et al. [58] demonstrated cancer detection using conventional 2D FFDM vs. reconstructed synthetic 2D imaging showing no statistical difference when using the most current software. They also reported that a single read of synthetic 2D with DBT detected more cancer than double read FFDM.

DBT may demonstrate subtle lesions which are not visible using conventional 2D mammography or ultrasound. DBT-guided biopsy/intervention is now available. This technique can be used not only for the biopsy of subtle lesions seen on DBT alone but also for the same indications as stereo-guided biopsy or wire insertion.

There are challenges and some uncertainties related to the implementation of DBT in routine screening. There is a continued requirement for 2D or synthetic 2D mammogram images. There is uncertainty about the continued effect of DBT on sensitivity and specificity following the first "prevalent" DBT screen.

There are mixed results from studies for recall rates as well as a possible increase in single reader/discordant cancer detection. This would imply there is a learning curve with the perception and interpretation of tomosynthesis images. It is also possible that DBT may further increase overdiagnosis rates. The Oslo Tomosynthesis Screening Trial showed increased cancer detection with biologically significant disease and no increase in the detection of DCIS. The improved performance of DBT was seen in all breast densities including fatty breasts.

There may be increased costs associated with the technology, image data storage and longer reading time (Bernardi et al. [59]). The increase in radiologist reading time which may improve with experience; however, this may limit reading volumes possible by a reader as well as have cost implications. The Oslo screening study estimated a reading time of 45 s for 2D and 91 s with DBT. It is possible that reading times are longer than this depending on experience, equipment and hanging protocols. The quality assurance workload for radiographic and physicist staff is increased as is the time to perform studies. This again has implications for a high volume screening workloads and cost. The Oslo study estimated an increase of 10 s per view for an experienced mammographer to perform DBT in combination with the 2D DM. A centre using tomosynthesis will also consider the increase in data storage capacity required (an approximation of 20 MB for 2D vs. 2000 MB for DBT).

CAD may play a role in DBT screen film reading. This is being investigated in an arm of the Oslo trial; however, Kilburn-Toppin and Barter [60] have suggested CAD would remain a supplementary tool only and will not substitute radiologist reading.

18.1.6 Contrast-Enhanced Spectral Mammography

This new technique has been described as a more accessible breast MRI study. Contrast-enhanced spectral mammography (CESM) utilises tumour angiogenesis in a similar way to contrast-enhanced breast MRI (CE-MRI). CE-MRI is currently accepted as the most sensitive imaging technique for detecting and staging breast cancer.

18.1.7 Technique

There are two recognised techniques used in CESM: temporal subtraction and dual energy. Both techniques involve the administration of iodinated contrast at a rate of approximately 3 mL/s.

Table 18.2 Table of prospective DBT Breast cancer screening studies with double reading

Study	No. of patients	Design	Recall	False-positive rate	Cancer detection rate	No. of cancers/1000 2D vs. 3D(+2D)
Oslo (Interim results: Skaane et al. [55])	12,621	2 view (V) 2D vs. 2 V 2D + 2 V 3D	Increase 32%	Decrease 13%	Increase 31%	6.1 vs. 8.0
Malmö Lang et al. [56]	7500	2 V 2D vs. 1 V 3D	Increase 43%		Increase 43%	6.3 vs. 8.9
STORM (Interim results: Ciatto et al. [57])	7292	2 V 2D vs. 2 V 2D + 2 V 3D		Decrease 17.2%	Increase 51%	5.3 vs. 8.1

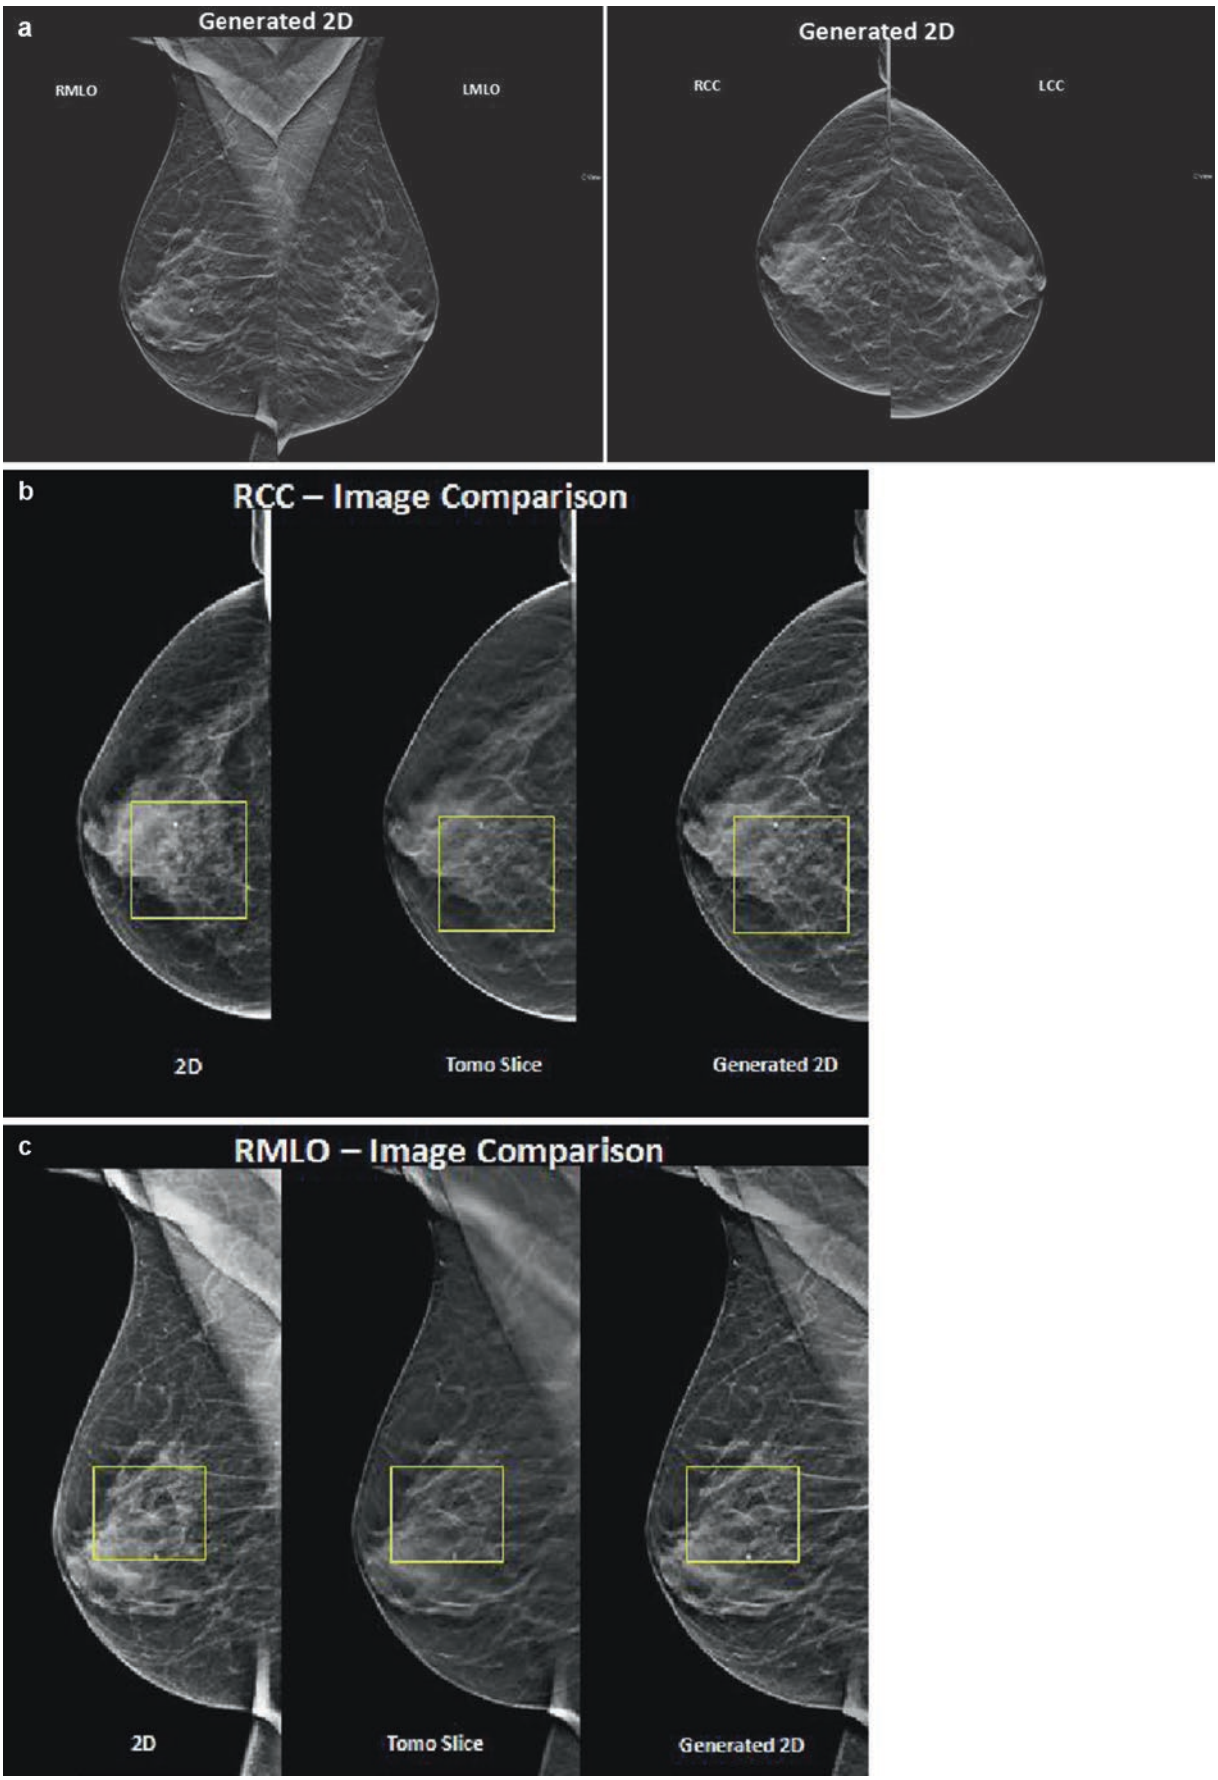

Fig. 18.14 (**a**–**c**) Images courtesy of Hologic, Inc. This is a case of invasive ductal carcinoma seen as an architectural distortion with associated microcalcification seen on the 2D, DBT and reconstructed 2D

Temporal subtraction acquires images with the patient's breast held in a single light compression which limits movement and minimises compression of the blood vessels. A pre-contrast image is taken and contrast is administered via power injector. Multiple high-energy images are taken over several minutes. The pre-contrast image is subtracted from the post-contrast images. Software enables the kinetic analysis of a lesion as with CE-MRI. A single contrast dose is required for each analysis with one breast in one projection.

In the dual-energy technique, images are acquired using high- and low-energy exposures following contrast administration via a power injector. A subtraction technique is then used to suppress the background of fibro-glandular tissue and fat, enabling clear demonstration of enhancing tissue. The light compression used is to avoid motion but enable blood flow. The shorter time to acquire the images in this technique limits motion artefact compared with the temporal subtraction technique. Images in MLO and CC projections of both breasts can be taken with a single contrast injection over 5–10 min. The dose is between 20 and 50% higher than that of a single mammographic view. Kinetic analysis is not possible with this technique (Fig. 18.15).

18.1.8 Possible Indications

This technique is predominately used in the research setting at the time of writing this chapter, although some centres have begun using this technique in diagnostic clinics and possibly in the screening of high-risk patients. It is proposed this technique can be used with similar clinical indications as CE-MRI, although this has yet to be established. These include:

- The staging of diagnosed breast cancer particularly in women with dense breasts or distracting benign lesions. This includes evaluating disease extent as well as multifocal disease and contralateral disease which may be mammographically occult.
- The investigation for equivocal breast lesions.
- An alternative to CE-MRI for the screening of high-risk family history screening.
- The detection of a primary tumour in patients with positive axillary lymph nodes and negative standard mammography and ultrasound.
- The potential evaluation of treatment response for breast tumours undergoing neoadjuvant chemotherapy or primary hormonal therapy.
- The investigation of recurrent disease where posttreatment changes may make mammographic interpretation challenging.

The sensitivity of CESM has been proven to be comparable to that of CE-MRI in the detection of index tumours. Jochelson et al. [61] demonstrated CESM and CE-MRI to both exhibit a sensitivity of 96% in detecting the index tumour (81% with conventional mammography) using the dual-energy technique. However, CE-MRI was significantly more sensitive in the detection of multifocal and multicentric additional ipsilateral disease than CESM (56% vs. 88%, respectively). CESM has been shown to give an accurate size measurement/disease extent compared with the final histology (Dromain et al. [62] and Jochelson et al. [61]).

The improved sensitivity of CESM in comparison to non-enhanced mammography is seen in all breast types (Diekmann et al. [63]). The higher spatial resolution of mammography to MRI enables a more critical analysis of lesion morphology as well as the visualisation of microcalcification, not visible with CE-MRI. This is evident by the high rates of specificity reported with CESM than with CE-MRI. Jochelson et al. [61] reported a PPV of 97% for malignancy with CESM compared with 85% for CE-MRI. The improved specificity with CESM may reduce the false-positive findings and benign biopsies secondary to CE-MRI as well as avoiding the practical limitations of scheduling the study by the woman's menstrual cycle, which does not affect CESM. Studies using the temporal subtraction technique have shown very variable kinetic analysis curves for malignant lesions that do not reflect those seen with CE-MRI. However, the enhancement patterns and distribution seen with CESM may mimick those seen with CE-MRI. Jong et al. [64] describe rim-like enhancement, irregular masses and inhomogeneous and linear enhancement of malignancies using a temporal subtraction technique.

CESM would be more cost-effective and time efficient in the diagnostic clinic setting where it may be performed along with standard mammography and ultrasound. CESM may also enable a more accessible means to biopsy and localise disease occult by conventional imaging methods.

The limitations of CESM include the contraindications for contrast administration which are documented contrast allergy, renal insufficiency and the relative contraindications of pregnancy and lactation. Similarly, potential complications include those of intravenous access and contrast reactions. Tumour conspicuity may be affected by the possible reduced blood flow and hence subsequent enhancement from compression of the breast, the reduced contrast resolution and the effect of enhancing overlying fibro-glandular tissue. The limitations of this technique in enhanced high-risk screening instead of CE-MRI would be secondary to the ionising radiation dose.

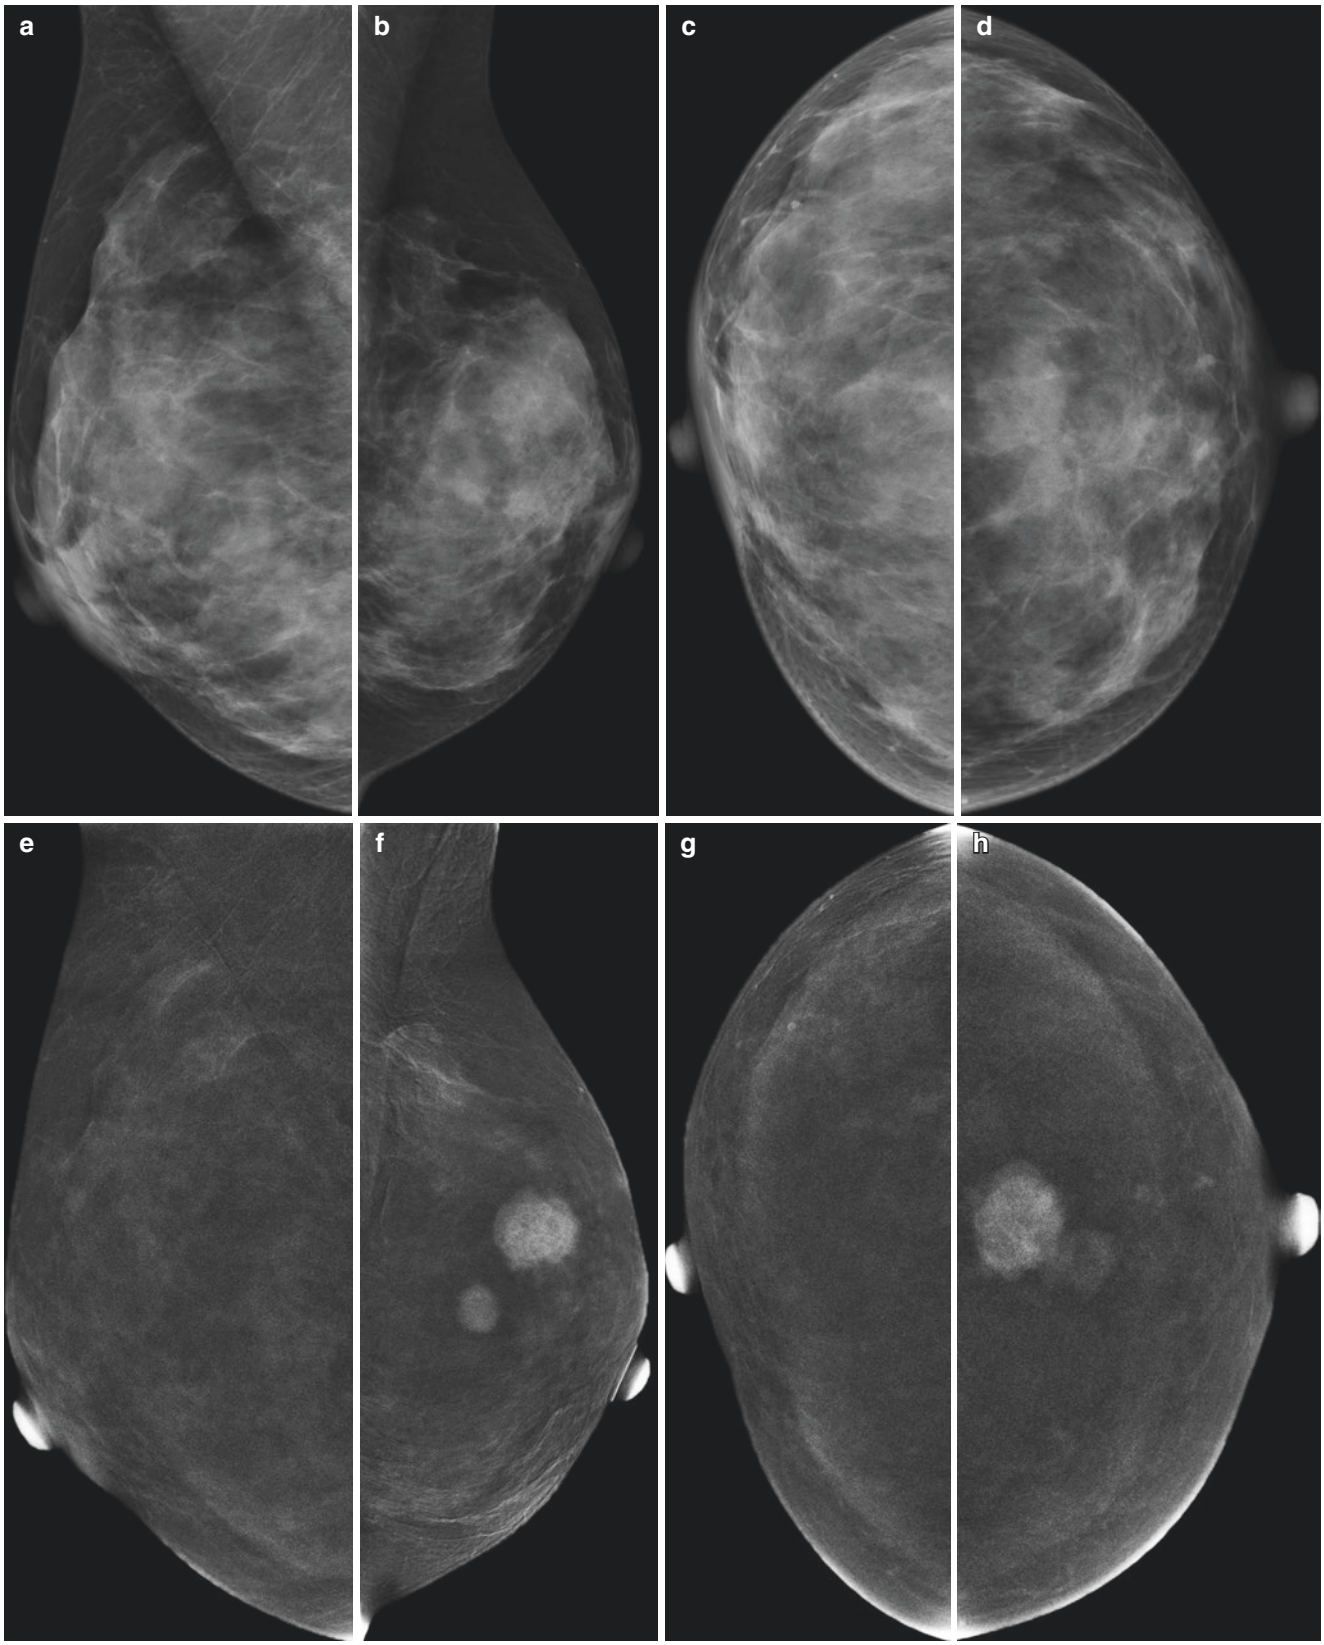

Fig. 18.15 (**a**–**h**) Images courtesy of Dr. Sarah Tennant, Nottingham University NHS Hospital and the Nottingham Breast Institute. (**a**–**d**) are the low-energy images of BI-RADS 4 dense breasts. The smaller tumour is seen on the (**b**) LMLO 2D FFDM with only a subtle increased density seen within the upper breast representing the larger tumour. This area of increased density may easily be overlooked on 2D DM. The post-contrast subtracted images (**e**–**h**) clearly demonstrate two grade 3 invasive ductal cancers measuring 19 and 13 mm on final histology without overlapping breast tissue or distracting lesions

18.2 Ultrasound

Viviana Londero, Chiara Zuiani, Martina Zanotel, and Massimo Bazzocchi

Abstract Breast ultrasound (US) is an indispensable tool in breast imaging, and, thanks to advances in US technology, its role is currently not limited to distinguish cystic from solid masses. In fact, a variety of new technical developments, the use of high-resolution probes and the application of a standardised BI-RADS US lexicon have improved characterisation of solid breast masses.

The authors provide an overview of recent advances in US technology, highlighting the applications of breast US in clinical practice. A description of BI-RADS US lexicon and the semiotic of cystic and solid breast lesions will also be presented.

Keywords Breast ultrasound • BI-RADS US • Breast disease • Colour Doppler • Elastography • 3D US • ABUS

18.2.1 Introduction

Breast ultrasound (US) has become an indispensable tool in breast imaging, usually complementary to mammography and magnetic resonance (MR) imaging. Although is under discussion the use of whole-breast US as supplement screening tool in women with dense breasts, its primary and routinely role is the characterisation of lesions detected at mammography, MR imaging or clinical breast examination [65].

The first clinical applications of breast US in the 1960s exploited the ability of US to distinguish cystic from solid masses, with the result that cystic benign lesions did not require further workup [66]. However, the poor image contrast and fair resolution of the first US machines did not allow further differentiation among solid breast masses [65]. Over the next decades, the advances in US technology, the development of high-frequency US transducers and the application of a standardised BI-RADS US lexicon allowed to obtain more detailed information about shape, orientation, margins, lesion boundary, echo pattern and posterior acoustic features of breast lesions, with the result to improve lesion conspicuity in the background of surrounding parenchyma and to improve characterisation of solid breast masses.

The US semiotic was subsequently ameliorated after the publication of Stavros' landmark study in 1995 [67], demonstrating that high-resolution greyscale US imaging could accurately distinguish benign from malignant lesions. In particular, Stavros et al. [67] developed a classification system for solid breast masses that achieved a 98.4% sensitivity and a 99.5% negative predictive value for malignancy. Among benign US features, the author included ellipsoid shape, gentle bi- or tri-lobulations, a thin echogenic capsule and a homogeneously echogenic echotexture [67]. Malignant US features included spiculated or angular margins, "taller-than-wider" orientation, marked hypoechogenicity, posterior acoustic shadowing and microcalcifications [67].

These important results were confirmed by other authors [68, 69], and the "Stavros' sonographic features" or "Stavros' criteria" are currently considered the cornerstones in the US assessment of breast solid lesions. Nowadays, these US signs ("descriptors") are widely illustrated and validated by the ACR BI-RADS US (Breast Imaging-Reporting and Data System) [70].

18.2.2 Conventional 2D Ultrasound, Compound Imaging and Harmonic Imaging

In addition to traditional greyscale US examination (B-mode), complementary tools now available in almost US units include compound imaging and harmonic imaging that can be used to ameliorate image contrast and resolution. Colour Doppler and power Doppler (more sensible to low-flow vessels) analysis allows to assess vascular architecture of the lesion and of surrounding breast tissue.

18.2.3 Compound Imaging and Harmonic Imaging

High-quality 2D US in combination with a precise examination technique, including radial and anti-radial scanner movements and a moderate tissue compression, is the basis for improving lesion conspicuity and for detecting small breast lesions and early-stage breast cancers.

Compound imaging and harmonic imaging represent 2D US technical advances introduced to ameliorate the image contrast and resolution, and these tools should be routinely used during US examination in order to optimise image quality. Compound imaging, with the use of an electronic beam steering, allows to acquire multiple US images from different angles, providing in real time a single final image that represents the average of these multiple images [71, 72]. The main advantage of compound imaging is that returning echoes from real structures are enhanced, with improved contrast resolution, resulting in a better definition of lesion margins, echogenic halos, posterior and lateral borders and better visualisation of microcalcifications and subtle architectural distortions [72]. Therefore, compound imaging is

able to reduce some advantageous artefacts such as artefacts behind Cooper's ligaments, but, at the same time, some helpful artefacts typically used as semiotic signs to differentiate cystic from solid nodules (such as posterior acoustic enhancement or shadowing) can be eliminated. Therefore, caution is necessary when applying this technique to lesion analysis.

Another modern algorithm, called "speckle reduction imaging" (SRI), that can be used simultaneously with compound imaging can help to enhance contrast and to optimise image quality during US examination.

To explain harmonic imaging, we have to consider that when US pulses travel along breast tissue, they can be distorted, creating harmonic frequencies [72]. The returning US signals may therefore contain both the original fundamental frequency and its multiples or harmonics. In harmonic imaging, the higher harmonic frequencies are filtered and used to create the greyscale US image with improved contrast, whereas lower-frequency artefactual internal echoes (typical of fluid components) are eliminated. As a consequence, the harmonic technology provides a better characterisation of simple cysts (especially if small) (Fig. 18.16) and a better definition of subtle lesions. Harmonic imaging also improves lateral resolution and assessment of lesion margins (Fig. 18.17).

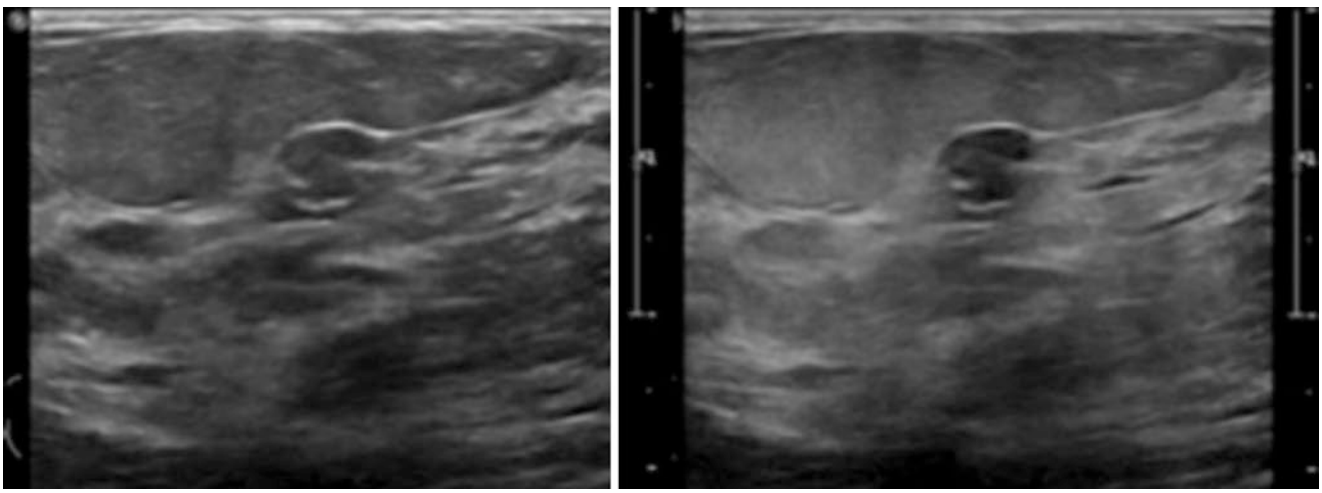

Fig. 18.16 Harmonic imaging. Solid hypoechoic lesion (fibroadenoma). Harmonic imaging (*right figure*) shows more accurately lesion margins and allows a significant increase of signal to noise ratio

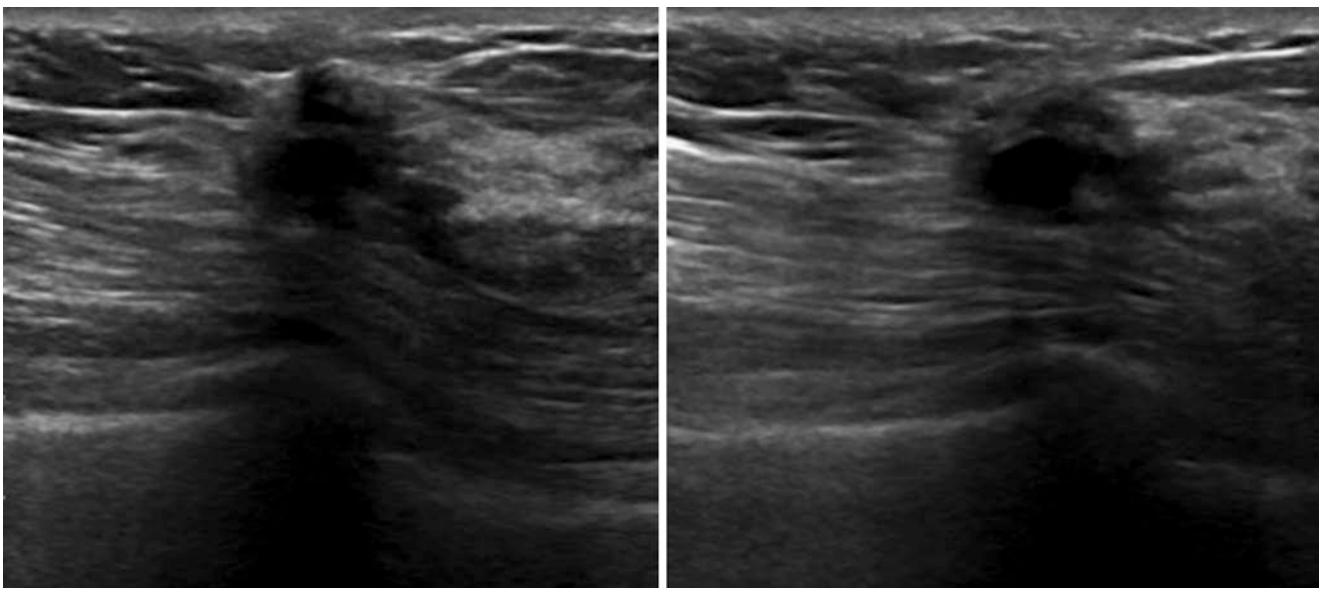

Fig. 18.17 Harmonic imaging. Hypo-anechoic lesion in woman with previous quadrantectomy; harmonic imaging (*right figure*) highlights with greater accuracy the oval morphology and partially circumscribed margins defining the cystic nature of the lesion (liponecrosis)

18.2.4 Colour Doppler and Power Doppler

With improvements in breast US technology, colour Doppler and power Doppler have become complementary tools to greyscale breast ultrasound, giving information about vascularity of solid lesion and of surrounding breast tissue. Power Doppler has been seen to be more sensible to low-flow vessels typical of breast lesions that, generally, require a moderate tissue compression in order to prevent occlusion of vessel lumen.

First applications of colour Doppler in the mid-1990s and early 2000s demonstrated that the presence of increased vascularisation within a solid breast mass could raise the suspicion of malignancy. In fact, Cosgrove et al. [73] in 1993 found that 99% of malignant lesions exhibited significant vascularisation at colour Doppler compared to only 4% of benign lesions. Sehgal et al. [74] found that benign lesions were two times more vascular than the surrounding tissue, compared to five times higher vascularity of malignant lesions.

Further studies in subsequent years did not confirm these initial promising results and concluded that colour Doppler should not be considered a reliable tool in the assessment of breast disease, because it could not accurately differentiate benign from malignant lesions [75, 76]. Although consensus has not been reached on usefulness of Doppler analysis, nowadays these vascular tools should be an integral part in every breast ultrasound practice.

In Gokalp's study [76], power Doppler criteria predictive of malignancy included hypervascularity, penetrating vessels within a solid mass and neovessels with branching-disordered course; however, the authors did not find any contribution to BI-RADS US, with the addition of power Doppler ultrasonography and spectral analysis.

Thanks to higher sensitivity to low-flow vessels, power Doppler may be useful in distinguishing a "centripetal" vascular pattern, generated by anomalous neovessels in malignant lesions, from the "centrifugal" vascularity (with a parallel artery and vein in the periphery or inside a lesion), predominantly associated with benign lesions (such as fibroadenomas) or with anatomic structures (such as lymph nodes). In particular, lymph nodes can be easily recognised because they exhibit a rich hilar vascularisation, also if small sized. Therefore, power Doppler, when used in addition to B-mode US, may reinforce the benign or malignant suspicion of a solid mass and can help to improve BI-RADS assessment category.

Assessment of lesion vascularity is recommended but is not considered mandatory in the BI-RADS US lexicon [70] that includes three descriptor choices ((a) absent, (b) internal vascularity, (c) vessels in rim). In the US section of the new BI-RADS fifth edition [70], the special category has been expanded with the additional terms of arteriovenous malformations and Mondor disease.

In addition to all potential uses above described, the application of colour Doppler may be helpful during breast interventional procedures, in order to avoid hitting great vascular structures with the risk of bleeding and obscuring the target lesion (particularly frequent in lesions of small dimensions or located deep in the breast). Besides, a biopsy marker clip may create a twinkle artefact, best appreciable with colour Doppler.

18.2.5 US Elastography

US elastography has the ability to measure tissue stiffness, in a similar manner of palpation during physical examination. Two types of elastography are available today: strain and shear wave.

Strain elastography requires gentle compression with US probes that results in a tissue displacement (or strain), usually inversely correlated with tissue stiffness [77]. This technique provides qualitative information, in a colour-scale image, although the strain ratio, comparing the strain of lesion to the surrounding breast tissue, can be calculated [78, 79]. Stiff malignant masses usually exhibit higher strain ratio in comparison with benign lesions.

In shear-wave elastography, the US probe generates transient, automatic pulses that induce transverse waves in the tissue. The US system measures the speed of these waves, which travel faster in hard tissue compared with soft tissue [80]. A quantitative information, represented by the tissue elasticity and measured in KPa or m/s, can be calculated.

Therefore, some parameters obtained with elastographic analysis such as strain ratio, shape, homogeneity and maximum lesion stiffness (Fig. 18.18) can enrich the conventional sonographic features, improving specificity in the diagnosis of breast lesions.

On elastography, malignant lesions typically appear more irregular, heterogeneous and larger compared with greyscale B-mode examination [81, 82]. Moreover, although malignant lesions exhibit maximum stiffness greater than 80–100 KPa [82, 83], a variability among lesions and among elastography techniques may exist [82].

Some papers found that high stiffness, measured at shear-wave elastography, is highly correlated with more aggressive behaviour tumours, including high-nuclear-grade, large-sized lesions and early lymphatic and vascular invasion [84].

Despite these initial promising results about usefulness of elastography in clinical practice, some limitations exist such as differences between the two methods (strain and shear wave) and among different US machines and the presence of inter- and intra-observer variability, affected by degree and method of compression, although shear-wave technique seems to be less operator dependent [85]. In addition, one must be aware that elastographic assessment is less accurate in lesions deeper than 2 cm and that soft cancers or hard benign lesions may exist.

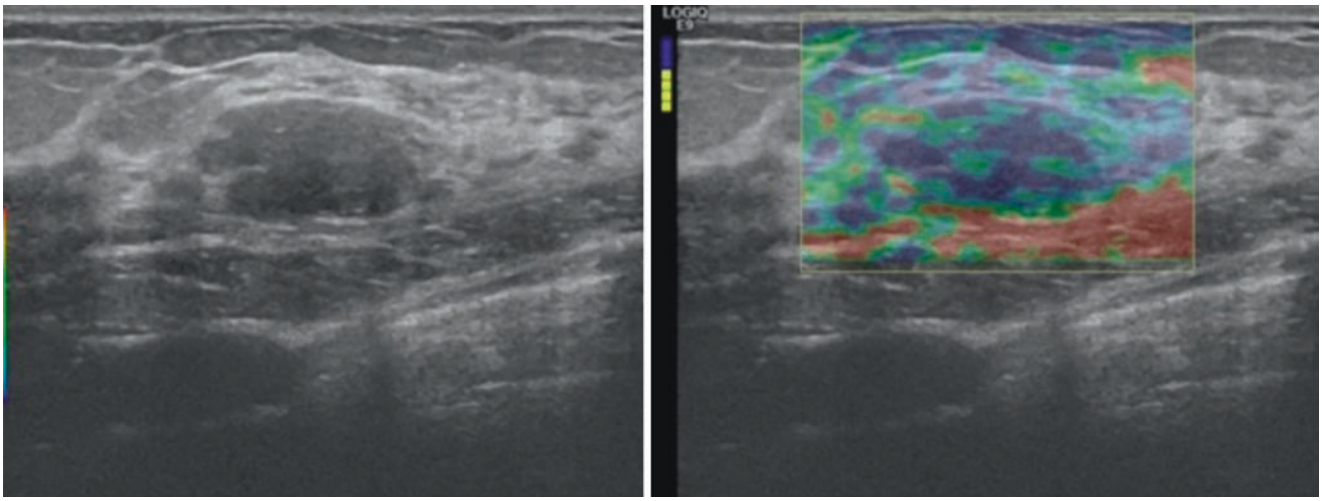

Fig. 18.18 Elastography. Hypoechoic circumscribed lesion (fibroadenoma) that is predominantly elastic, depicting the typical mosaic pattern of *green* and *blue* (BI-RADS US 2) on elastography (*right image*)

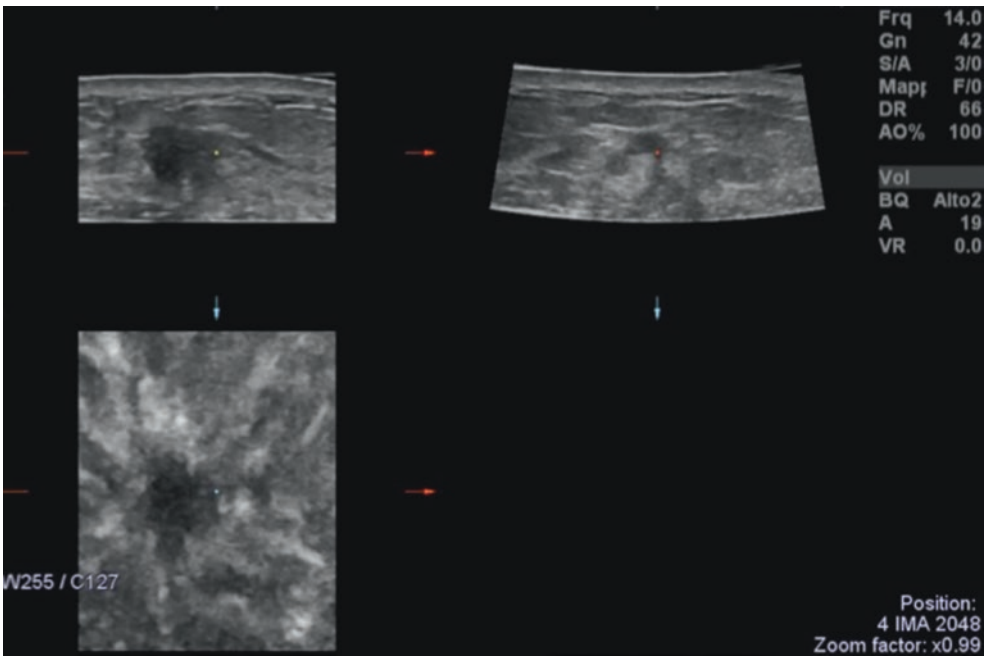

Fig. 18.19 3D ultrasound. Invasive ductal carcinoma grade 1. Images of 3D US are presented in three planes ("multiplanar display mode"). The coronal plane allows a better evaluation of tumour margins and distortion type of growth pattern, typically associated with malignant lesions

18.2.6 Advances in US Technology

New technical developments such as 3D ultrasound, dedicated CAD (computer-aided diagnosis) and automated whole-breast ultrasound (ABUS) are promising methods suitable for the future clinical practice [65, 72, 86].

18.2.7 Three-Dimensional (3D) Ultrasound

3D ultrasound has been recently developed, and high-resolution linear 3D transducers are available in new US machines for a new multidimensional breast imaging. 3D US technology, with a single pass of the ultrasound beam, allows the acquisition of a volume data set, from which the static 3D information will be reconstructed. In 3D US, reconstructed 3D sonographic images are displayed in a "multiplanar display mode" allowing the representation of breast lesions and of surrounding breast tissue in three spatial planes (coronal, sagittal, and transverse plane) [86, 87] (Fig. 18.19). The system allows to navigate through the entire volume, performing parallel movements through the image slices in the three orthogonal planes.

Compared to standard 2D US, 3D images provide a more accurate assessment of tumoural margins and of surrounding breast tissue; moreover, the multiplanar representation is available for a double reading.

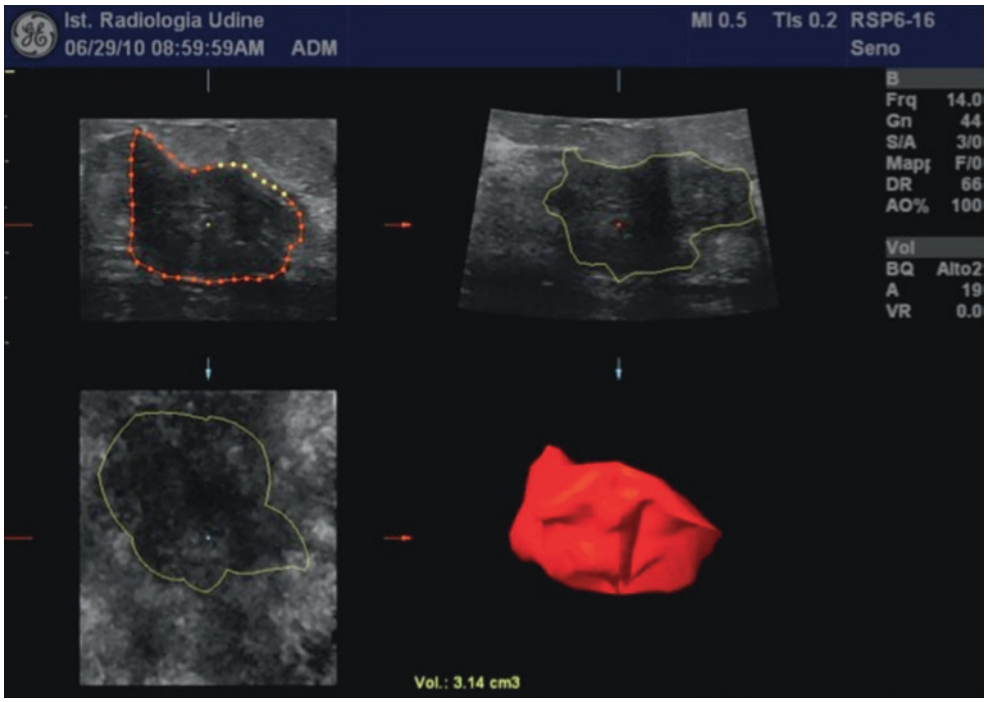

Fig. 18.20 3D Ultrasound. Invasive ductal carcinoma grade 2 with intraductal component, with lesion's volume calculation. 3D US can easily obtain calculation of tumour volume (cm^3) by the VOCAL software ("virtual organ computer-aided analysis")

In particular, Rotten [87], by using 3D US, described two main peritumoural tissue patterns, particularly visible in the coronal plane, corresponding to "compressive pattern", typically associated with benign lesions, and "converging or stellate pattern", associated with malignant lesions. By using these criteria of peritumoural tissue pattern, the authors [87] achieved a 91.4% sensitivity, a 93.8% specificity, an 86.9% positive predictive value and a 96% negative predictive value in the differentiation between malignant and benign lesions.

Moreover, 3D US has a potential role in the assessment of tumoural response to neoadjuvant chemotherapy, offering a precise and reliable volume calculation with VOCAL software ("virtual organ computer-aided analysis") [86] (Fig. 18.20). 3D US can also be used for the volumetric assessment in the preoperative evaluation of breast lesions [88].

A future application of 3D technology should include 3D ultrasound guidance during breast needle biopsies, with the goal of reducing sampling errors due to "partial volume effect", especially with small-sized breast lesions.

18.2.8 Automated Whole-Breast Ultrasound (ABUS)

ABUS is a new technological advance in which breast scanning is performed automatically by using a curved transducer that is larger compared to traditional handheld (HHUS) probe and is similar, in size and shape, to a mammography compression paddle. This automated transducer is placed over the breast using a moderate tissue compression, with patient lying supine on the table, and allows to scan the whole breast automatically. Usually, three acquisitions (AP, lateral and medial) for each breast are needed, which may increase to four or five acquisitions in women with larger breasts. On average, total acquisition time is 15 min, with medium-sized breasts [89].

All imaging data obtained during scanner acquisition are processed and stored on a computer hard drive and finally can be visualised on a standard workstation during reporting and interpretation session. On workstation screen, ABUS images can be displayed in the transverse, coronal or sagittal plane (Fig. 18.21), typically not available with traditional 2D US imaging. In particular, the coronal view is particularly helpful in detecting areas of architectural distortions, which may be difficult to appreciate on standard axial images [90] (Fig. 18.22). ABUS offers also the possibility to visualise real-time images at the time US examination is performed, in a similar manner of HHUS examination.

Automated US offers several advantages over traditional HHUS scanning, such as higher reproducibility, less operator dependence and less physician time for image acquisition. In fact, the physician time required by ABUS includes only time for interpretation, approximately 3 min to read a negative examination, whereas time for image acquisition has been now eliminated [89].

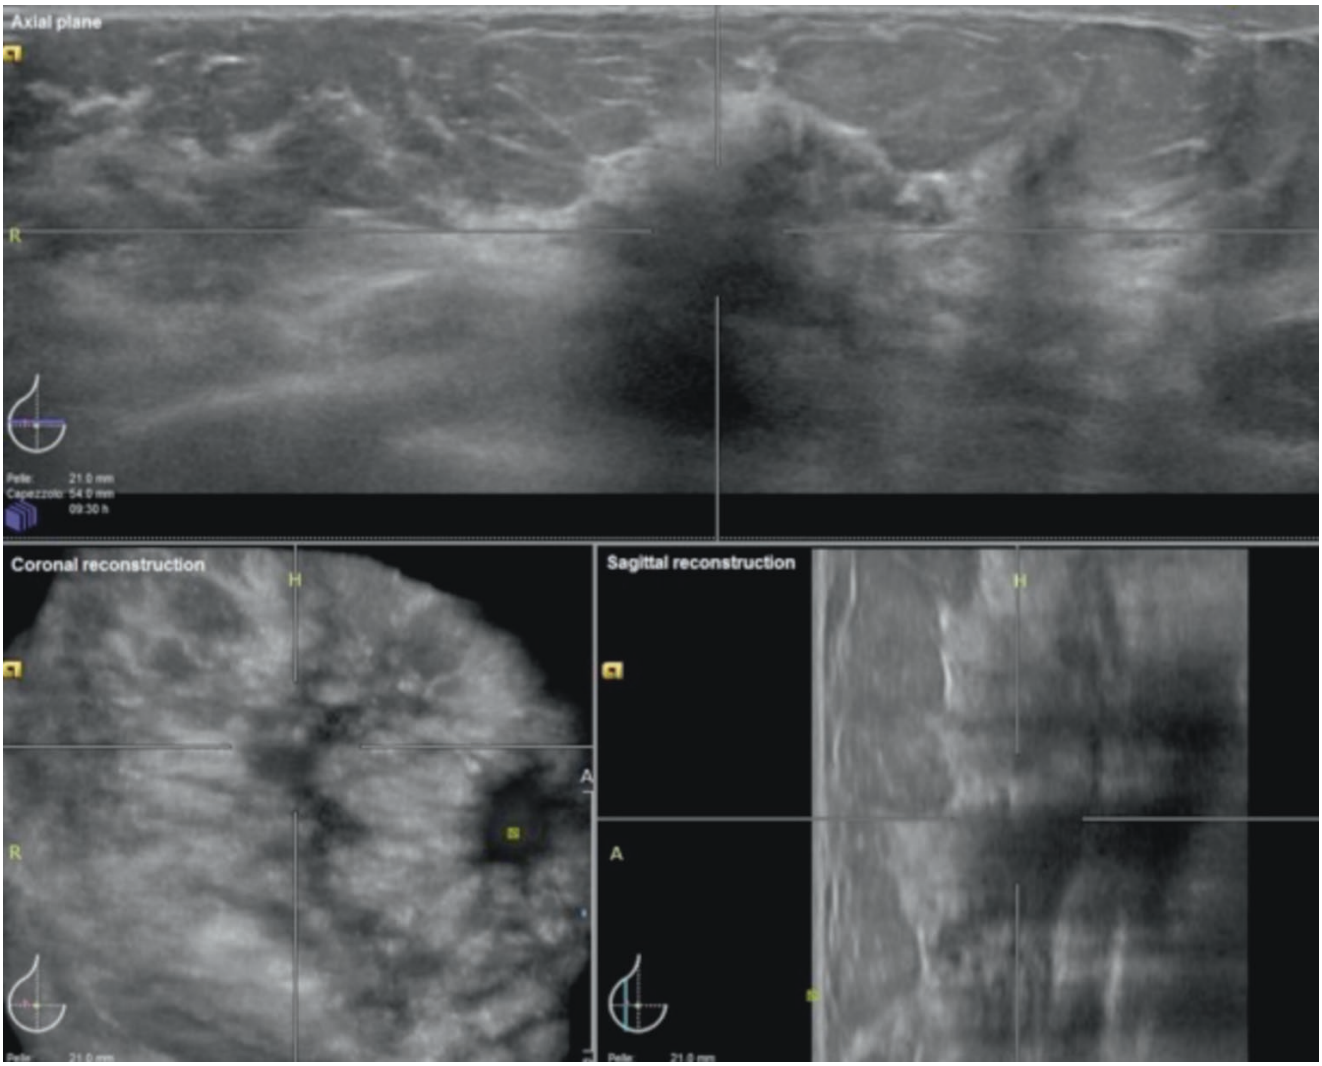

Fig. 18.21 ABUS. Invasive lobular carcinoma. Hypoechoic lesion with indistinct margins and posterior shadowing artefacts (BI-RADS US 5) shown in axial, sagittal and coronal planes

There are some limitations in automated US technology, which are the presence of shadowing artefacts in the subareolar region (that may obscure actual lesions or create unreal findings) and the incomplete assessment of breast tissue, being the axillary region not included in the automatic scanning [89]. Some authors [91] report that ABUS is a promising diagnostic tool with a good interobserver agreement, comparable to that of HHUS, on lesion characterisation and on final category assessment.

One topic of interest is the potential application of ABUS, as a promising screening tool in adjunct to mammography, for examining radiologically dense breasts [89]. In the large observational study of Brem [92], the addition of ABUS to screening mammography in women with dense breast tissue has resulted in an increase of cancer detection rate (1.9 additional cancers per 1000 screened women) but also in an increase of false-positive results. In fact, 552 additional needle biopsies were performed to identify 30 cancers detected with ABUS alone (most of these were invasive clinically important cancers). This high false-positive rate inducing to perform unnecessary biopsies should be however overtook with higher operator experience and higher diagnostic confidence. Some recent works have demonstrated an equivalence in lesion detection [93] and an equivalence or, in some cases, a superiority in lesion characterisation in the comparison between ABUS and HHUS [94, 95].

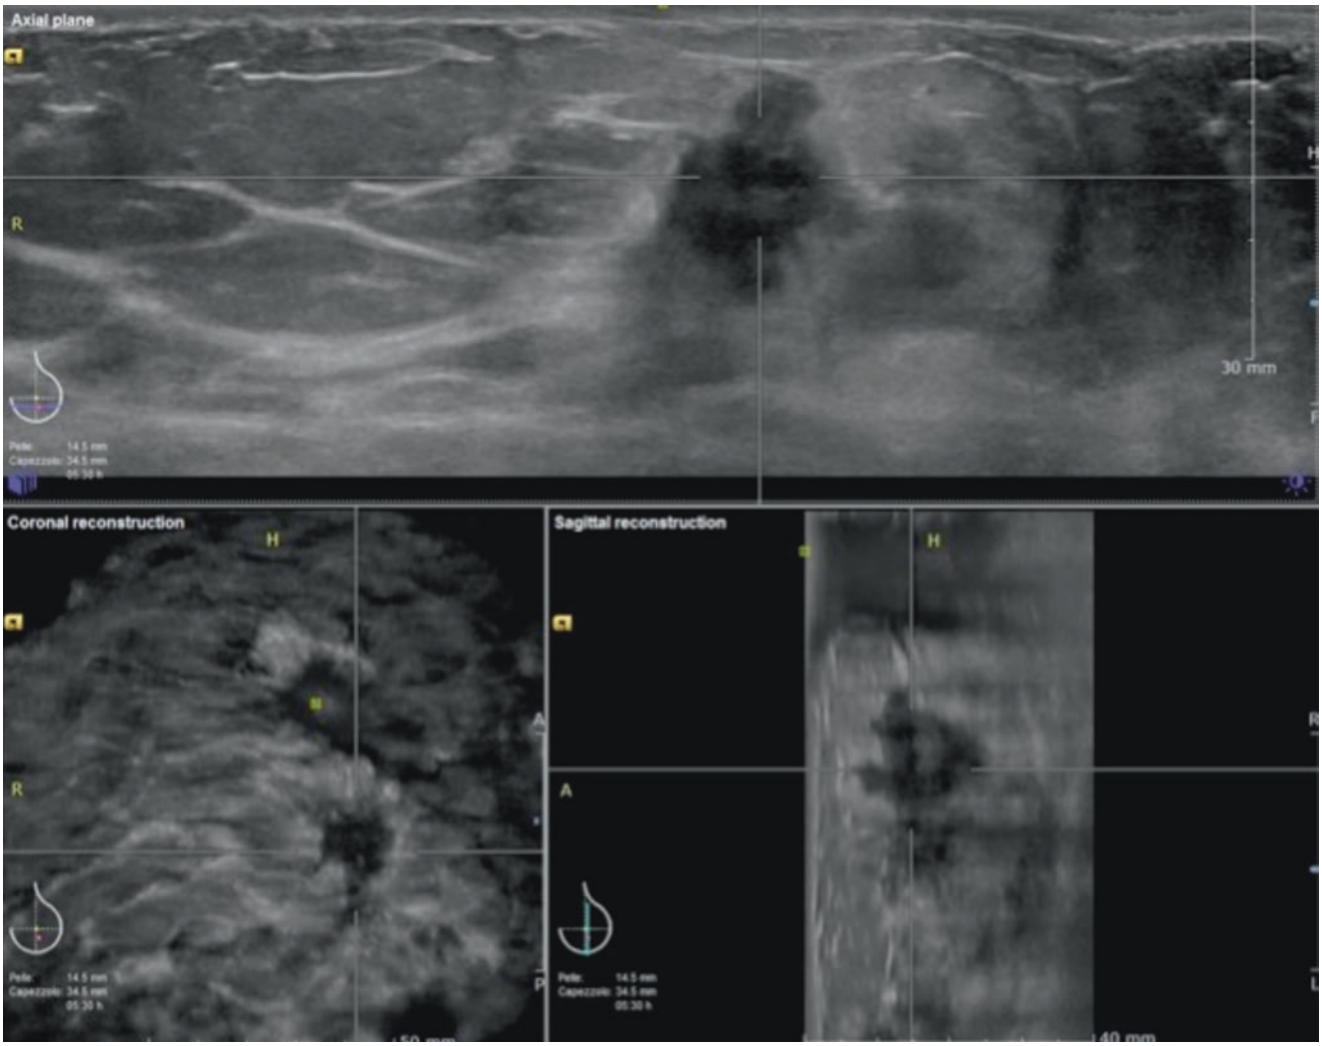

Fig. 18.22 ABUS. Invasive ductal carcinoma. Hypoechoic lesion with vertical growth and irregular margins (BI-RADS US 5) shown in axial, sagittal and coronal planes

18.2.9 Breast Ultrasound in Clinical Practice

Breast ultrasound (US) is the modality of choice for differentiating cystic from solid breast masses, and its primary role is the characterisation of lesions detected at mammography, at MR imaging, or at clinical breast examination [96].

Current indications for breast ultrasound, as recommended by the ACR Practice Guidelines [96], include the evaluation and characterisation of palpable masses or other breast symptoms and the evaluation of abnormalities detected with other imaging modalities, including the role of targeted US after a contrast-enhanced breast MR examination to find an ultrasound correlate. US can also be used as first-line imaging modality for palpable masses in women under 30 years and in lactating and pregnant women and for evaluation of breast implants. In addition, US can be used as guidance for breast biopsy or other interventional procedures, including biopsy guidance of abnormal axillary lymph nodes [96]. The use of bilateral whole-breast US, in women with dense breast tissue, as an adjunct to screening mammography, is a topic of discussion and debate [89, 96].

18.2.10 ACR BI-RADS US

In light of the widespread use and implementation of breast US in clinical practice, a standard lexicon for sonography was initially developed in 2003 by the ACR in order to provide a standardised lexicon for sonographic reporting, to facilitate final category assessment and to validate management recommendations. The correct adherence to BI-RADS

US lexicon can improve differentiation between benign and malignant lesions and potentially reduce the number of unnecessary biopsies [97].

The BI-RADS sonographic categories include size, shape, orientation, margins, echogenicity, lesion boundary, attenuation features, special cases, vascularity, and surrounding tissue [70]. In the last BI-RADS fifth edition [70], new terms have been added to the US lexicon to simplify reporting and to reflect technologic advances (such as the addition of elastography). In particular, a new section, including "elasticity assessment" with three descriptor choices ((a) soft, (b) intermediate, (c) hard), has been added. The ACR recommends the use of these elasticity descriptors instead of the colour scale, not yet standardised.

Some authors report an interobserver variability with the use of BI-RADS US lexicon comparable to that for mammography. Abdullah et al. [98] found a fair interobserver agreement ($k = 0.30$) in the final BI-RADS category, in particular in final BI-RADS 4 a, b, and c subcategories ($k = 0.33$, 0.32 and 0.17, respectively), reflecting difficulties of radiologists to indicate a degree of suspicion. Promising results were obtained by Heinig et al. [99] that reported malignancy rates in BI-RADS US category 3, 4 and 5 similar to those of mammography (1.2%, 17% and 94%, respectively), underlying the usefulness of BI-RADS US descriptors to obtain a final degree of suspicion.

18.2.11 Sonographic Findings of Cystic and Solid Breast Masses

Thanks to its ability to differentiate cystic from solid masses and to state a suspicion degree among solid masses, breast US is usually complementary to mammography in the characterisation of breast lesions, characterisation that sometimes may appear difficult if lesion is small (<5 mm) or located deep in the breast [100, 101].

The traditional sonographic signs used in breast US reporting refer both to the "Stavros' sonographic criteria" [67], which represent a landmark in this context, and to the US descriptors illustrated and validated by the ACR BI-RADS US [70].

1. **Cysts**

   Simple cysts are defined as well-circumscribed, anechoic masses, with posterior acoustic enhancement. Complicated cysts are hypoechoic masses, not vascularised at colour Doppler analysis, that may contain internal echoes or exhibit indistinct margins. Complicated cysts are benign findings, typically associated with low malignancy rate (0–0.08%) [102]; however, when associated with a mammographic correlate or with a palpable mass, they should be classified as BI-RADS 3, and a short follow-up or an US-guided aspiration should be recommended.

   "Complex masses" present a heterogeneous echo pattern with an anechoic (liquid) component and a hypoechoic (solid) vascularised component; sometimes mural nodules, thick walls or irregular internal septations may coexist. In relation to their high malignancy rate (23–31%), these complex masses should be assessed as BI-RADS 4 and should require further characterisation with US-guided needle core biopsy.

   The application of harmonic imaging can improve characterisation of simple cysts (particularly if small sized), allowing the elimination of artefactual internal echoes, whereas the application of elastography is useful in improving the specificity of lesions assessed as BI-RADS 3 or BI-RADS 4a, including complicated cysts, with the result of reducing the need of unnecessary biopsies [82].

2. **Solid Breast Masses**

   (a) Sonographic criteria of benignity

   The benign sonographic features described by Stavros [67] and later confirmed by Hong [103], typically associated with a low risk of malignancy, include ellipsoid or oval shape (negative predictive value, 84%), circumscribed margins with gentle bi- or tri-lobulations (90%), the "wider-than-taller" appearance with parallel orientation (78%), as well as the absence of any malignant features.

   Lesions with these sonographic benign findings are typically fibroadenomas that may be managed with a short-term imaging follow-up, even if the mass is palpable [97, 104].

   However, considerable overlap between benign and malignant US features exists; therefore, a careful correlation with mammography is essential, keeping in mind that an US benign-appearing solid mass requires biopsy if it exhibits any suspicious mammographic features.

   (b) Sonographic criteria of malignancy

   Sonographic findings predictive of malignancy include spiculated (positive predictive value, 86%) or angular (60%) margins, irregular shape (62%), the "taller-than-wider" appearance with antiparallel orientation (69%), posterior acoustic shadowing (52%) and echogenic halo (70%), expression of peritumoural desmoplastic reaction [67, 103]. Other sonographic Stavros' criteria predictive of malignancy include marked hypoechogenicity, microcalcifications, duct extension, branch pattern and the presence of microlobulated margins [67].

   Among US descriptors, Lazarus [40] found a good agreement for lesion orientation, shape and boundary ($k = 0.61$, 0.66 and 0.69, respectively), a moderate agreement for margins and posterior acoustic shadowing ($k = 0.40$, for both) and a fair agreement for lesion echo pattern ($k = 0.29$) and final assessment category ($k = 0.28$).

   In addition to sonographic signs, the value of these criteria in distinguishing benign from malignant solid

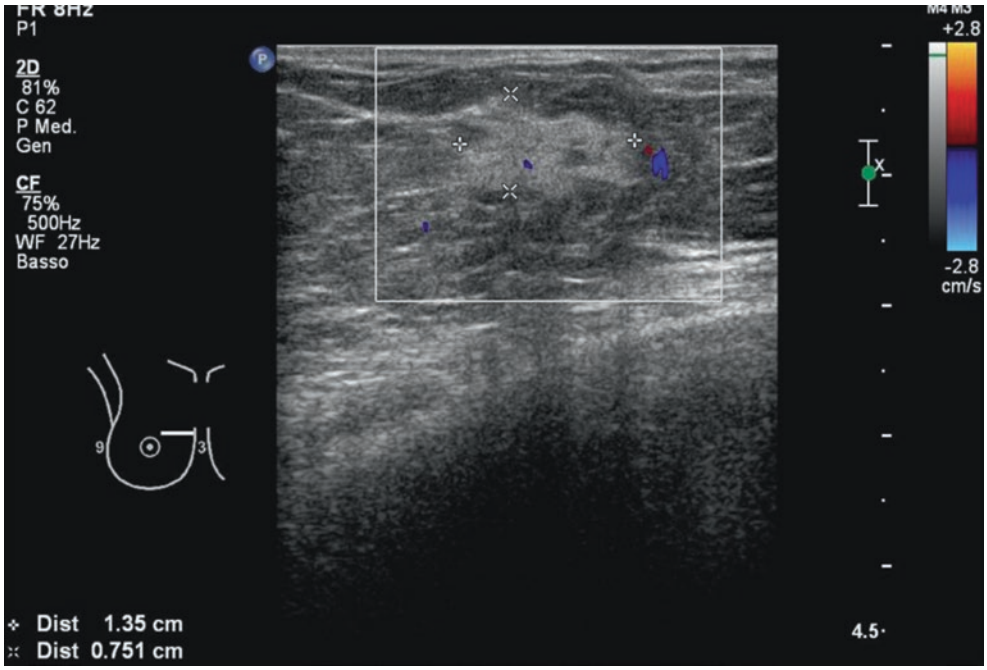

Fig. 18.23 Invasive ductal carcinoma grade 2. Hyperechoic lesion, with irregular morphology and indistinct margins (US signs suspicious for malignancy)—BI-RADS US 4b

lesions is affected also by lesion size, with improving accuracy of breast US when evaluating lesions greater than 7 mm [105].

3. **Hyperechoic Breast Masses**

   Although lesion hyperechogenicity is considered the benign feature with the highest (100%) negative predictive value for malignancy [67, 103, 105], hyperechogenicity at US alone does not exclude malignancy, and uncommon hyperechoic malignancies may exist [106, 107].

   When evaluating a hyperechoic lesion, suspicious sonographic features that should help to avoid misdiagnosis include the presence of focal hypoechoic areas within the hyperechoic lesion, non-parallel orientation, non-circumscribed margins, posterior acoustic shadowing and rich internal vascularisation at colour Doppler examination (Fig. 18.23). In addition, correlation with clinical history and with mammographic appearance should be recommended.

4. **Ductal Carcinoma In Situ and Microcalcifications**

   Ultrasound is considered to have a marginal role in the evaluation of ductal carcinoma in situ (DCIS), in relation to the poor demonstration of microcalcifications, particularly when located in a dense breast parenchyma.

   The advances in US technology with the use of high-frequency transducers (high-resolution sonography) and with improved spatial and contrast resolution allow a better depiction of microcalcifications, particularly when they form large (>10 mm) clusters or when they are located in solid hypoechoic masses, highly suspicious for malignancy.

   US features associated with DCIS usually include hypoechoic masses, intracystic masses, and architectural distortions [108, 109]. In Moon's study [108, 110], a microlobulated mass, with mild hypoechogenicity, ductal extension and normal acoustic transmission, was the most common US finding of DCIS.

   Some studies [108–110] have investigated the potential roles of US in the evaluation of DCIS, including those without calcifications; in particular, (1) US can be used to visualised large (>10 mm) clusters of microcalcifications, suspicious for malignancy; (2) US may be helpful in detecting DCIS without calcifications and in evaluating disease extent; and (3) US may reveal mammographically occult DCIS in dense breasts.

   Another main benefit of US detection of DCIS is to identify the invasive component and to guide interventional procedures that are usually more comfortable and less time-consuming compared with stereotactic breast biopsies.

18.2.12 Conclusions

Breast ultrasound has become an indispensable tool in breast imaging, and, thanks to technological advances, its role is currently not limited to distinguish cystic from solid masses and to characterise solid breast masses but also to identify small malignancies in mammographically dense breasts or to detect abnormalities in patients with breast implants or breast reconstruction.

Re-evaluation of the breast with US targeted upon the site of a suspicious MRI-detected lesion ("second-look US" or "targeted sonography") offers the possibility to identify a correlative lesion on ultrasound so that needle core biopsy

may be obtained using sonographic guidance (as an alternative to MR-guided biopsy).

Finally, US can be used to guide interventional breast procedures (such as needle core biopsies or preoperative needle localisations), with several advantages compared with stereotactic guidance.

18.3 MRI

Christiane K. Kuhl

Abstract Magnetic resonance imaging (MRI) is one of the fastest developing fields in contemporary diagnostic radiology. Within the field of breast MRI, there are currently two major research directions. One direction is to increase the complexity of image acquisition methods in order to further improve our ability to characterise disease, i.e. to distinguish nonproliferative changes, changes with atypias, preinvasive and invasive cancer as well as for improved prognostication, prediction and response assessment, according to the concept of "multiparametric breast MRI". The other direction is to reduce the complexity and facilitate image acquisition as well as interpretation, according to the concept of "abbreviated breast MRI". These two research directions are complemented by the development of new methods for MR-guided biopsy and MR-guided surgery. This chapter reviews the current status of the three development directions.

18.3.1 More Technology for Better Answers: Why We Strive to Improve Breast Cancer Imaging Methods

Today, breast cancer is understood as an entire group of diseases that exhibit significant biological differences in terms of their clinical course and outcome [111]. Former breast cancer classification systems that relied mainly on morphological features have been refined or replaced by classification systems that are determined by the cancer's variable molecular features. Improved knowlegde of these features and their role in cancer progression is not only useful for prognostication, but opens up the possibility to exploit these features for targeted therapies. However, heterogeneity is not only observed between cancers but also within a given cancer [112]. Based on current oestrogen receptor, progesterone receptor or human epidermal growth factor receptor 2 (HER2) and Ki-67 classification systems, it is possible that the majority of individual cells within a given cancer exhibit features that are inconsistent with the assigned overall classification. Such intra-tumoural variations are even more important on a genomic or proteomic level.

Yet the more targeted breast cancer therapies become, the more important will be the issue of intra-tumoural heterogeneity as a source of tumour resistance. The overall clinical course of a given patient may be driven by a relatively small subset of primary tumour cells—the primary cancer and its metastases may thus exhibit different types of receptor status. Accordingly, during the course of disease, targeted therapies may need adjustment to account for secondary mutations and/or compensatory pathways that may yield resistant tumours. This, in turn, has sparked interest in the development of advanced imaging methods that help demonstrate intra-tumoural heterogeneity, depict and quantify response or depict resistance to treatment.

Currently, information on a cancer's biological potential is mainly obtained from histologic, immunohistochemical and molecular biological/genomic processing of cancer tissue that needs to be retrieved from invasive methods, i.e. image-guided biopsy. In patients undergoing novel adaptive neoadjuvant therapies, such biopsies may have to be done even repetitively over the course of treatment in order to monitor treatment-related changes. Research on risk stratification of breast cancer relies on such tissue-based markers that provide information on molecular biology, i.e. genomic and proteomic alterations found in cancer. These techniques have been readily integrated into clinical decision making. A possible shortcoming of this focus on tumour genomics and proteomics is the fact that successful tumour growth does not only depend on a tumour's genomic toolbox but also on its microenvironment, i.e. features of the tissues that host the cancer [113].

Noninvasive, "functional" in vivo imaging tests such as multiparametric MRI refer to the acquisition of information on tissue microstructure and tissue metabolic homeostasis through the use of advanced and increasingly complex MR imaging methods such as higher magnetic fields (3.0–7.0 T systems), improved surface coil technology, improved digitisation of signal transduction, new pulse sequence approaches or hybrid imaging, i.e. a combination of MRI with positron-emission tomography, among many other approaches. Functional imaging helps assess the interaction between a cancer and its microenvironment and the degree to which a cancer is successful in shaping its environment to sustain its growth. Growth pattern, cellular turnover, cellularity, degree and type of vasculature and immune cell infiltrate have an impact not only on clinical behaviour but also on presentation in imaging, i.e. yield the "imaging phenotype" of cancers. Accordingly, functional MR imaging methods provide in vivo imaging biomarkers that correlate with, and, thus, provide surrogate markers of, cancer biology. Such imaging methods therefore promise to provide further independent diagnostic and prognostic information that will add to our understanding of a cancer's ability to grow and metastasize.

Established and new "functional" MRI pulse sequence approaches discussed in the following are diffusion-weighted imaging and its derivatives: diffusion tensor and diffusion kurtosis imaging (DTI and DKI) and "intravoxel incoherent

motion imaging" (IVIM); dynamic contrast-enhanced (DCE) MR imaging including its many varieties and kinetic analyses; blood oxygenation level-dependent imaging (BOLD); and MR spectroscopy (MRS) and spectroscopic imaging (MRSI) of proton (1H) or phosphorus (31P) nuclei—all of which can, in principle, be combined into so-called "multiparametric" breast MRI protocols (mp breast MRI). Moreover, there are completely new pulse sequence approaches such as MRI fingerprinting and chemical saturation transfer or CEST imaging which will probably be used for advanced non-invasive breast cancer phenotyping in the foreseeable future.

Currently, the commonest way to use MRI for breast cancer detection, staging, and classification is by exploiting the angiogenic activity of breast cancers. We identify enhancement, i.e. a signal intensity increase, in images obtained early after intravenous injection of an intravenously administered contrast agent [114, 115]. Tissues that accumulate the injected contrast agent appear bright on so-called T1-weighted post-contrast MR images. To track the enhancement of lesions, clinical breast MRI protocols always consist of a so-called dynamic series. This means that a stack of cross-sectional images is obtained before and then repetitively after the i.v. bolus injection of the contrast agent. Cancers are characterised by fast and strong enhancement that is observable already on early post-contrast images, usually followed by a washout of signal intensity. Benign changes and the normal fibro-glandular tissue exhibit less and usually only slowly progressive enhancement over time. Since angiogenic activity is the main driver of enhancement, all regular clinical breast MR protocols will reflect this activity (Figs. 18.24 and 18.25). Accordingly, even the most basic breast MRI study will contain "functional" information on pathophysiological changes that are implicated in carcinogenesis and metastatic growth [116]. Moreover, MRI depicts these changes by true 3D

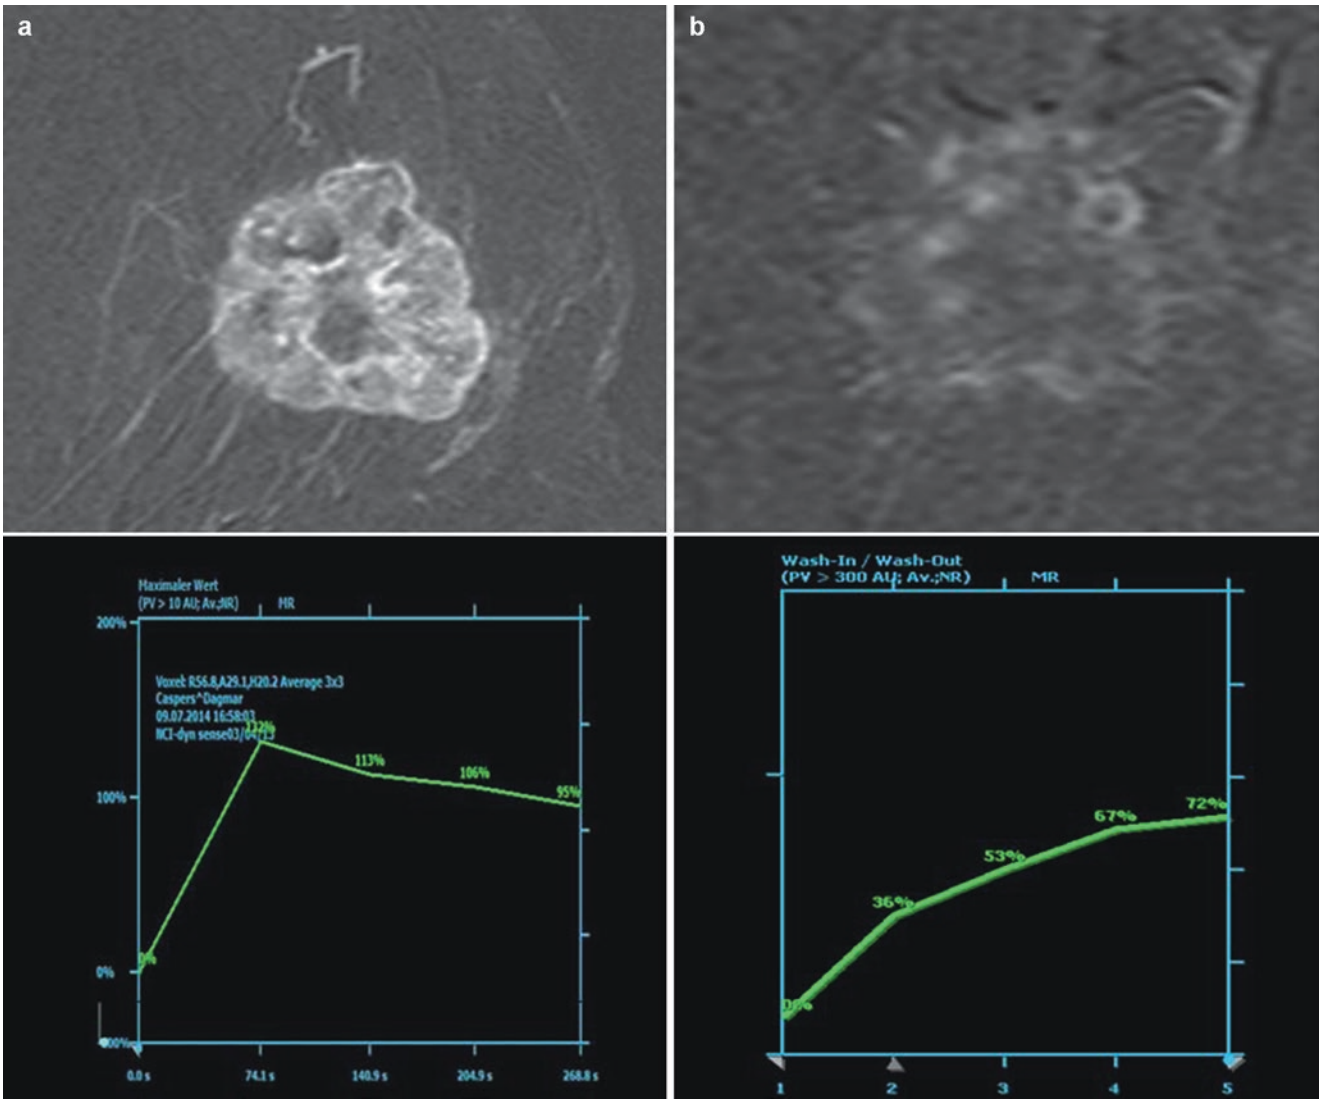

Fig. 18.24 DCE-MRI for response assessment: Note strong and early enhancement with washout time course at baseline and slow enhancement with flattened enhancement curve after the first cycle. Tumour size is still unchanged. (**a**) Before chemotherapy, (**b**) after first cycle of chemotherapy

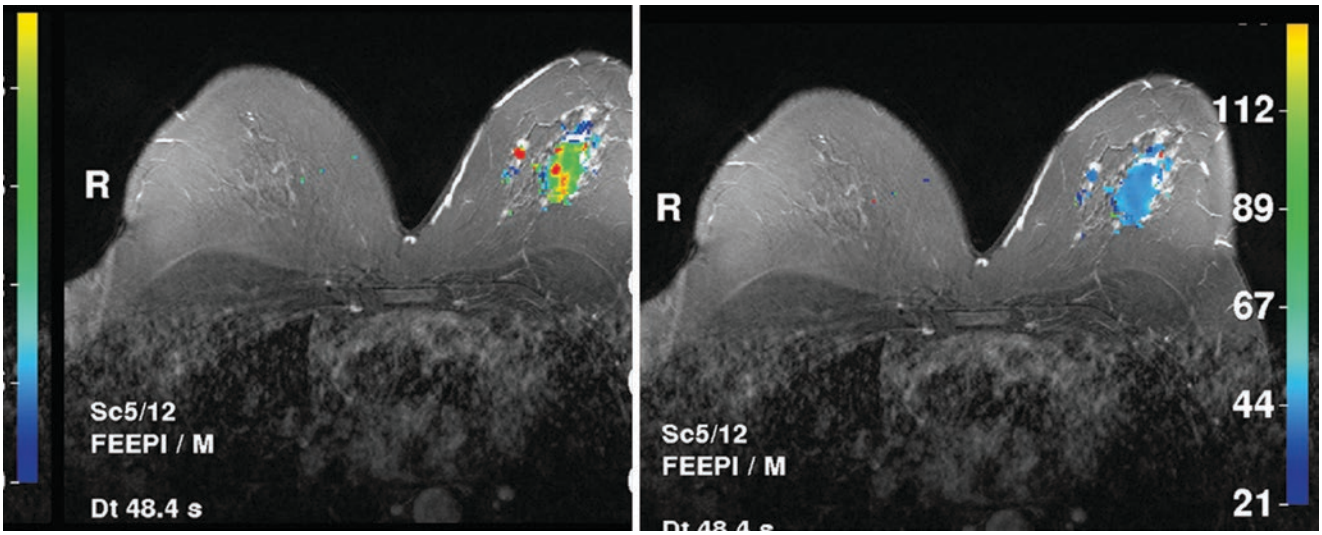

Fig. 18.25 Colour coding can be used to depict within-tumour heterogeneity of enhancement kinetics and the change of enhancement after neoadjuvant chemotherapy. *Left image*, enhancement map of the cancer at baseline, before treatment. *Right image*, enhancement map of the cancer after the first cylce of neoadjuvant chemotherapy. Note that the size of the cancer is unchanged, but the enhancement pattern has changed towards slowly-progressive enhancement

cross-sectional imaging—unlike, e.g. breast tomosynthesis that provides planigraphic images that are not true, but only "quasi" cross-sections—similar to conventional tomography used before the advent of CT. In contrast, breast MRI allows the depiction of tumour margins and internal architecture with very high spatial and contrast resolution. The assessment of such morphological details is usually best possible in images obtained early after contrast injection, i.e. at a time when the signal intensity difference (i.e. the contrast) between the enhancing cancer and the progressively enhancing adjacent fibro-glandular tissue is maximal.

Diffusion weighted imaging (DWI) is based on the Brownian molecular motion of free (interstitial) water. The distance over which an interstitial water molecule can travel depends on its microenvironment. The smaller the interstitial space, and/or the more cell membranes build barriers against free diffusion, the slower will water diffuse, and the shorter is the distance water can travel within a given period of time. The concept of diffusion-weighted imaging is to "label" water molecules and, after a specific waiting time, sample their response. The more diffusion is restricted, the more molecules will stay in place and be able to contribute to the MR signal [117]. Diffusion is restricted in tissues with increased intracellular, and thus, reduced interstitial space, either due to cell swelling, e.g. in the context of hypoxia, or due to increased cellularity of tissue, e.g. in the context of cancer. DWI can thus be used as a noninvasive measure of the cellularity, to serve as surrogate marker of the proliferation fraction of cancer [118]. Tumours with high Ki-67 levels are hypercellular compared with surrounding normal breast tissue, which translates into restricted diffusion of free water molecules on DWI. It has been shown that tissue apparent diffusion coefficient or ADC values correlate with proliferation rates in luminal-B cancers [119, 120]. Another important clinical application of diffusion-weighted imaging is assessing response of breast cancer to neoadjuvant chemotherapy (Fig. 18.26).

Diffusion tensor imaging and diffusion kurtosis imaging investigate not only the mobility of water but also its directionality [121]. Diffusion might be directed, i.e. facilitated in specific directions, and impeded along other directions of tissue, depending on the microstructure of tissue. Accordingly, DTI as well as DKI can be used to demonstrate tumour ultrastructure and infiltrative growth way beyond the resolution of regular structural MR imaging [118, 122]. IVIM is increasingly used as a non-contrast means to depict perfusion of tissue, again on a microstructural, i.e. capillary level [123, 124].

MR spectroscopy is a well-established technology that has been in use for decades for analytical tests in biochemistry. It interrogates noninvasively the (quantitative) distribution of specific metabolites in a given probe. The underlying principle is the fact that the Larmor (resonance) frequency of a given nuclide, usually proton or phosphorus, depends on (a) the respective type of nuclide and on (b) the individual magnetic field in which the nuclide resides. The magnetic field experienced by a given water or phosphorus nucleus will depend on the individual molecular environment of that nuclide, because there will be shielding of the magnetic field by different neighbouring atoms. The individual, specific structure of molecules will thus modulate the magnetic field experienced by a proton or phosphorus nuclide. Thus, nuclei bound in different molecules will be exposed to a slightly different magnetic field. Since there is a direct correlation

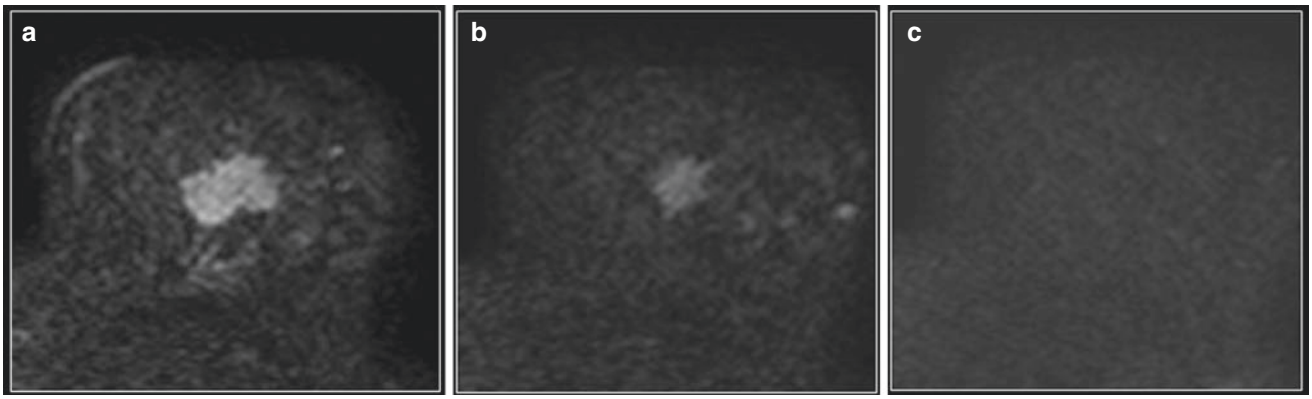

Fig. 18.26 Use of diffusion-weighted imaging for response assessment. (**a**) Baseline, (**b**) Mid-treatment and (**c**) After treatment. Note on (a) the bright signal on DWI at baseline, due to diffusion restriction secondary to the high cellularity of cancer. At mid-treatment (**b**), the cytotoxic effects lead to reduced cellularity of the tumor, such that diffusion of free water is improved, and the DWI signal drops. At conclusion of treatment, the diffusion of free water is back to normal; the DWI signal is isointense to normal tissue. Histology confirmed complete pathological response (pCR)

between the magnetic field and a proton's resonance frequency, protons or nuclei located in different molecules will exhibit slightly different resonance frequencies. Magnetic resonance spectroscopy displays the distribution of resonance frequencies and, thus, of different metabolites or molecules in a given probe. For in vivo MR spectroscopy of the breast, most experiences exist with proton MRS. Compared with ex vivo biochemistry measurements, many effects such as field inhomogeneity and low SNR lead to the fact that the spectral resolution that is attainable in patients is not as high as in ex vivo MRS of biochemical probes. Thus, the individual resonances of individual molecules are broadened; the observable spectral peaks usually comprise several different resonances (and, thus, metabolites). For 1H MR spectroscopy of the breast [125], detection of protons bound in choline compounds has been found to be clinically useful [126]. The detectable choline peak represents proton bound in free choline, in phosphocholine and in glycerophosphocholine. Other constituents will be phosphoethanolamine and myo-inositol. Cellular turnover, either anabolic or catabolic, may increase the contribution of phosphocholine to the observable choline [127, 128]. 1H MRS has been shown to help discriminate breast cancer from benign enhancing lesions and as a prognostic marker to assess cellular (i.e. membrane) turnover. Especially rapidly growing tumours will lead to a detectable choline peak (tCho). Moreover, MR spectroscopy is useful to demonstrate early response to neoadjuvant chemotherapy. Reduction of total choline helps distinguish between responders and nonresponders after two treatment cycles (PPV and NPV of 89% and 100%); with current technology, it is, however, limited to the analysis of larger tumours, i.e. locally advanced breast cancer [127–130].

Tumours need to maintain growth by increasing their local supply with oxygen and nutrients. This is achieved by releasing peptides like VEGF that induce local angiogenesis. Angiogenesis leads to a fundamental change of a tumour's microvascular architecture, with sprouting of existing vessels as well as development of de novo formed vessels, usually with fenestrated vessel wall linings that go along with increased vessel permeability. The increased metabolic turnover leads to an increased amount of toxic waste products that are removed through dilated drainage veins. The increased perfusion leads to the well-known strong and early enhancement in DCE-MRI, and the increased permeability, together with the efficient venous drainage, causes the washout time course that is characteristic for breast cancer [131]. It has been shown that DCE-derived enhancement kinetics correlate with estrogen receptor status, HER2 status, nuclear grade/Ki-67 and EGFR expression.

The increased permeability leads to leakage of larger molecules such as proteins from the intravascular to the interstitial space, which will increase the oncotic (colloid osmotic) pressure within the cancer—a fact that drags water from the intravascular into the interstitial space and thus increases the interstitial water volume fraction. This, in turn, will correlate with a cancer's signal in T2-weighted imaging. If angiogenesis fails, or is insufficient to reach the innermost cell layers of a cancer, then hypoxia will occur, again detectable through the tumour's internal architecture of enhancement in DCE-MRI (rim enhancement) or through BOLD contrast MRI [132].

The abovementioned functional MR imaging methods are thus used to depict tissue features on a microstructural level. The respective pulse sequences are usually associated with borderline signal to noise ratio (SNR). To improve SNR, the use of higher magnetic fields such as 3.0 T or, more recently, even 7.0 T promises an even more accurate and extensive assessment of tumour biology [127, 133, 134].

Functional imaging methods can be used for classification of enhancing lesions seen in breast MRI, i.e. for the further differentiation of benign, high-risk and malignant lesions in breast MRI. The combination of high-resolution cross-sectional

morphological information, enhancement kinetics and lesion's signal in T2-weighted images and in diffusion-weighted images yields a high specificity and positive predictive value of contemporary breast MRI protocols. Even the most basic, 1.5 T dynamic contrast-enhanced breast MRI protocols are inherently "multiparametric" compared with, e.g. mammography or DBT. The diagnostic accuracy achieved with such protocol is sufficient to be used for so-called problem-solving.

Accordingly, and in contrast to currently held beliefs, we have recently shown that breast MRI can indeed be used definitely to settle screen-detected mammographic or ultrasound findings and thus help avoid unnecessary biopsies [135].

More importantly, functional imaging methods provide additional, independent diagnostic information that adds to our understanding of a cancer's ability to sustain its growth and/or its propensity to metastasise. Multiparametric MRI techniques can therefore be used to investigate a tumour's aggressiveness and its biologic and prognostic importance or its response to systemic treatment [120, 123, 136–140].

In the neoadjuvant situation, the local breast cancer serves as an in vivo marker to rate the efficacy of systemic treatment protocols. Since even regular, clinical breast MRI studies provide functional information on tissue perfusion, it is possible to depict response to treatment earlier than what is achievable by imaging methods that rely on tumour size estimates only such as radiographic imaging methods (digital mammography, digital breast tomosynthesis) or ultrasound-based methods (Figs. 18.24, 18.25, 18.26, 18.27, 18.28, 18.29 and 18.30; Table 18.3) [141–146]. Results on the use

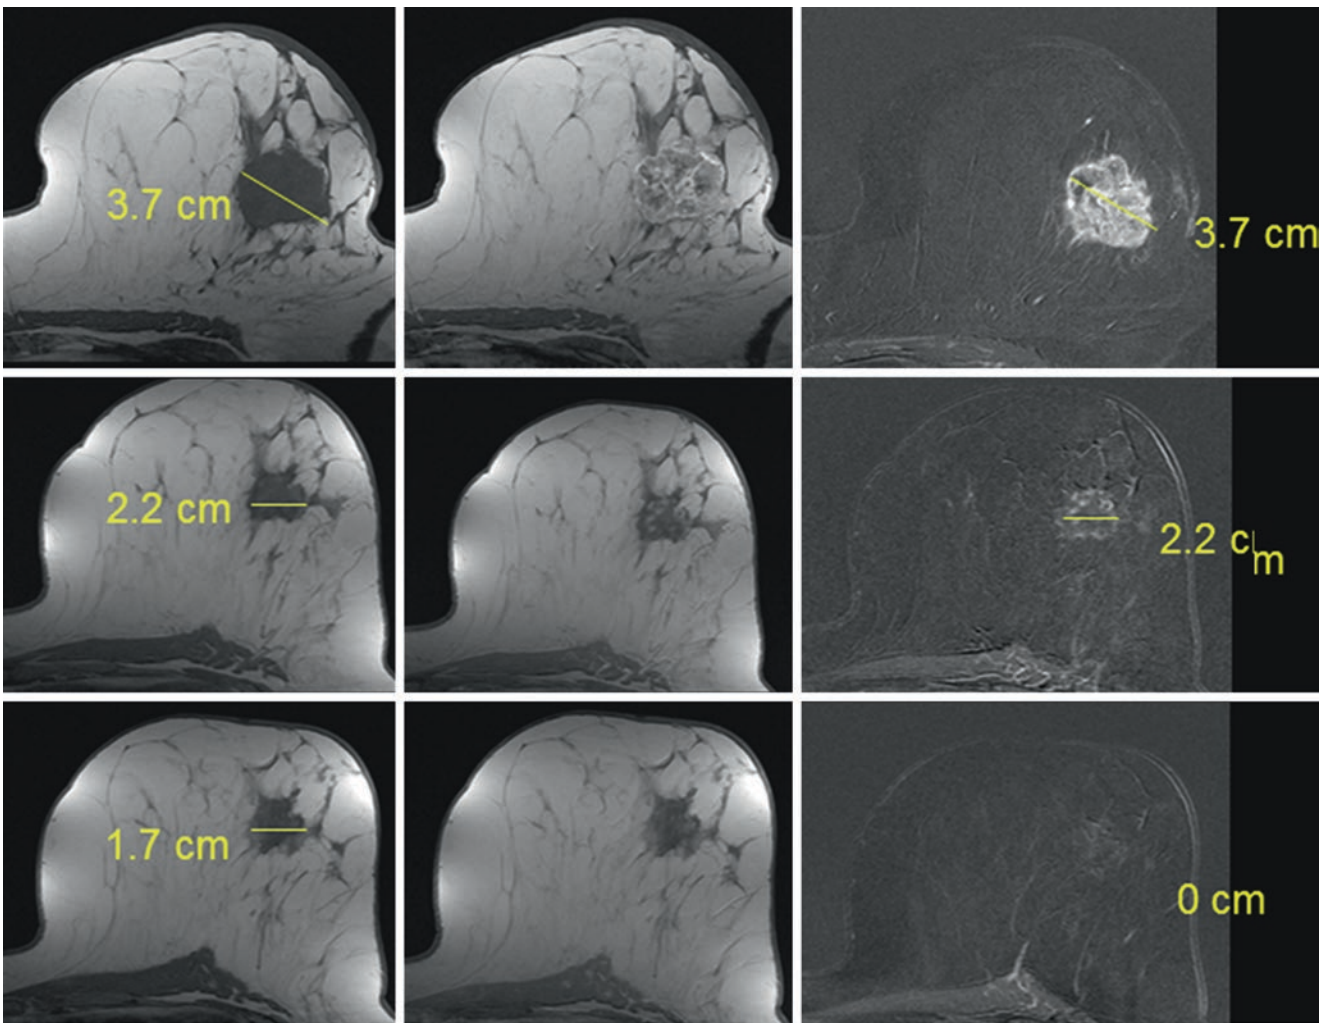

Fig. 18.27 Utility of DCE-MRI vs. structural breast imaging. Patient with triple-negative breast cancer. Incomplete response was suggested based on breast ultrasound and mammography, with residual diameter of 1.7 cm. This residual mass is also visible on pre-contrast T1-weighted imaging of her breast MRI study (*right column*). However, after contrast injection, DCE-MRI (*middle column*, post-contrast source images; *left column*, corresponding subtracted images) reveals absence of enhancement in the remaining tumour, suggesting presence of scar formation. Complete pathologic response with fibrotic tumour remnants without vital tumour cells was found at histology

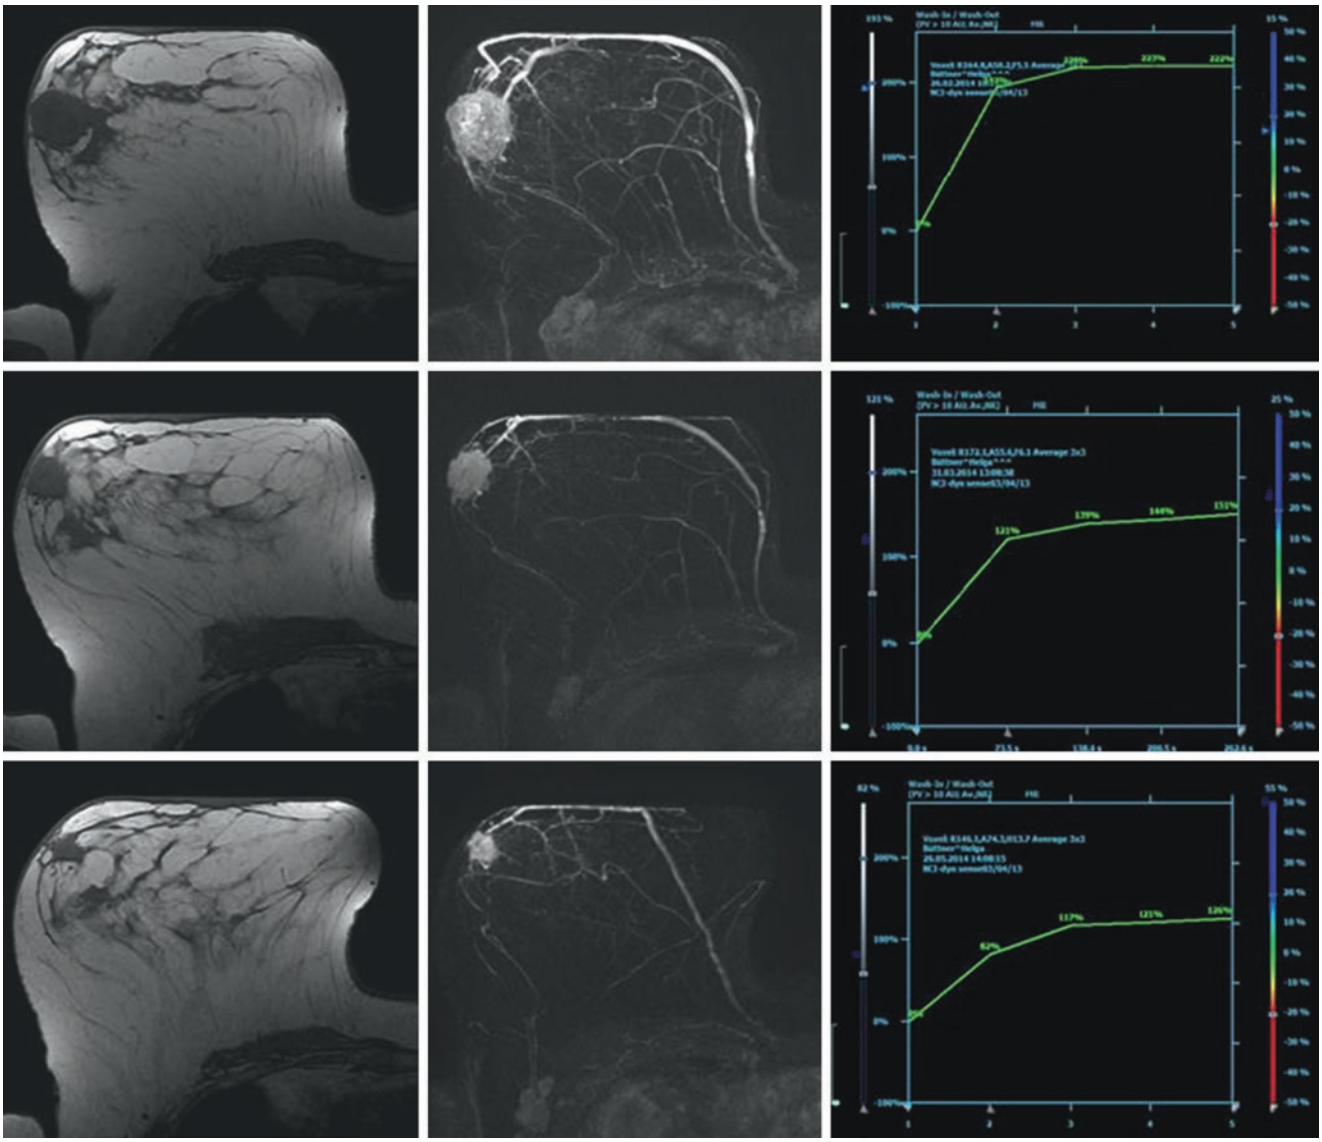

Fig. 18.28 Patient with residual disease after neoadjuvant chemotherapy. Minimal residual mass visible but with strong enhancement. Histology confirmed presence of a 9 mm residual vital tumour. *Upper row*, MRI before chemotherapy. *Middle row*, MRI at mid-treatment. *Bottom row*, MRI after conclusion of neoadjuvant chemotherapy

of more advanced functional imaging methods or "multiparametric MRI" for this purpose are emerging [141]. For instance, diffusion-weighted imaging and DKI are candidate methods to further improve assessment of response; an increase in mean tumour ADC (apparent diffusion coefficient) of over 20% from baseline is predictive of response in triple-negative and HER2-enriched cancers (Fig. 18.30) [143, 146, 147]. Similar results have been obtained for the detection of changes as early as a couple of days after even a single administration of chemotherapy by proton spectroscopy [128, 140, 146–151].

Another task in the neoadjuvant setting is to identify residual disease. Since there can be scar tissue formation at the site of the previous tumour, this is a difficult task with imaging methods that rely on depiction of structure alone. Since regular DCE-MRI, but even more so advanced multiparametric MRI provides information beyond structure, it is much more accurate than, e.g. mammography or ultrasound for this purpose. Marinovich et al. provided an excellent review on the evidence of using regular clinical breast MRI for predicting response to neoadjuvant chemotherapy. They reported on 13 different studies, comprising 2549 patients who underwent DCE-MRI before and after one to two cycles of neoadjuvant treatment. They found that the accuracy for prediction of response is highest in studies that evaluated enhancement kinetics and found a mean accuracy of 88% [142].

The next step now is to use the plethora of imaging features provided by multiparametric breast MRI to describe "MR imaging phenotypes" of breast cancers. Modern methods of machine learning ("deep learning") can then be used

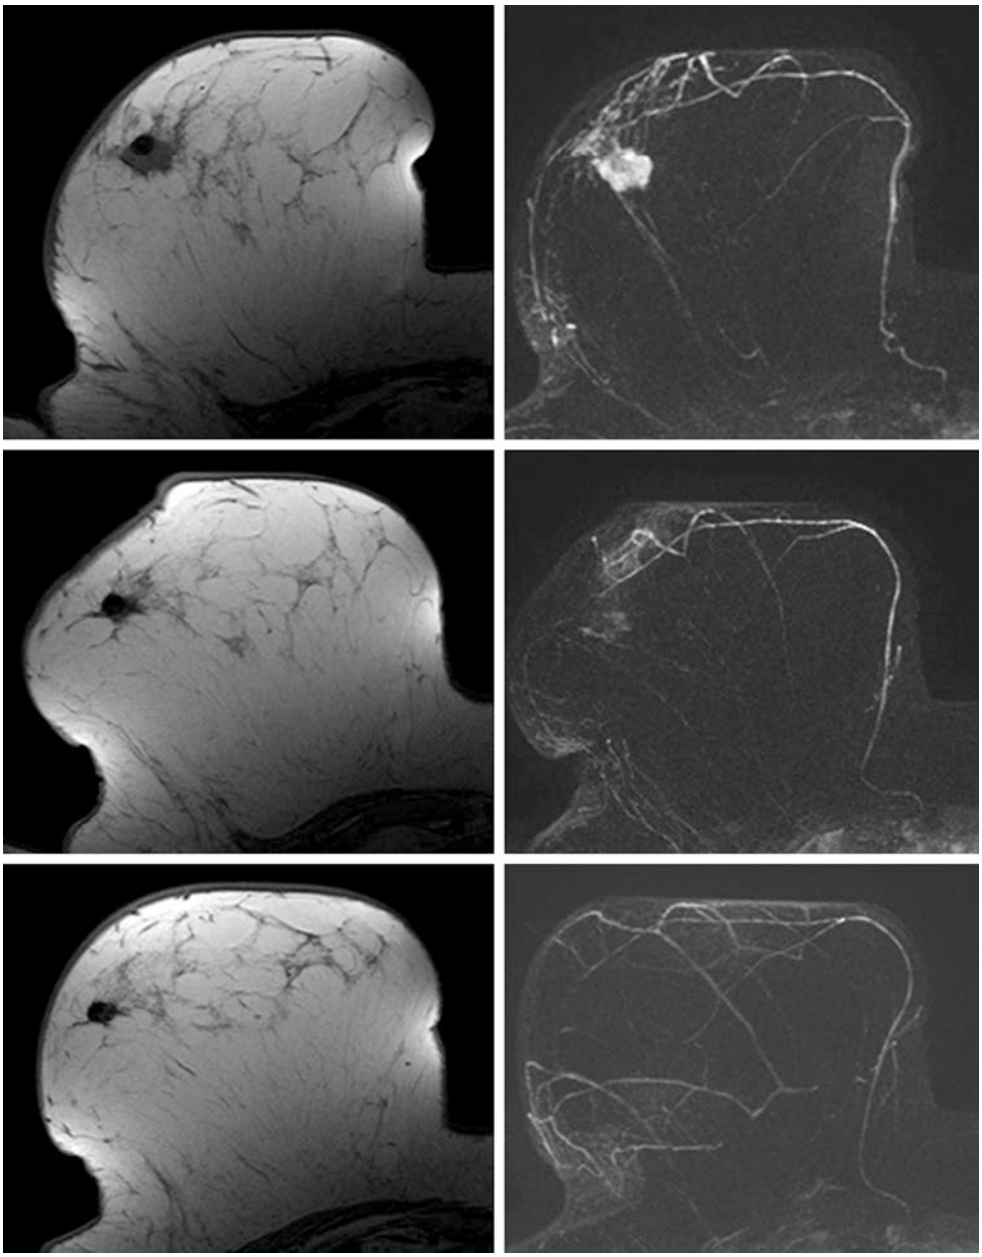

Fig. 18.29 Prediction of pCR based on DCE-MRI. Pre-contrast images (*right column*) to provide structural information and post-contrast subtracted images (*left column*) to demonstrate enhancement. Already at mid-treatment (*middle row*), there is almost complete loss of enhancement at the site of the cancer. Absence of enhancement was noted at completion of neoadjuvant treatment (*lower row*). Pathological complete response was found. The focal black spot at the site of the cancer corresponds to the clip inserted after US-guided biopsy

to correlate different MR imaging phenotypes with patient outcomes, similar to the way genomic typing has been correlated with outcomes to establish their prognostic utility. It is to be expected that such "radiomics" will be helpful to amend the predictive and prognostic information derived from genomic and proteomic studies.

18.3.2 Keep It Simple and Short: Abbreviated Breast MRI for Cancer Screening

Although there has been a decline in breast cancer mortality over the last two decades, breast cancer continues to represent the first (Europe) or second (USA) leading cause of cancer death in the female population. Notably, several decades of mammographic screening programmes have not changed this situation. Since there is a close correlation between disease stage (i.e. the size and stage distribution of cancer) at the time of diagnosis and ultimate survival of an individual woman, the persistently high mortality rates indicate that there is room and need for improved methods of early diagnosis of breast cancer. Interval cancer rate, i.e. the number of cancers that occurs in women who did participate in mammographic screening, but are not diagnosed by mammography, compared to the number of cancers that are mammography detected, ranges between 30% and 50%. These interval cancers are associated with adverse biologic profiles and poor prognosis compared to screen-detected cancers. Accordingly, the current scientific evidence suggests that mammographic screening is associated with a

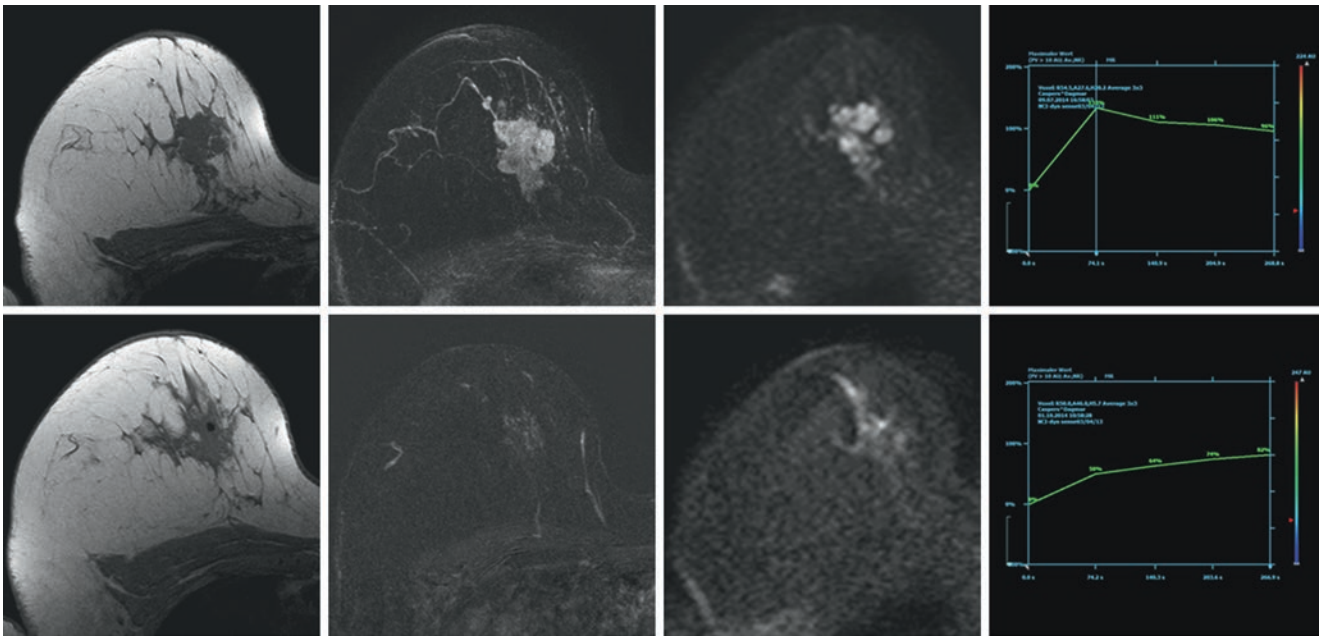

Fig. 18.30 Utility of diffusion-weighted imaging to complement DCE-MRI for response assessment. *Upper row*, baseline study. *Lower row*, study after completion of neoadjuvant treatment. *Left column*, pre-contrast T1-weighted images. *Middle left column*, contrast-enhanced subtracted images. *Middle right column*, corresponding DWI at $b = 800$. *Right column*, corresponding time/signal intensity curves. Note that there is still questionable enhancement at the site of the index cancer. DWI supports the diagnosis of incomplete response or presence of residual disease, with still visible diffusion restriction. Note the clip that marks the centre of the index cancer in the images after treatment

Table 18.3 Published meta-analyses on using breast MRI for predicting pCR after neoadjuvant chemotherapy

Author	Journal	No. of studies	No. of patients	Sensitivity for pCR	Specificity for pCR

significant underdiagnosis of breast cancer, that is to say, mammography fails to pick up cancers that are prognostically relevant [152, 153].

In addition, mammographic screening has been associated with overdiagnosis of breast cancer. Overdiagnosis relates to the fact that cancers that are picked up by mammography may be biologically unimportant. Some breast cancers can exhibit rapid growth and become life-threatening and difficult to treat; others are relatively slowly growing. Some cancers, especially many screen-detected DCIS, may indeed prove self-limiting and will not progress to a life-threatening disease, even if left undiagnosed and thus left untreated [154, 155].

An important reason for overdiagnosis is a well-established effect referred to as "length-time bias". Women whose cancers were screen detected, i.e. women whose cancers were mammography detectable, enjoy a better prognosis than women whose cancers were not screen detected, i.e. mammographically occult. In short, mammography-detectable cancers are associated with a better prognosis than cancers that are occult on mammography. This, in turn, is attributable to the fact that for diagnosis of breast cancer, radiographic breast imaging methods (mammography or also tomosynthesis) rely on the depiction of regressive changes such as calcifications, architectural distortions and fibrosis, i.e. pathophysiological processes that are associated

with slowed growth, with tissue hypoxia or with frank tissue necrosis. Overdiagnosis is length-time bias put to an extreme. Overdiagnosis causes a huge financial burden to the society; most importantly, however, it leads to unnecessary anxieties and morbidity in women who are stigmatised as "cancer patient" and treated as such, without benefit for the involved women.

In summary, mammographic screening is associated with both significant underdiagnosis of prognostically important breast cancer and overdiagnosis of prognostically unimportant, i.e. self-limiting breast cancer, or rather pseudo-disease.

Magnetic resonance imaging (MRI) has been used to diagnose breast cancer over the last three decades; it is in use for screening for 15 years. Over and over again, it has been shown that contrast-enhanced MRI is by far the most accurate imaging method to diagnose invasive as well as intraductal breast cancer and primary as well as recurrent cancer, irrespective of breast density [9–13, 156–162]. In view of the important discussion around overdiagnosis, the most important feature that makes breast MRI an attractive screening tool is its sensitivity profile. The sensitivity of breast MRI increases in parallel with the prognostic importance of breast cancer. It is exceedingly high in rapidly growing, heavily perfused disease, and it is desirably lower than that of mammography for low-grade DCIS. Thus, MRI is associated with a "reverse length-time bias". This, together with the fact that MRI works without ionising radiation, makes MRI the most promising screening tool that is currently available.

A screening trial completed in our department suggests that MRI screening is not only beneficial in high-risk women but also in average-risk women. The gradient between the diagnostic sensitivities of MRI, compared to that of mammography or even the combined use of mammography and ultrasound, appears similar, more or less independent of the respective lifetime risk of women [163]. We found that if MRI is used in women at average risk, the interval cancer rate drops down to zero—which compares to an interval cancer rate, i.e. missed cancer rate, of around 30–50% for quality-assured European mammographic screening programmes. Since interval cancer rates are the single most important driver of mortality rates, there is good reason to assume that using MRI instead of mammography for breast cancer screening would allow a substantial further reduction of breast cancer mortality. Also the positive predictive value—a major driver of costs associated with screening—is similar for mammographic and MRI screening, suggesting that the previously held belief of the low specificity of MRI has been overcome with growing clinical experience with screening breast MRI.

The single main reason why MRI is not used on a broader scale is the cost associated with this method. Therefore, in 2014, our group inaugurated the concept of "abbreviated breast MRI" (AB-MRI) [164]. We were able to demonstrate that MRI, due to is high-contrast images, can be completed within a magnet, i.e. examination time of only 3 min, and, most importantly, can be read by radiologists within a few seconds. The superior diagnostic accuracy and cancer yield that is afforded by MRI was preserved also for these abbreviated protocols. A group of 443 women with mildly increased risk of breast cancer and with normal screening mammograms and normal screening ultrasound underwent 606 screening MRI studies with abbreviated and full protocol. Abbreviated MRI detected a total of 11 cancers that had been occult on the respective digital mammograms and screening ultrasound studies, for an additional cancer yield of 18.2 per 1000 (Fig. 18.31a). The examination time of the abbreviated protocol had been 3 min, and the average radiologist reading time to establish absence of breast cancer had been 2.8 s. For comparison, even batch reading of a screening mammogram

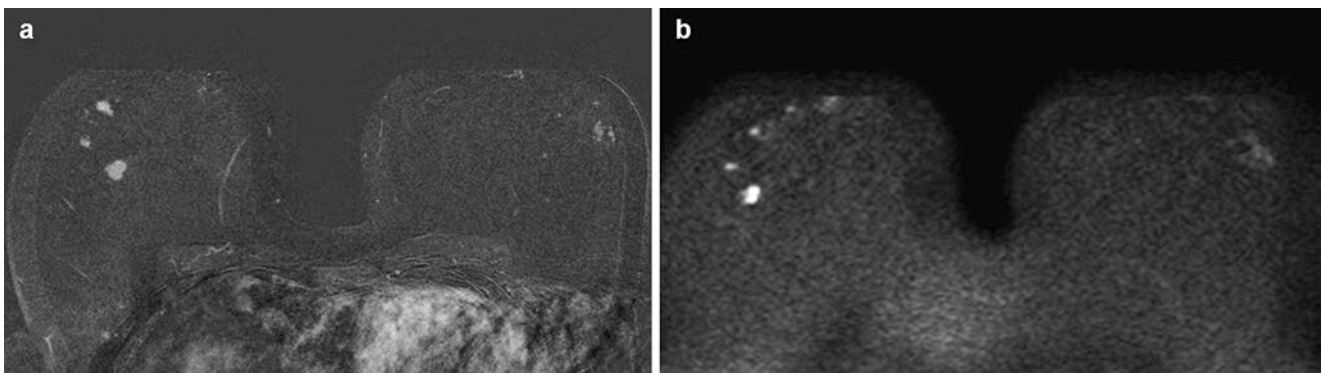

Fig. 18.31 Utility of abbreviated breast MRI, and un-enhanced diffusion-weighted imaging in a 52-year old woman at average risk undergoing MRI screening; her mammogram was normal. (**a**) First post-contrast subtracted or FAST image, generated by subtracting the image obtained within 60 s after contrast injection from the pre-contrast image, for a total acquisition time of 2 minutes. Note the multifocal breast cancer visible in the right breast and absence of cancer in the left breast. Note that similar information is provided by the diffusion-weighted image, which was obtained prior to contrast injection

usually takes over 60 s, and the acquisition of the four views that constitute a screening mammogram takes well over 4 min. For screening ultrasound, the reading and/or scanning time takes about 20 min on average, i.e. takes far more radiologist time and is thus far more expensive—and far less sensitive or specific than breast MRI. Abbreviated breast MRI has sparked great interest in the broader use of breast MRI for breast cancer screening. Several studies have meanwhile been published that confirm the high accuracy of abbreviated protocols. The ECOG/ACRIN (Eastern Cooperative Oncology Group/American College of Radiology Imaging Network) has launched a multicentre prospective randomised trial (EA1141) that will investigate not only the cancer yield but also the type of cancers detected by abbreviated breast MRI compared with contemporary, digital breast tomosynthesis [165]. Several countries have started their own abbreviated breast MRI screening studies.

Moreover, there is evidence to suggest that abbreviated protocols could even work without injection of contrast agents. By using diffusion-weighted imaging with background suppression (DWIBS), cancers are detectable and correctly classifiable with an image acquisition time of only a couple of minutes and very short radiologist reading times (Fig. 18.31b) [166–168].

To fully exploit this for improved breast cancer screening, it would be important to develop dedicated breast MRI systems that are optimised for imaging the breast and optimised to support the fast throughput that is required for broader screening applications. Very similar to the development of dedicated X-ray machines for imaging the breast (i.e. mammography systems) back in the 1940s, this could be done for MRI scanners.

18.3.3 Advances in MR-Guided Interventions

Breast MRI studies are done to obtain information on presence and extent of breast cancer beyond what is available through radiographic or ultrasound imaging. If this is achieved and breast cancer is identified or suspected on MR imaging, it is important to offer noninvasive means to retrieve tissue from the suspected area. No breast radiologist would ever offer a breast imaging service without being able to also offer mammography and ultrasound-guided needle localisation and (vacuum) biopsy—but it seems to be quite popular to run a breast MRI service without such interventional capacities. This is increasingly inacceptable, regarding the fact that equipment for MR-guided vacuum biopsy and MR-guided needle localisation and bracketing is commercially available and has been commercially available for almost two decades now. Accordingly, the American College of Radiology requires availability of such equipment or proof of an established collaboration with sites that offer these interventions in order to receive an accreditation for breast [169].

Recently, we inaugurated the concept of MR-guided vacuum-assisted large-volume biopsy (VALB). For this intervention, we collect larger amounts of tissue than what is usually retrieved during mammography or MR-guided vacuum biopsy procedures, i.e. between 24 and 60 samples with a 9G needle. Such MR-guided VALB was done on a cohort of 1414 consecutive MR-only visible lesions with a false-negative rate, i.e. a rate of missed lesions, of 0.3% (4/1414), all four discovered immediately after the procedure due to an obvious radiologic-pathologic mismatch. The cohort consisted of target lesions with an average size of 9 mm for mass enhancement, and 23 mm for non-mass enhancement, found in small to very large breasts and located in all locations, including far dorsal, far medial, far lateral or immediate retroareolar locations. The results suggest that MR-guided VALB helps avoid previously reported causes of technical failures of MR-guided biopsies. Moreover, we could show that MR-guided VALB procedures are very well tolerated, with a complication rate (major complications) of 0/1414 (Fig. 18.32) [170].

Reoperation rates tend to be high for breast cancer surgery, especially if a high rate of breast conservation is attempted. A recent editorial published in the New England Journal of Medicine was entitled *Re-excision—The Other Breast Cancer Epidemic* [171]. There are numerous reports that consistently show that MRI is more accurate than mammography or ultrasound for demonstrating the extent of a given cancer. If MRI is done for this purpose, however, it is of utmost importance to help the surgeon translate the imaging information into the operating theatre. Only if this is achieved, it is possible to actually exploit the diagnostic advantage afforded by MRI compared with mammography or ultrasound. If one strives to reduce the number of surgical procedures, it is of course important to use nonoperative, nonsurgical biopsy methods to obtain histologic proof of presumed additional disease components prior to surgery. We have used MRI, followed by MR-guided vacuum biopsy, and MR-guided bracketing of the disease extent if needed (Fig. 18.33), in a cohort of 600 women with biopsy-proven breast cancer. We found that this led to a positive margin rates below 4%, which was achieved at a very high breast conservation rate of close to 90%. These data suggest that, if MRI is combined with contemporary methods of MR-guided biopsy, as well as methods to guide surgery, the improved diagnostic information provided by MRI do indeed translate into improved surgical results, low reoperation rates and very low mastectomy rates [172].

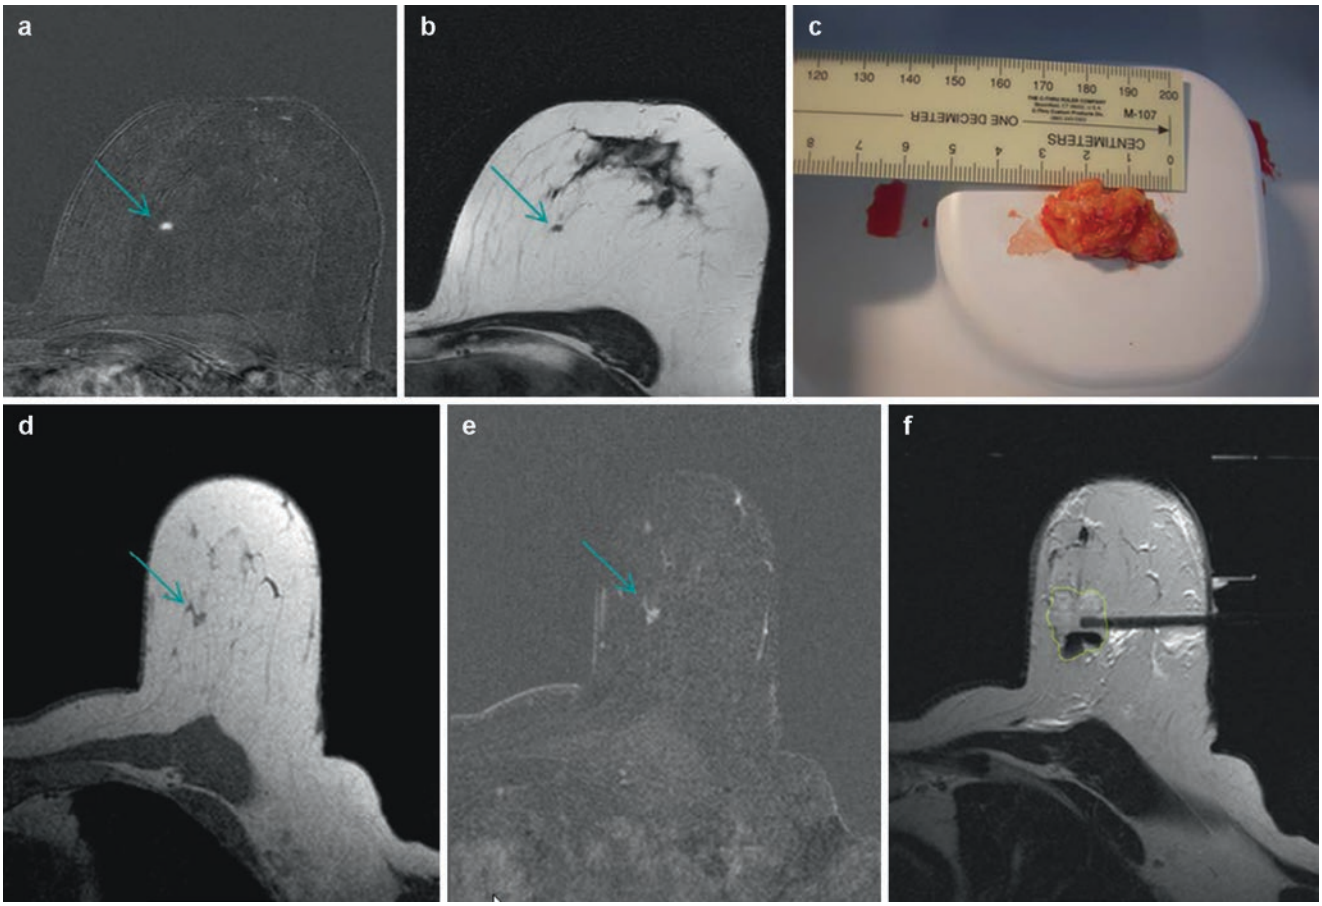

Fig. 18.32 MR-guided vacuum-assisted large-volume breast biopsy (VALB). (**a**) FAST image that highlights a small enhancing lesion in the upper inner quadrant, 4 mm in longest diameter. (**b**) Corresponding T2-weighted structural image. (**c**) T1-weighted image prior to contrast injection during the intervention. (**d**) Corresponding post-contrast subtracted image reveals the target lesion. (**e**) T2-weighted image after completion of vacuum-assisted large-volume breast biopsy, with the biopsy needle still in place. The *yellow line* encircles the biopsy cavity that includes an *air bubble* (*black* signal inside the cavity). Note that the biopsy cavity includes the entire lesion, plus safety margin. (**f**) Removed tissue volume during MR-guided VALB. Histology confirmed pT1a; subsequent surgery proved absence of residual tumor

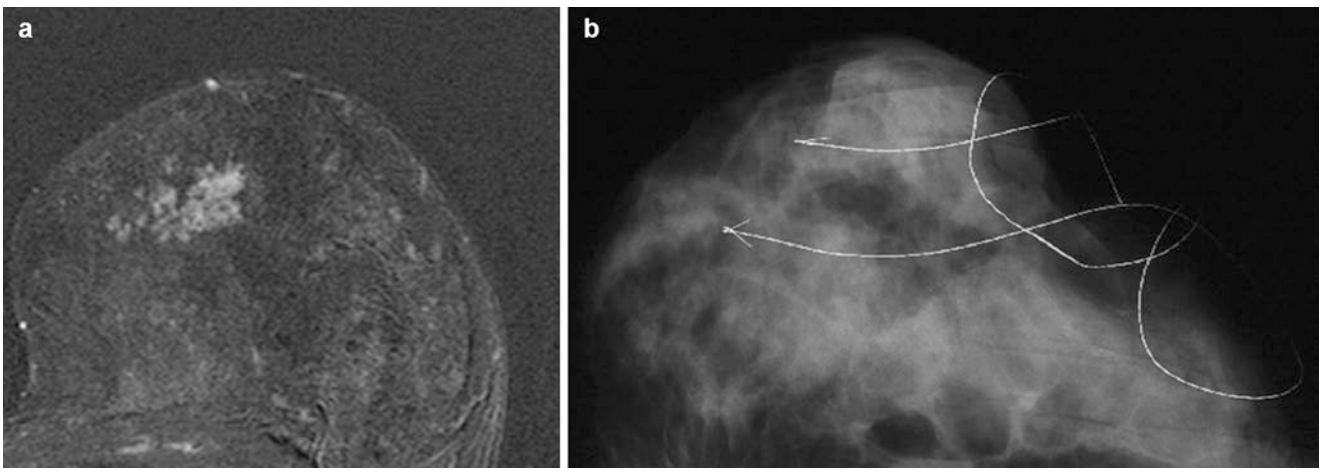

Fig. 18.33 MR-guided surgery. (**a**) Patient with MRI screening detected non-mass enhancement suggestive of DCIS. MR-guided biopsy (not shown) confirmed presence of high-grade DCIS. Patient underwent MR-guided bracketing of the two poles of the enhancing segment. (**b**) Mammogram obtained after MR-guided bracketing displays the guide wire position in the breast and absence of any correlate of the DCIS on mammography. MR-guided surgery was done and revealed a 3 cm high-grade DCIS, resected with free margins (R0)

19.1 The Radio-Guided Occult Lesion Localization (ROLL)

G. Paganelli and F. Matteucci

19.1.1 Introduction

The most important goal of modern surgical oncology is to utilize the less aggressive methods while maintaining radicalism. The evolution of imaging techniques and the option of using screening tests more and more reliable and effective have permitted an increasingly early diagnosis, identifying malignant lesions of ever smaller dimensions. This is particularly common in the case of breast cancer, where clinically occult lesions are diagnosed with increasing frequency, now represents approximately 25–35% of all breast cancers diagnosed in developed countries [1, 2].

Numerous techniques have been used to localize non-palpable lesions, but there is no international consensus about which technique combines the best conditions and should be considered the gold standard.

The wire-guided localization (WGL) is currently the location method most commonly used in many centers. [3–5]. This technique, however, has some disadvantages, due to various factors: in general there is a difficulty of the wire positioning in the dense breasts; a dislocation of the wire once it has been positioned is rather frequent [6] resulting in excessive volumes of tissue removed. Finally, thread breaks or dislocations can lead to complications and inconvenience for patients [7, 8].

e-mail: giovanni.paganelli@irst.emr.it

In 1996 at the European Institute of Oncology in Milan, the ROLL technique (ROLL: radio-guided occult lesion localization) was introduced for the first time, gaining popularity because of the many benefits associated with the ability to center with greater precision the lesion within the surgical sample, thus reducing the volume of the breast removed with consequent best aesthetic results [9–11].

Moreover, feasibility studies have shown that the technique is simple, rapid, and precise; furthermore, the method is intuitive, and necessary skills are easily acquired [12].

Recently a cost-benefit analysis published by Postma et al. [13] in a randomized controlled trial (RCT) found no difference considering both economic costs associated with morbidity and reoperation.

Retrospective and prospective studies performed on very large populations have shown that the ROLL procedure allows the surgeon to make a precise removal of non-palpable lesions of the breast thus overcoming most of the disadvantages of the previous techniques.

19.1.2 Technique

The day before surgery, a dose of human serum albumin macroaggregates (MAA), with particles of diameter between 10 and 150 μm, labeled with 7–10 MBq of Tc-99m is injected in correspondence of the central portion of the lesion. The tracer preparation mode as well as the quality controls on the dose must be carried out by following the instructions from the product package insert.

In the presence of microcalcifications, opacity, or distortions highlighted with mammography but not visible in ultrasound, it is necessary to use the mammographic apparatus incorporating a computerized stereotactic system (Fig. 19.1a), while in the presence of lesions visible by ultrasound, the radiopharmaceutical is injected under guide ultrasound (Fig. 19.1b).

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_19

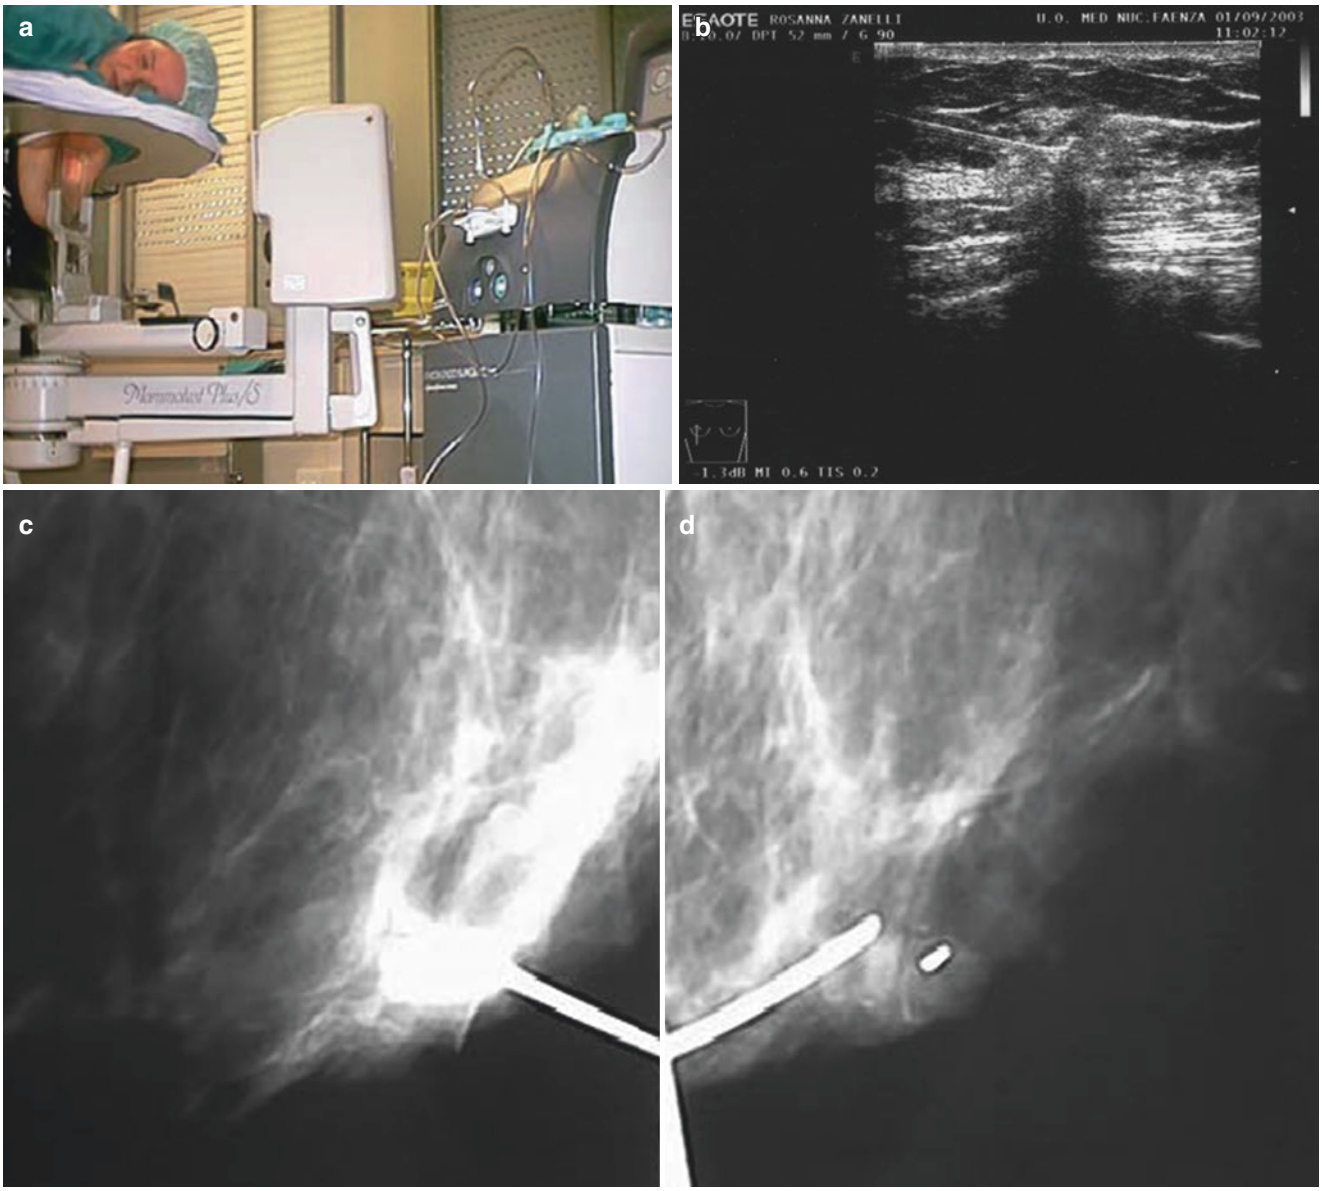

Fig. 19.1 Injection of 99mTc-MAA under (**a**, **c**, **d**) stereotactic or (**b**) ultrasound guidance

For lesions visible by both methods, the tracer is preferentially injected under ultrasound guidance, which allows for greater precision in locating the lesion. Once injected of the dose, the site of inoculation is indicated on the skin with a skin marker pen, so as to serve as a guide both for the next scan and that for surgery.

The control of the exact site of inoculation can be performed by introducing a minimum amount of radiopaque solution within the lesion, immediately after the radioactive substance, and performing a radiological control (Fig. 19.2).

19.1.3 Scintigraphy

Scintigraphic images are acquired usually about 10 min after injection of the tracer in the front and lateral projection. A cobalt-57 source (point source or flexible wire) is used to outline the contour of the breast during the acquisition and to facilitate the viewing of the site of inoculation.

Scanned images must highlight the presence of a focal spot of the tracer accumulation with well-defined margins, without contamination of the skin or spreading in the neighboring locations to the lesion (Fig. 19.3).

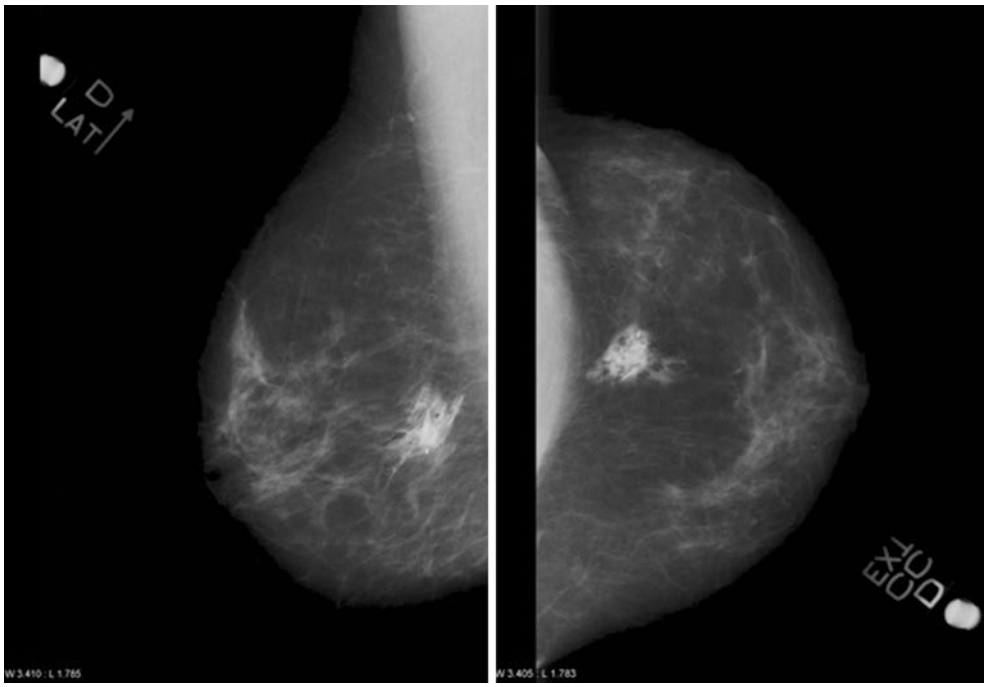

Fig. 19.2 Radiological verification of the exact site of inoculation, immediately after MAA and radiopaque solutions' administration

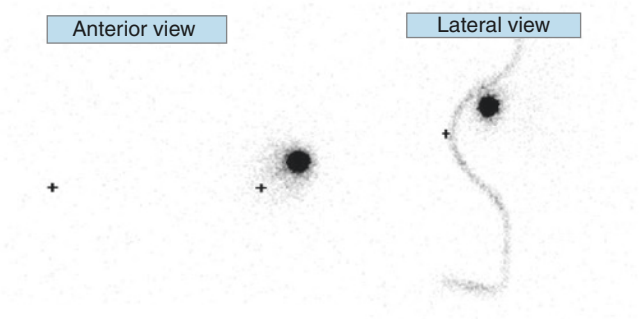

Fig. 19.3 Scintigraphic images of the right breast in frontal and lateral projection performed after injection of 99mTc-MAA. The contour of the breast is outlined by a thread-flexible 57Co source. A hot focal spot is present in the upper quadrants. The cross indicates the position of the nipple

In the event of contamination, the acquisition must be repeated after properly cleaning the skin with a decontaminant substance; in the case of spread of the uptake to the surrounding breast parenchyma, it is necessary to repeat the location of the lesion using a different method.

19.1.4 Surgery

During surgery, the lesion is localized by using a gamma probe, wrapped in a sterile sheath (Fig. 19.4): the surgeon provides then to remove the "hot spot," and the edges of the excision are defined as the locus of points surrounding the hot spot where radioactivity falls off sharply. All of the area of the tissue with a higher radioactivity count compared to the background is removed.

Once the lesion has been removed, it is therefore necessary to verify whether radioactive tracer is still on the operating table: when noted, it is necessary to extend the resection until the complete disappearance of the counting rate.

19.1.5 Results

In 2010, Veronesi and coworkers published a work which analyzed the characteristics and prognosis in 1258 women with a primary clinically occult carcinoma operated at the European Institute of Oncology between 2000 and 2006 [14].

The results obtained, after an average follow-up of 60 months, showed a low rate of local events (1.5%), of regional events (1%), and occurrence of distant metastases (1.6%), with a high rate of 5-year overall survival (98.6%). The authors therefore concluded that the radio-guided surgery was able to identify the occult lesions, allowing to make an efficient and safe breast resection with good margins of normal tissue around the primary lesion.

In a review, published in 2011, Lovricks et al. [15] analyzed 87 studies comparing WGL and ROLL: the results showed that the ROLL technique had a lower rate of positivity of resection margins, resulting in reduction of reoperation rate (combined

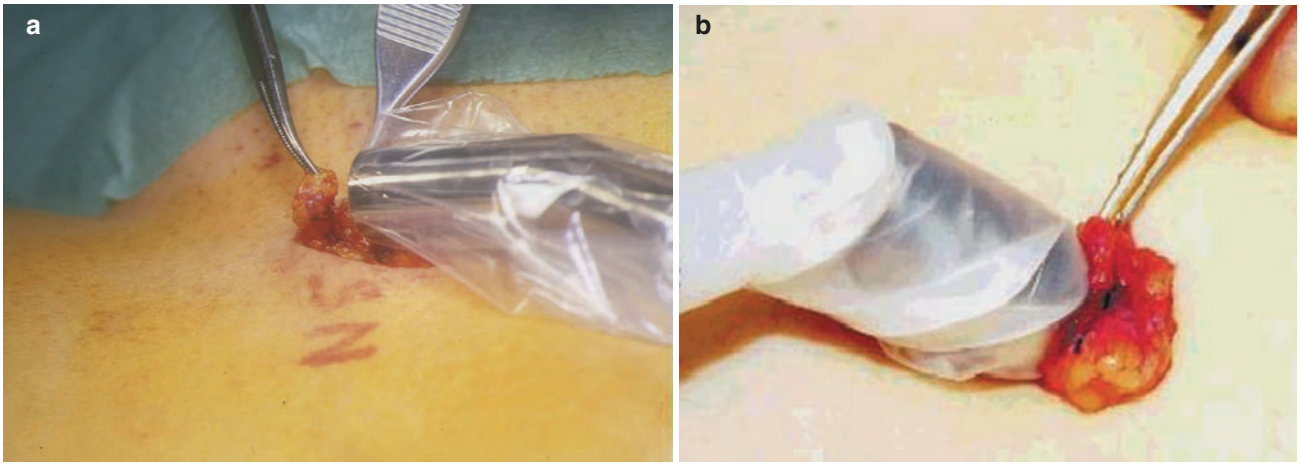

Fig. 19.4 (**a**) Lesion's localization using a gamma probe, wrapped in a sterile sheath; (**b**) lesion's counting after removal

odds ratio (OR) of 0.367 and 95% confidence interval (CI) 0277 to 0487 ($p < 0.001$) for margin status and OR 0.347, 95% CI 0.250 to 0.481 ($p < 0.001$) for reoperation rates).

Postma et al. [16], in a multicenter randomized controlled trial, compared the radio-guided occult lesion localization (ROLL) with respect to wire-guided localization (WGL), enrolling 314 patients (162 were assigned to the radio-guided localization and 152 for WGL), by analyzing primary outcomes as the percentage of complete tumor excision, the proportion of patients in need of re-excision, and the volume of the removed tissue. The authors concluded that the two procedures are comparable in terms of complete tumor excision and re-excision rates, but ROLL leads to excision of largest volumes of tissue and therefore concluded that it cannot replace WGL as the standard of care.

In evaluating the results of this study, it is necessary to consider that the radio localization method used differs from that described by the IEO group to some key features: firstly the choice of a different tracer (99mTc-nanocolloid vs. 99mTc-MAA) with a volume and a higher dose. The use of albumin nanocolloids can in fact be reflected in a larger share of lymphatic drainage and therefore in a subsequent spreading of the radioactive dose with necessity of extending the limits of the resection [17].

Recent studies have compared the ROLL with the localization method which involves the use of a titanium seed containing iodine-125 (RSL), implanted in the tumor before surgery under stereotactic or ultrasound guidance [18].

The retrospective study comparing RLS and ROLL in non-palpable breast lesions showed margin status and re-excision rates are comparable.

The RSL allows to improve the logistics for both the patient and the surgical department: in fact, in relation to long half-life of the radioactive tracer used (about 60 days), it is possible to position the seed even at a distance of time from the intervention.

Recently, Chan et al. [19] have published a review, which has considered 11 randomized controlled trials (RCTs) to assess the therapeutic outcomes of a new form of guided surgical intervention for non-palpable breast lesions against WGL, considered as the gold standard. The authors concluded that ROLL demonstrated favorable results in successful localization (RR 0.60, 95% CI 12:16 to 2:28), positive tumor margins (RR 0.74, 95% CI 12:42 to 1.29), and reoperation rates (RR 0:51, 95% CI 12:21 to 1:23) versus WGL, although the results were not statistically significant.

The authors conclude that today the WGL is still the approach most widely adopted in the location of non-palpable lesions for breast surgery. The review of the literature indicates that the ROLL can be used in clinical practice as it has proved to be a safe method, thus constituting a valid alternative to WGL with the added advantage of being able to highlight the sentinel node simultaneously.

19.2 The Sentinel Node Biopsy (SNB)

G. Paganelli

19.2.1 Introduction

The introduction of the sentinel node technique in clinical practice has resulted in a significant change in the treatment of early breast cancer, becoming the standard of care and thereby reducing the number of unnecessary axillary dissection.

The concept of "sentinel lymph node" is connected with the idea that the metastatic spread of cancer through the lymphatic follows an orderly and predictable pattern [20–22]. On the basis of this hypothesis, the histological evaluation of the "sentinel node," *which is the first lymph node that drains fluid directly from the primary tumor*, allows to exclude the presence of malignant cells in other lymph nodes. Therefore, the status of the sentinel node is able to accurately predict the pathological state of the successive lymph node stations.

During the 1990s, the concept of sentinel node showed its potential role in the surgical treatment of breast cancer [23–25]. Since then, lymphoscintigraphy has increasingly emerged as a reliable method for detecting sentinel lymph node showing success rates higher than the method so far used (blue dye). These studies started with the work published in 1993 by Alex and Krag [26] on melanoma and breast cancer to reach the optimized approach developed by our group at IEO in 1995–1996 [27] and then applied in thousands of breast cancer patients in Europe.

The first randomized trial comparing total axillary dissection versus the only sentinel lymph node biopsy was performed by Veronesi and colleagues [28], which randomized 516 patients with breast tumors smaller than 2 cm.

The study had planned to recruit 1000 for each experimental arm, but after the known preliminary results, the patients randomized to axillary dissection arm refused treatment. These results confirmed those of the NSABP B-32 study [29, 30] that showed how the sentinel node biopsy is predictive of axillary nodal status with great accuracy (96.9%), with a low false-negative rate (8.8%). In addition, the postoperative comorbidities were much less frequent in the sentinel node group.

19.2.2 Methodological Aspects of Lymphoscintigraphy

Despite its spread, there is no consensus on the methodological aspects of the sentinel lymph node procedure: there are still many controversies regarding the type of tracer to be used (different between the USA and EU), the method of injection, the type of images to perform (planar, SPECT), and the subsequent revelation in the operating room.

19.2.3 Radiotracers

The perfect radiopharmaceutical for sentinel lymph node biopsy should be easily drained from the administration area on the first node, accumulating preferentially only at this level and limiting the drainage toward the subsequent lymph node stations.

The intranodal retention is due to macrophages that line the sinusoidal spaces of the lymph nodes, whose main function is to filter the lymph-rich particulates, on the basis of an active phagocytosis [31].

After administration, the colloidal particles pass into the lymphatic circulation with a speed that is inversely proportional to particle size [32, 33].

In our experience, the ideal tracer is composed of particles with sizes between 100 and 200 nm, in order to obtain the best compromise between speed of drainage and accumulation in the sentinel node. In fact, tracer colloidal particles with sizes less than 50 nm in the lymphatic vessels drain very quickly but also pass in the lymph nodes of the second and third level (Fig. 19.5). On the other hand, the tracers consisted of too large particles (diameter >300 nm) that accumulate only in the sentinel lymph node, but with a speed of migration excessively slow.

Unfortunately the tracer colloidal particles with a diameter between 100 and 200 nm are not commercially available; currently the most widely used radiopharmaceutical in the USA is the technetium-labeled sulfur colloid in a nonfiltered (with particles ranging from about 15 to 50 nm) or filtered form, whereas in Australia and in Canada, antimony trisulfide is used (range, 3–30 nm). Many European researchers use human serum albumin particles with diameters between 40 and 100 nm (95% < 80 μm).

In our first series of 240 consecutive patients, the mean number of lymph nodes visualized using a radiocolloid particles with sizes ranging between 15 and 50 nm was equal to 2.1 (SD 1.1), while it was 1.6 (SD 0.8) for the tracer particles up to 80 nm and 1.3 (SD 0.5) with larger particles [24].

19.2.4 Injection

The optimal injection approach has been much debated in the last 20 years. The different proposed methods can be summarized into two main categories: deep injection (intratumoral, peritumoral) or superficial (intradermal, subcutaneous, or periareolar).

Several studies have been carried out to compare the results obtained with the various methods of injection. So far, only two prospective randomized clinical trials have been published [34, 35], and the results are not quite clarifiers. In fact Povoski et al. have shown that the rate of identification of the SN is greater when the injection is made intradermally, while Rodier and colleagues have shown that the most effective route of administration is the periareolar that obtains an SN detection rate of 99.11%.

Data from a study of our group [24], using both injection intradermally and peritumoral, showed no significant differences in the identification rate of sentinel node. The only difference is related to a time delay in the display of the sentinel lymph node when using the administration by peritumoral.

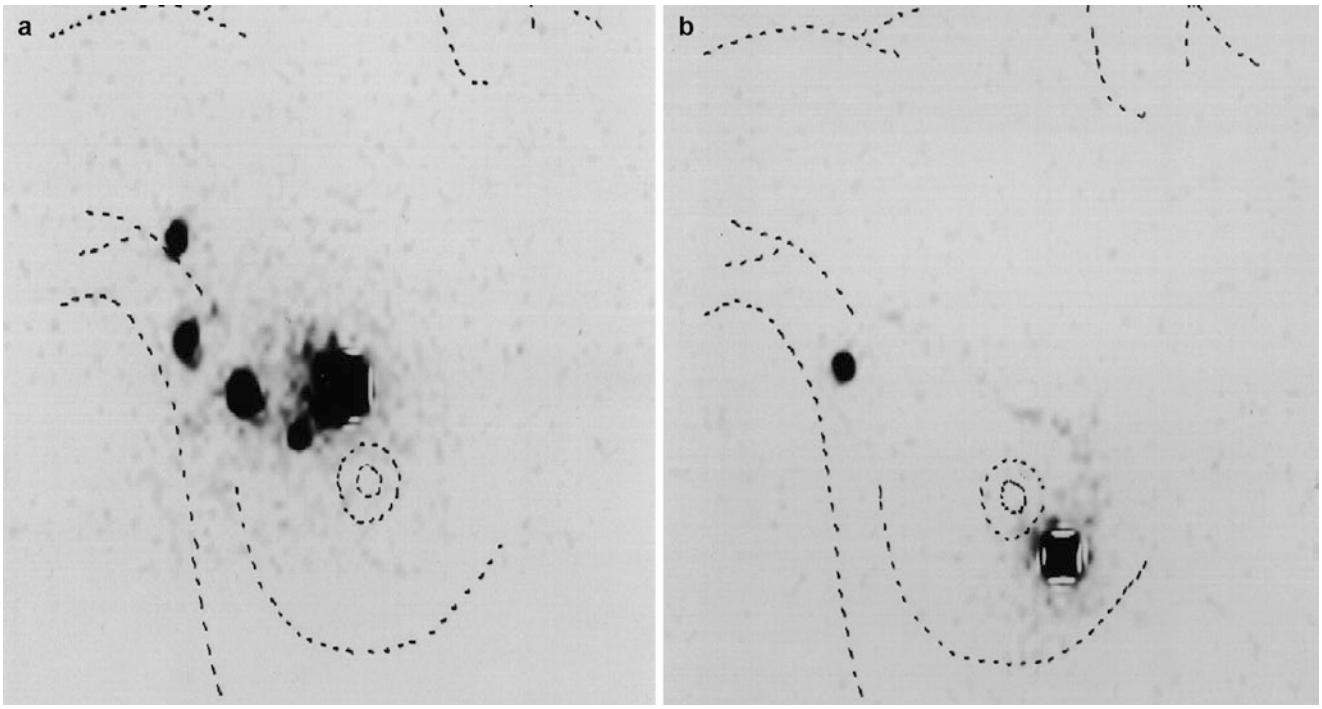

Fig. 19.5 (**a**) Scintigraphic image in the right anterior oblique projection obtained after subcutaneous injection of 99mTc-labeled sulfur colloid antimony in the upper outer quadrant of the right breast: multiple uptake areas in the ipsilateral axillary level are highlighted. (**b**) Scintigraphic image in anterior oblique projection right after subcutaneous injection of 99m Tc-labeled albumin (particle diameter comprised between 100 and 200 nm) in the inferior-inner quadrant of the right breast: it shows the presence of a single spot of uptake corresponding to the sentinel lymph node in the ipsilateral axilla

Superficial injection has the advantage of being an extremely easy method to perform, not requiring an ultrasound or stereotactic guidance for its execution also in the presence of non-palpable tumors, instead necessary in the case of peritumoral injection.

We believe that both deep and surface approach injection techniques are valid and are often complementary; the combination of both injection techniques (both peritumoral injections and retroareolar/areolar [36] or subcutaneous/peritumoral injection [37]) can improve the detection accuracy and decrease the false-negative rate (FNR). This is also supported by a study on the anatomy of the breast, lymphatic, which has shown that in some cases there are different lymphatic drainage ways, although most of the superficial lymph vessels converge in the same sentinel node [38]. Our current approach is to prefer the hypodermic injection in superficial tumors and to reserve the peritumoral administration in deep tumors.

19.2.5 Imaging

The execution of lymphoscintigraphy in the afternoon before surgery (15–18 h before surgery) is both logistically convenient for the routine in nuclear medicine and consistent with the pathophysiology of lymphatic drainage for radiocolloids with any particle size. However, when radiocolloids with small particle size are used, it may be preferable to perform the imaging 2–4 h before the surgery in order to avoid the uptake of multiple lymph node stations.

Generally, the acquisition of lymphoscintigraphy for identifying the sentinel node is performed using a large field gamma camera equipped with a high-resolution collimator. The patient should be placed in a supine position, with the arm above the head to allow placement of the gamma camera's head as close to the axilla.

The acquisition may be carried out in dynamic scan to highlight the route of drainage and then followed by the static acquisitions placing the gamma camera in anterior oblique position (+45°). Once the lymph node is displayed, it is necessary to mark the skin projection of the sentinel lymph node in the axilla using a permanent marker, positioning the arm at 90° with respect to the body in the same position of the intervention.

It seems rather unclear the added value of SPECT/CT for visualization of sentinel nodes: some authors have proposed its use especially when there is evidence of an extra-axillary drainage [39], but at present it is of little use.

19.2.6 Intraoperative Gamma Probe Counting

The intraoperative localization of sentinel nodes involves the use of a gamma probe sensor, wrapped in a sterile sheath: the sequence can vary according to the surgeon's habits, being able to perform before the removal of the primary tumor and then the sentinel node or vice versa. In patients where the primary tumor is located in the upper outer quadrant, it may be possible to use a single incision to remove the tumor that is the sentinel node.

The location of the sentinel lymph node with the gamma probe is based on the detection of a focal spot of radioactivity accumulation in the draining lymph node/s. Once the sentinel lymph node/s are localized and excised, a further search of the tracer accumulation areas must be performed to highlight the possible presence of other "hot" lymph nodes. The complete removal of the sentinel node/s is confirmed by the reduction of the rate in the axilla to background levels.

In the most recent series, the overall success rate of lymphoscintigraphy in the identification of the sentinel lymph node is very high, about 97%, higher than that of the colorimetric technique with the vital blue (mostly around 75–80%).

19.2.7 Results, Clinical Indications, and Controversies

Sentinel lymph node localization and biopsy (SLNB) represents the "standard of care" for the assessment of axillary lymph nodes in patients with breast cancer. This procedure has completely replaced the axillary lymph node dissection (ALND), in women with breast cancer in stages I and II with no clinical evidence of metastasis to the axilla [24, 40, 41].

Currently, in patients with negative sentinel node biopsy, the axillary dissection is not performed, regardless of the type of tumor present.

Axillary dissection remains, however, the standard treatment for patients with axillary metastases.

SLNB has undergone changes and improvements over the years, and the procedure is routinely performed in many situations that were considered as contraindications only a few years ago.

19.2.7.1 Minimal Lymph Node Involvement

One aspect not entirely clarified is the meaning of micrometastases and isolated tumor cells (ITC) in sentinel lymph node. Micrometastases are defined as a tumor deposit greater than 0.2 mm and/or more than 200 cells, but less than 2.0 mm, while the ITC are groups of cells not exceeding 0.2 mm or less than 200 cells [42].

Between 2001 and 2010, the International Breast Cancer Study Group (IBCSG) 23-01 recruited women from 27 institutions with breast cancer, with tumor size of ≤5 cm, and with micrometastases in the sentinel node, randomizing into two arms which included SLNB or standard treatment with ALND. After a 5-year median follow-up, the axillary recurrence rate was <1% in both arms. Survival was similar in the ALND and SLNB-alone group (DFS, 84% vs. 88%, respectively) [43].

In 2011, the St. Gallen Consensus Conference [44] recommended that the micrometastases in the sentinel node should not represent an indication for axillary dissection irrespective of the type of surgery performed.

19.2.7.2 Ductal Carcinoma In Situ (DCIS)

DCIS metastasizes to the axillary lymph nodes in a small proportion of patients (estimated at 1–2% of cases), and, if present, the meaning of these metastases is not yet clear. For these reasons, the National Cancer Institute has not recommended the use of SLNB in patients with ductal carcinoma in situ [45].

However, it was shown that approximately 40% of patients will have an underestimation of ductal invasion, so the sentinel node biopsy is currently recommended in patients undergoing mastectomy for DCIS [46]. In patients undergoing conservative surgery, the sentinel node biopsy can be performed successively in the presence of an invasion examination of the surgical samples.

However, some centers perform SLNB in patients with DCIS considering the fact that a wide local excision can cause an alteration of the lymphatic drainage, making a subsequent SLNB difficult [47].

19.2.7.3 Reoperative SLNB with Prior Breast or Axillary Surgery

The sentinel node approach has always been limited to women that have not previously undergone surgery, in relation to the fact that the lymphatic system should be intact in order to have an excellent drainage.

Published reports have shown that sentinel node biopsy can be performed after surgical treatment, either conservative or radical: in 117 patients [48], previously treated with surgery, the search for the lymph node was effective in 55% of patients, with a success rate directly proportional to the number of lymph nodes removed during the first intervention. This series revealed no locoregional recurrence after an average of 2.2 years of follow-up, but the 5% of patients developed recurrences.

Another series of 56 patients showed an 80% detection rate; after 2 years of follow-up, axillary recurrences were not reported. The same group later published a similar series in patients with a previous ipsilateral lymph node dissection, noting only a 29% success rate [49].

19.2.7.4 Pregnancy

There are several dilemmas in the management of breast cancer during pregnancy, one of which is how to assess the lymph node status of the patient. The introduction of the SLNB technique requires a careful assessment of risks and benefits in this patient population.

First, the problem that arises is linked to the use of a radioactive substance: studies have shown that the risk of radioactive teratogenicity is minimal. The SLN method both in the case of melanoma than in breast cancer usually uses doses of 0.3–3 mCi of 99mTc-nanocolloids, with a fetal absorbed dose of about 0.43 cGy [50]. It is estimated that the risk of embryonic or fetal genetic defects is equal to 0.024–0.099% per cGy [51], while the liable threshold for fetal teratogenic effects is 5 cGy [52].

Studies reported in the literature in pregnant women [50] suggest that SLNB can be performed safely in pregnancy, although data are based on currently too small populations. For this reason, the SLNB in these patients may be used, but it requires a large informed consent before embarking on this technique.

19.2.7.5 Sentinel Lymph Node of the Internal Mammary Node (IMN)

Study of the sentinel node has allowed a better evaluation of the nodal status at the level of IMN, whose valuation is generally not included in the standard surgical procedure. It was shown that the IMN metastases represent a negative prognostic factor [53], with a higher incidence of distant metastasis and reduced survival [54, 55]. The involvement of IMN is more frequent in the case of tumors located in the inner quadrants, even in the presence of subcentimeter lesions.

The risk of distant metastases increased 30% in mammary tumors located in the interior quadrants, with an increase in mortality of 20%; in particular, the risk of metastasis to the IMN is associated with the age of patients (decreases with increasing age), the size of the primary tumor, and the presence of axillary metastases [56, 57].

From a methodological point of view, the identification of IMN sentinel node requires administration of the tracer peritumorally.

This method of administration allows the display of atleast one IMN node in 60% of the tumors, while it is extremely rare that a node of the IMN is displayed using intra / subcutaneous Injection (2.1%).

However, the significance of IMN biopsy continues to be discussed. There is evidence that the mapping of IMNs brings to stage migration and treatment planning changes; however, more data are needed to support the idea that the mapping of IMNs improves treatment outcome and survival [58, 59].

19.2.7.6 ROLL and SNOLL

The sentinel lymph node biopsy (SLNB) and radio-guided occult lesion localization (ROLL) can be used in combination (SNOLL) and for cancers or high-grade-infiltrating ductal atypia.

A recent review [60] analyzed the results emerging from seven studies that evaluated 983 patients with non-palpable breast cancer. The rate of complete resection with negative margins is between 82 and 90.5%, while the need for a second operation has occurred in a percentage of between 2 and 12%.

The systematic review has shown that SNOLL is feasible, safe, and effective for the treatment of non-palpable breast cancers.

19.2.7.7 New Tracers

The techniques of SNLB and ROLL/SNOLL involve the use of radioactive substances whose use may be restricted only to the centers with a nuclear medicine department. This limiting factor is probably at the base of finding that in respect of an increased incidence of cancer, the use of the procedure of sentinel node biopsy has reached a plateau, with about 60% in developed countries who have access to this procedure [61, 62]; the percentage goes down to 5% in China and the rest of the world [63].

A recent review [64] has analyzed 21 studies investigating the use of new molecules for the research of SLN such as fluorescence of indocyanine green (ICG), contrast-enhanced ultrasound (CEUS) microbubbles, or superparamagnetic iron oxide nanoparticles (SPIO). The endpoint in this review was limited to the sentinel lymph node identification, and few data were available for other endpoints, such as false-negative and locoregional recurrence rates.

The authors conclude that there is no significant benefit of the new methods compared to the SLNB performed with radiolabeled compounds.

19.3 Positron Emission Tomography (PET)

L. Gilardi, F. Matteucci, and G. Paganelli

19.3.1 Introduction

Positron emission tomography/computed tomography (PET/CT) is an imaging modality that uses positron-emitting radiotracers associated to radiologic imaging in order to provide in vivo data on receptor and biochemical and metabolic processes of various types of tumors. The CT portion of the tomograph provides an anatomical map used for attenuation

correction of positron images and is also useful for an accurate interpretation of PET signal.

The oncological biomarker most commonly evaluated with PET/CT is fluorine 18 (^{18}F) fluorodeoxyglucose (FDG) uptake, as most malignant tumors overexpress glucose transporters and show increased hexokinase activity [65–68].

However, breast tumors have other important features, such as cell proliferation, hormonal receptor status, and HER2 status that have been explored through PET imaging with other radiotracers.

Within this chapter, we examine the actual impact of FDG-PET/CT on clinical management of breast cancer patients; moreover, we discuss future opportunities given by the development of specific non-FDG radiotracer.

19.3.2 FDG-PET/CT

19.3.2.1 Staging

An accurate staging of breast cancer patients at the time of the initial diagnosis has a major impact on the choice of the optimal therapeutic strategy [69]. Breast cancer staging includes detecting cancer spread to regional lymph nodes, both in the axilla and internal mammary chain, and also to distant sites. As a total-body procedure, PET/CT is able to assess these data all at once, providing morphological information associated to an evaluation of the metabolic activity of the disease.

There is no currently defined role for FDG-PET/CT in breast cancer detection, mainly due to its poor spatial resolution. Indeed, the sensitivity of the procedure is less than other conventional imaging modalities and depends first of all on primary breast tumor size [70, 71]. In particular, Cermik et al. found that the sensitivity of FDG-PET in detecting non-palpable, small (<10 mm), invasive malignancies ranged from 53% for T1mic and T1a tumors to 63% for T1b tumors [72].

Moreover, PET imaging accuracy is affected by tumor histology: lobular and ductal intraepithelial neoplasia (LIN and DIN) can be missed, and invasive lobular carcinomas are detected with less sensitivity than ductal carcinoma, due to their pattern of growth [73, 74].

Actually, the main contribution of PET in primary breast tumor assessment consists in measuring FDG uptake through the standardized uptake value (SUV), which is useful to evaluate the subsequent response to neoadjuvant therapy in cases not submitted directly to surgery, even at an early point during treatments. Moreover several studies reported the correlation between SUV of breast cancer and prognostic parameters such as tumor size, axillary lymph node involvement, negativity of estrogen receptor expression, high tumor grade, and HER2 overexpression [75–77]. An association has also been found between primary tumor FDG uptake and immunohistochemical-defined subtypes of breast cancer, more biologically aggressive tumors, i.e., HER2 positive and triple negative, demonstrating higher SUV values than luminal ones [78, 79].

An evolution of PET in this setting is the development of positron emission mammography (PEM) that is a relatively new technique being investigated for use in breast cancer diagnosis. After FDG injection, the breast is positioned in a device similar to a mammography cassette. PEM demonstrated improved sensitivity if compared to whole-body PET/CT, in particular for detection of small lesions [80]. Other benefits are that PEM is relatively unaffected by breast density and that it is able to detect in situ lesions [81], suggesting a potential role in high-risk patients, in women with dense breast, and in the diagnosis and postsurgical follow-up of intraductal lesions.

For staging of the axilla, it has been demonstrated that PET/CT cannot be used as a substitute of sentinel node biopsy (SNB) due to the limited spatial resolution that precludes an adequate evaluation of small size lymph nodes, of metastatic lymph nodes with few FDG-avid cells, and of the axillas with few involved nodes. Sensitivity values as low as 20% have been found in some series [82–84]; in particular, in a study by Veronesi et al., only 37% of 236 patients with clinically negative axilla and with a positive sentinel node biopsy had FDG-positive axillary lymph nodes at presurgical PET scan [82].

On the other hand, a node-positive PET scan has high specificity and positive predictive value for axillary staging and indicates a higher disease spread to this region [85, 86]. Therefore PET/CT is useful in differentiating low- vs. high-burden nodal disease and could guide the choice of surgical treatments on the axilla: direct axillary lymph node dissection (ALND), foregoing SNB, has been proposed in PET node-positive patients, while SNB actually remains the choice as a staging procedure in PET node-negative cases.

In contrast with the limited accuracy in axillary lymph node staging, as a total-body procedure, PET/CT has a great value in the diagnosis of extra-axillary lymph node metastases and distant sites of disease (Fig. 19.6). The detection of Berg level III (infraclavicular) or extra-axillary local-regional (supraclavicular or internal mammary) nodal disease or of distant metastases has important implication in surgical and radiation therapy planning and in the definition of the real aim (curative vs. palliative) of therapeutic strategy in newly diagnosed breast cancer. Some studies have demonstrated that PET is superior to conventional imaging in this setting [87–90]. Ng et al. detected occult metastases in 17/154 patients (11%); locoregional nodal spread missed by conventional imaging was instead found in 15/154

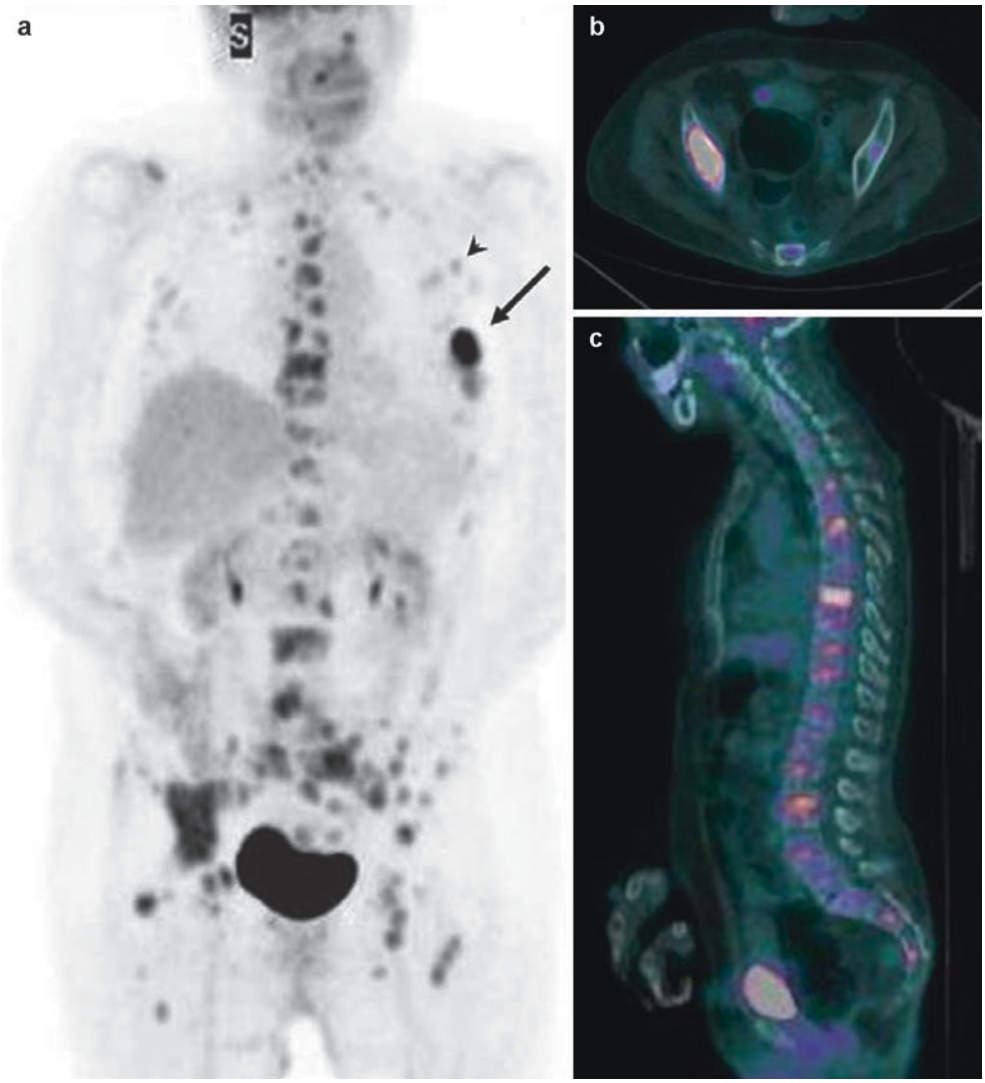

Fig. 19.6 Staging PET/CT scan in a 62-year-old woman with invasive ductal carcinoma of the left breast (cT2N1, ER 90%, PgR 90%, HER2 negative, Ki67 28%). (**a**) Maximum intensity projection image shows FDG uptake in primary breast tumor (arrow) and axillary lymph nodes (*arrowhead*), associated to multiple, hypermetabolic lesions in the bone. (**b**) Axial PET/CT fusion image shows FDG uptake in pelvic bones. (**c**) Sagittal PET/CT fusion image shows multiple foci of uptake in the spine

patients (10.8–13% had ipsilateral internal mammary node involvement and 2% ipsilateral supraclavicular nodal metastases), leading to a change of the radiation treatment field [88]. Likewise, in 13/154 (8%) and 7/70 (10%) patients, there was a therapeutic change due to PET/CT detection of occult metastases in Koolen et al. and Segaert et al.'s studies, respectively [89, 90].

PET/CT is a valuable tool in locally advanced breast cancer, but also in early-stage disease [90–93]. In a study by Groheux et al., PET/CT demonstrated a nonnegligible yield in patients with stage IIB and primary operable stage IIIA breast cancer. In these patients with T3N0, T2N1, or T3N1 disease, the overall yield was 13% with a change in therapeutic management due to the finding of N3 disease or distant metastases. Moreover, 2 of 36 patients with stage IIA disease were upstaged due to the discovery of internal mammary lymph node (one patient) and contralateral supraclavicular and mediastinal nodal disease (one patient) [92]. Extra-axillary lymph node involvement was also detected in almost one third of stage II–III breast cancer patients in the study of Aukema et al. PET/CT upgraded the TNM stage in 10/60 patients (17%), with a change of the radiotherapy plan in 7/60 (12%) [94].

These studies demonstrate that FDG PET/CT imaging is applicable to a patient population with a wide range of breast cancer stages, including T1–T4 carcinomas. Nevertheless, actually some uncertainties remain about the

exact characteristics (clinical TNM stage and histopathological features) of newly diagnosed breast cancer for which this imaging procedure should be systematically performed with a favorable cost-effectiveness balance. Targeted prospective studies with a large number of patients are necessary to better define this point.

19.3.2.2 Monitoring Response to Therapy

It is well known that changes in metabolic activity generally occur earlier during treatments than those in tumor size. This is particularly true for new targeted therapies that are more cytostatic than cytotoxic and that can render tumors metabolically inactive without significant changes of their morphological aspect. Moreover, in the specific case of breast cancer, common sites of dissemination such as bone metastases, pleural effusion, and lymphangitis are difficult to assess with conventional imaging.

Even if the specific criteria for therapy response assessment proposed by various working groups are not actually accepted and widely used [95, 96], PET/CT demonstrated to be a valuable tool in this setting.

In particular, in the case of bone metastatic breast cancer, FDG-PET/CT is emerging as a standard of care.

Initial reports found that FDG-PET and bone scintigraphy had similar sensitivity for the detection of bone metastases, ranging from 57 to 100%, while the specificity was superior for PET, approaching 96–100%. These data reflect inherent limitations of the two imaging procedures, as bone scintigraphy poorly detects osteolytic lesions and PET is often less sensitive in pure osteoblastic metastases [97–99]. However, the development of integrated FDG-PET/CT has improved the accuracy in the detection and response evaluation of bone metastases by adding information on bone morphological changes.

As regards morphologic imaging, it does not directly reflect tumor cell viability but rather the secondary effect on bone adjacent tissue. Afterward, morphologic changes are often delayed during therapy [100] and do not seem to correlate with the presence of residual active tumor [101]. Change in tumor size is also not a good surrogate of bone lesion response, and the RECIST 1.1 criteria specify that bone lesions without soft tissue components cannot be considered as measurable [102]. Moreover, a "flare" reaction can be assessed on CT or bone scan, expression of the sclerotic healing, making the response evaluation difficult or even leading to a misinterpretation of the disease course [103, 104].

PET/CT is not burdened by these limitations, as FDG uptake reflects the metabolic feature of bone metastases independently of their CT pattern (osteoblastic and osteoclastic) [101] (Fig. 19.7).

As a total-body procedure, PET/CT is also able to provide information about all sites of disease in a single test; response to therapy may indeed be heterogeneous, with the coexistence of responding and not responding lesions within the same patient. Huyge et al. studied metabolic response by comparing PET/CT scans carried out before and during a new treatment phase in 25 bone-dominant metastatic breast cancer patients and found that, in the subset with both bone and extra-bone metastases, PET/CT showed discordant responses between bone and extra-bone metastases in 30% of treatment phases. Moreover, a heterogeneous metabolic response seemed to have prognostic implication, as time to progression was longer in patients with a heterogeneous nonresponse of bony lesions compared with those with a homogeneous nonresponse [105].

In the neoadjuvant setting, several studies have shown promising results for the early prediction of pathological complete response of breast cancer using PET/CT, even after only one cycle of therapy [106–108]. The early prediction of response during neoadjuvant therapy might offer the opportunity to change strategy in case of ineffectiveness, avoiding unwarranted side effects at the same time.

An impact of the different breast cancer subtypes on FDG uptake during neoadjuvant treatment has been reported, with conflicting results. For example, in Koolen et al.'s study, PET/CT resulted predictive of response in ER-positive/HER2-negative and triple-negative tumors but was less accurate in HER2-positive tumors [109], while Humbert et al. found that the metabolic imaging procedure was efficient in the determination of final pathological complete response only in patients with HER2-positive tumors [108]. Moreover, Groheux et al. found that quantitative indexes derived from interim FDG-PET/CT that are best correlated with pathologic response vary by subtypes, opening new areas of investigation.

Despite the growing evidence supporting the use of PET/CT in this field and the benefits that would result for patients, its use has not yet entered into the routine. This is mainly due to the heterogeneity of the available studies, in particular with regard to the timing of the interim evaluation and to the degree of SUV decrease used to define the response.

19.3.2.3 Recurrent Breast Cancer

Early diagnosis and correct localization of recurrent breast cancer are important to allow the appropriate treatment that

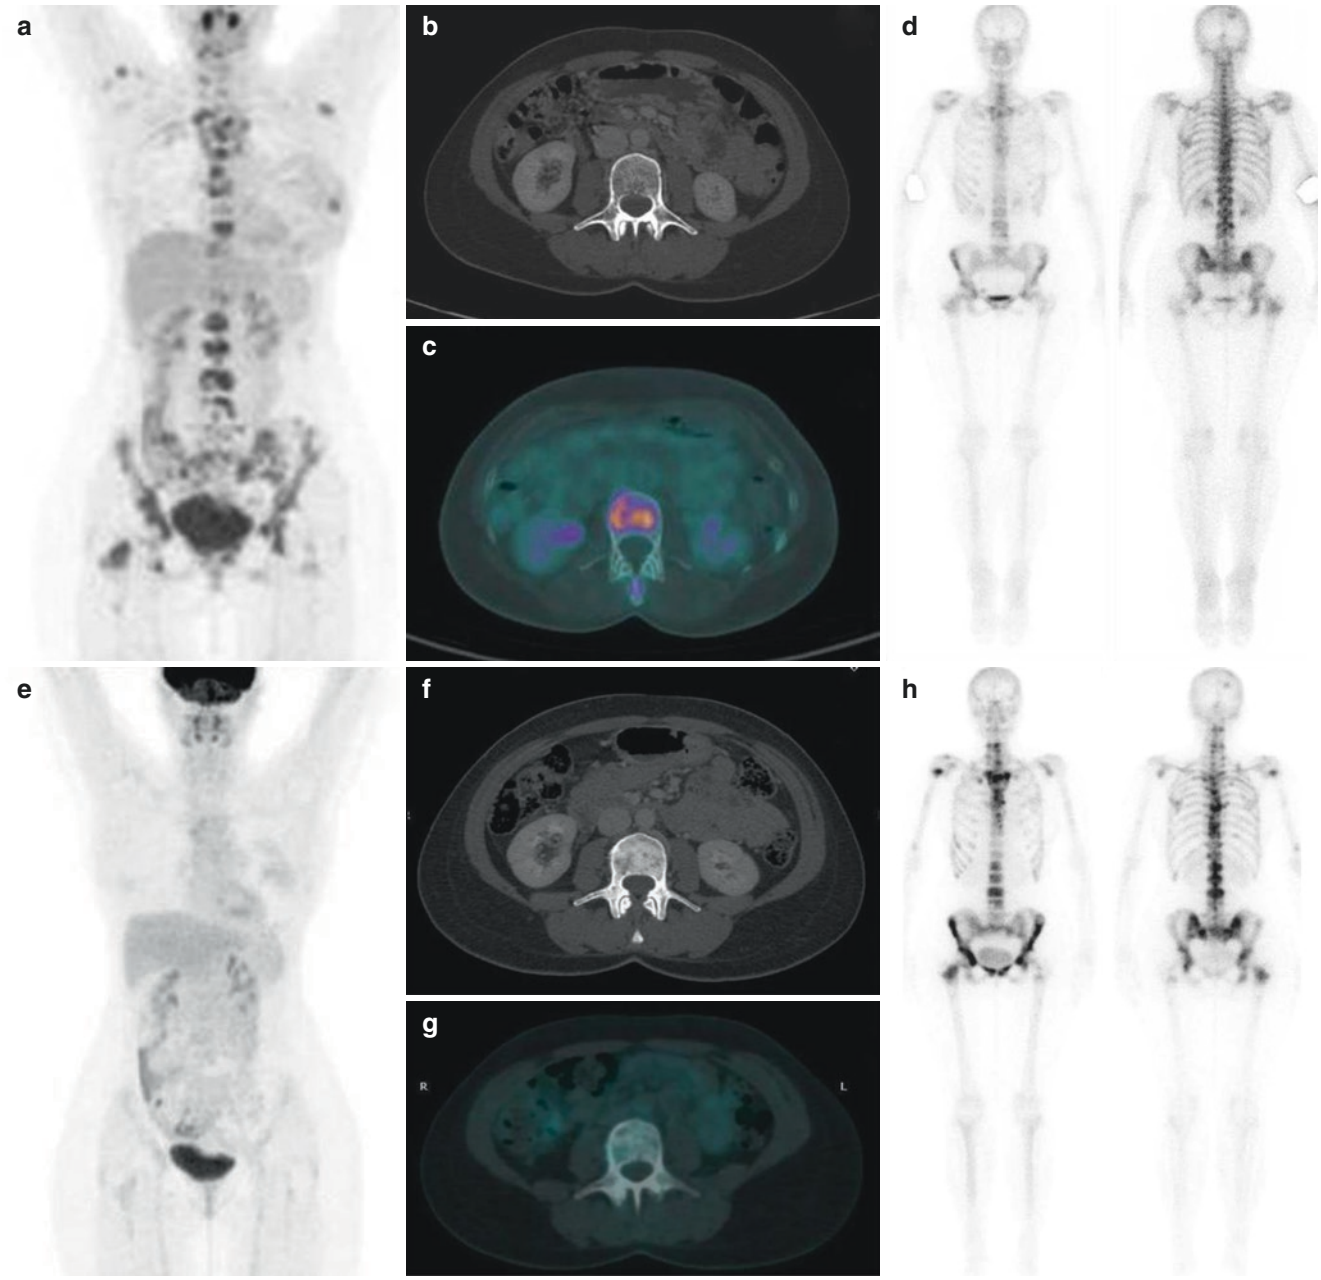

Fig. 19.7 A 43-year-old woman treated with surgery, chemotherapy, and radiotherapy due to left breast cancer in 2013. Follow-up PET/CT demonstrated diffuse bone disease (maximum intensity projection image and fused PET/CT axial image that refers to L3 (**a**) and (**c**), respectively) that was confirmed, with lesser extent, by a bone scintigraphy (**d**). Contrast-enhanced CT detected only few of the bone lesions; in particular L3 didn't show significant alterations (**b**). After chemotherapy and administration of zoledronic acid, PET/CT was negative (maximum intensity projection image and fused PET/CT axial image that refers to L3 (**e**) and (**g**), respectively). On the contrary, bone scintigraphy (**h**) and CT scan (axial image that refers to L3 (**f**)) showed an increase of foci of abnormal uptake and of osteoblastic bone lesions, respectively ("flare" reaction)

could offer the better prognosis and a good outcome. Disease recurrence may be suspected owing to the presence of symptoms or increase of tumoral markers or because of radiologic findings. PET/CT has been shown to perform better than conventional imaging in all these different settings [110–113]. This is not unexpected, as FDG-PET is a molecular imaging technique that detects metabolic changes in tissues. Since functional changes precede morphological changes,

FDG-PET has the potential to detect viable tumor tissue earlier in the course of disease evolution.

In particular, PET/CT showed an important role in asymptomatic patients with rising tumor marker levels and negative conventional imaging results. Grassetto et al. studied 89 breast cancer patients that met these characteristics. Tumor deposits were detected in 40/89 patients in the chest wall, internal mammary nodes, lungs, liver, and bone; in 23/40 patients, solitary small lesion was amenable to radical therapy [110].

Chang et al. performed PET/CT on 71 patients with increased serum CA15-3 levels and/or clinical/radiological suspicion of recurrence and, as control group, on 69 asymptomatic breast cancer patients in their post-therapy surveillance. Recurrences were proven in 56.3% (40/71) of the patients with suspected recurrence, but also in 13% (9/69) of the control group [114].

Moreover, PET/CT has the major advantage of evaluating the entire body in a single procedure and the possibility of determining whether the recurrence is isolated or not, providing essential information for patients' management. In Aukema et al.'s study, 56 patients with confirmed locoregional recurrence were evaluated to visualize the extent of recurrence and to exclude distant involvement. PET/CT confirmed all the known sites of disease and depicted additional lesions not visible on conventional imaging in 25 patients (45%). The procedure had an impact on clinical management in 27 patients (48%) by detecting more extensive locoregional disease or distant metastases. In 20 patients (36%), extensive surgery was prevented, and treatment was changed to palliative therapy [115]. Similarly, even in other studies, PET/CT results have been shown to have a great impact on management of patients with suspected recurrence, leading to changes of the treatment modality or intent in 48–54% of the cases [112–114].

Therefore, PET/CT appears to be the imaging modality of choice in this category of patients and should be performed as early as possible in case of any suspicion of recurrence or metastases.

19.3.3 PET/CT with Non-FDG Tracers

As previously reported, ^{18}F-FDG is not the only radiopharmaceutical available to evaluate patients with breast cancer. Other important features of this tumor have already been tested in human with novel PET tracers such as ^{18}F-fluorothymidine (^{18}F-FLT), ^{18}F-fluoroestradiol, and anti-HER2 radiopharmaceuticals that may provide additional useful information about breast cancer marker expression, heterogeneity of the disease, and responsiveness to therapy [116–119].

FLT has been developed to evaluate an increased cellular DNA synthesis and a good correlation between the tracer uptake and Ki-67 labeling index of breast cancer that has been reported [120]. FLT-PET may not be useful for staging purposes, as the tracer has a high physiological uptake in the liver and bone marrow. However, encouraging results have been reported in the early evaluation of response to therapy, even a week after initiation of chemotherapy [121, 122].

^{18}F-fluoroestradiol, that binds to estrogen receptors (ER), has been so far the most studied of the new tracers: its uptake demonstrated a correlation with ER expression in primary breast cancer tumors but even in locoregional lymph nodes and distant lesions (Fig. 19.8) [111, 123].

FES-PET could therefore be useful in the assessment of ER expression heterogeneity (as metastases can display different characteristics that could also not match those of the primary tumor [124]), leading to the evaluation of the entire tumor volume receptor status through a single, non-invasive procedure, bypassing the possibility of an error in the pathological determination of ER and assisting the individualized treatment decisions. Sun et al. and Van Krutchen et al. investigated the value of FES-PET in breast cancer patients presenting with a clinical dilemma. Both studies included 33 patients and found changes in treatment plans due to the PET results in 48% of the cases [125, 126].

FES uptake in disease sites has also been shown to be predictive of response to therapy. Linden et al. studied 47 heavily pretreated metastatic breast cancer patients with immunohistochemical ER-positive tumors and found that none of the 15 patients with initial SUV less than 1.5 responded to hormonal therapy, compared with 11 of 32 patients (34%) with SUV higher than 1.5 ($p < 0.01$) [125]. FES-PET could be used to identify patients unlikely to obtain an objective response and could lead to the exclusion of an ineffective treatment.

Finally, preclinical results with tracers with high specificity for HER2, such as ^{68}Ga-labeled affibody and ^{89}Zr-trastuzumab, are abundant and promising, but clinical data are still limited to small series of patients [112, 113, 126]. Further study is needed to identify the best radiopharmaceutical in this setting (concerning the optimal dosage, the isotope that should be used, and the time of image acquisition) and to define the real impact of HER2-PET on clinical management of breast cancer patients.

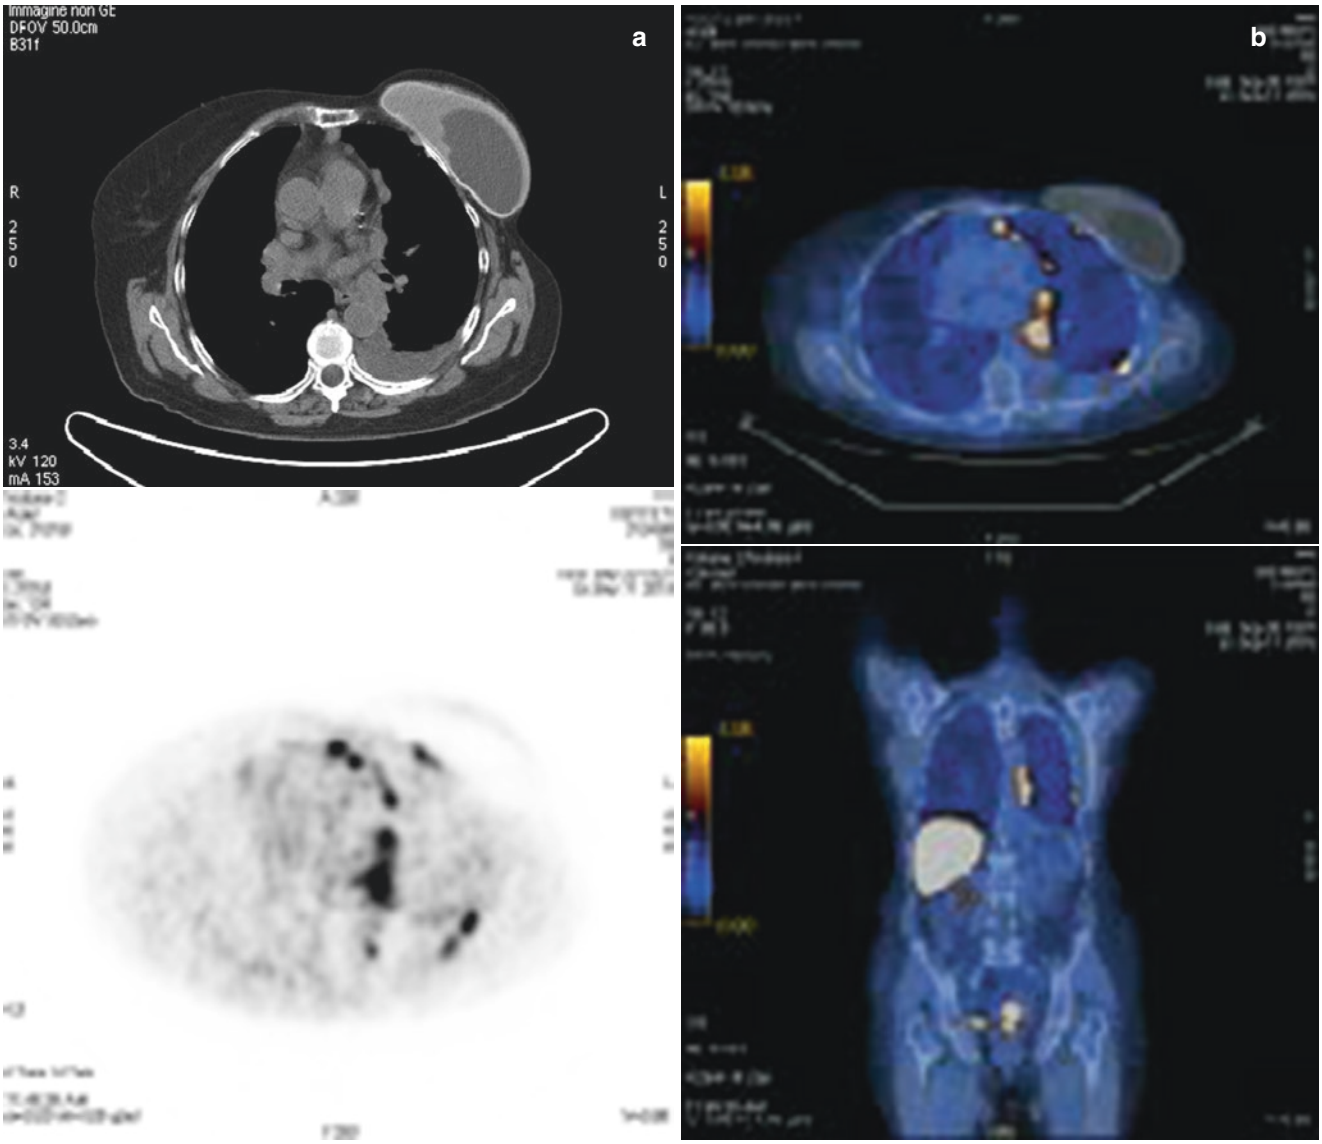

Fig. 19.8 A 79-year-old woman treated with surgery, chemotherapy, and radiotherapy due to left breast cancer in 2008 (invasive ductal carcinoma of the right breast; G3, pT1cN1M0 ER 100, PR 15%, Mib1 15%, HER2 not amplified).

Conclusion

In conclusion, FDG-PET has a big impact at different phases of the disease in breast cancer patients, from staging to assessing response to therapy or suspected recurrence. At present, many efforts have to be made to standardize study methodology, in order to allow the results to be compared and reported widely in clinical practice. It will also be important to consider the disease heterogeneity, with the aim of target studies on subpopulations that show inherent differences in prognosis and treatment (subtype-tailored PET imaging). Finally, the implementation of new PET tracers, with an overall in vivo assessment of the different characteristics of the disease, could help in the definition of the optimal therapeutic strategy. A combined, personalized determination of glycolytic activity and molecular marker expression may therefore become the basis for treatment of individual patients with different subtypes of breast cancer.

One-Step Systemic Staging for Patients with Breast Cancer

20

Giuseppe Petralia and Anwar R. Padhani

20.1 Background

Despite advances in the treatment of primary breast cancer, metastatic spread of the disease remains a substantial clinical burden. Nearly 30% of breast cancer patients already have tumour spread to regional lymph nodes at diagnosis, and 5% will have metastases at presentation [1]. The prevalence of metastatic disease has increased along with the duration of survival, with some 20% of patients developing metastases during the course of the disease [2].

Breast cancer commonly metastasizes to the lymph nodes, bone, liver, lung and the central nervous system [3]. Of these, bone is the most frequent, being the first site of metastasis in more than 50% of the cases of relapsing disease [4], and present at the time of death in over 70% of those patients who die of breast cancer [5].

In order to effectively manage metastatic breast cancer patients, it is essential to have consistent, reproducible and validated methods for the detection of metastatic disease and for the evaluation of therapy response. These methods include clinical assessments, serum biomarkers and imaging techniques.

20.2 Clinical Assessments

Clinical assessments addressing pain, energy levels and mobility, often by means of questionnaire tools [6], are for the most part in the form of structured measures of quality of life. Although widely used in clinical trials, these questionnaires are not integrated into daily practice.

20.3 Serum Biomarkers

The serum biomarkers applied to the evaluation of metastatic breast cancer include CA 15.3, the oncofoetal protein carcinoembryonic antigen (CEA), the oncoprotein HER-2/neu and the cytokeratin tissue polypeptide-specific antigen (TPS) [7]. Although serum biomarkers are helpful in the detection of recurrent disease, they perform variably in the evaluation of treatment response [8] and are not useful for evaluating heterogeneous response across different metastatic sites.

Serum biomarkers of bone heath are complementary and seem to be particularly useful in patients who have bone disease that is difficult to assess by means of other methods [9]. Markers such as N-telopeptide of type I collagen (NTX) and bone-specific alkaline phosphatase (BAP) are related to osteoclastic/osteoblastic bone activity, respectively, and their elevation or reduction (in the case of NTX) has been related to increased or diminished risk of developing skeletal-related events, as well as being correlated to survival [10, 11].

Of increasing recent interest for assessing therapy response is the use of circulating tumour cells (CTCs) and circulating tumour cell-free DNA. It has been demonstrated that levels of CTCs at baseline and after chemotherapy are predictive of progression-free survival and overall survival in metastatic breast cancer [12, 13]. However, changing therapy on the basis of persistently elevated CTC levels despite treatment does not bring an increase in overall survival [14]. CTC evaluations have demonstrated an advantage over conventional radiological studies for predicting overall survival, but show low correlation with radiographic tumour load [13]. Circulating tumour cell-free DNA has shown early promise, and there is evidence of superiority to CTCs, in small studies of treatment response assessment in metastatic breast cancer [15]. Guidelines from the International Consensus Conference for Advanced Breast Cancer, therefore, state that changes in serum biomarkers alone should not be used alone to initiate changes in treatment [16].

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_20

20.4 Imaging

20.4.1 Bone Scintigraphy (BS)

Planar bone scans with 99mTc-MDP (technetium-99m-methylene diphosphonate) are useful for the identification of metastatic bony disease as they have acceptable sensitivity [17]. Modern extensions to BS with SPECT or CT-SPECT improve bone scan performance [18, 19]. It is important to remember that 99mTc-MDP is bound to the bone as part of osteoblastic activity [20], and so BS does not necessarily reflect the full burden of disease within bone marrow space. In particular, pure lytic bone changes without an osteoblastic reaction may be missed (Fig. 20.1). In addition, it is impossible to assess patients with very advanced bone disease objectively because new disease cannot be confidently identified on the background of already elevated bone scan uptake (so-called superscans).

The utility of BS to positively identify response (as opposed to stable/progressive disease) is severely limited, because reductions of bone activity occur late in responding patients, which compromises the timeliness of bone scan readouts. Moreover, it is recognized that isotope BS can show transient increases in the size of detected lesions or new lesions in patients who are later shown to be responding to therapy (*flare reaction*) [21]. The biological explanation for the flare reaction is that successful treatment leads to osteoblast healing, which increases MDP uptake. The evaluation of response to therapy using BS is thus indirect (not reporting on tumour cell kill), and there is no evidence that bone scans may be used to assess positive therapy benefits [22].

20.4.2 Computed Tomography (CT)

Computed tomography (CT) is superior to bone scintigraphy for detecting bone disease [18]. CT scans allow measurement of the size of body metastases, extent of disease involvement and quantification of response to treatment, particularly of soft tissue disease. While CT measurements of soft tissue disease are incorporated into the RECIST [23], bone metastases are considered non-evaluable/measurable according to these criteria. Under RECIST, therefore, CT scans are used to assess response to treatment only for those bone metastases that have a measurable soft tissue component. The MD

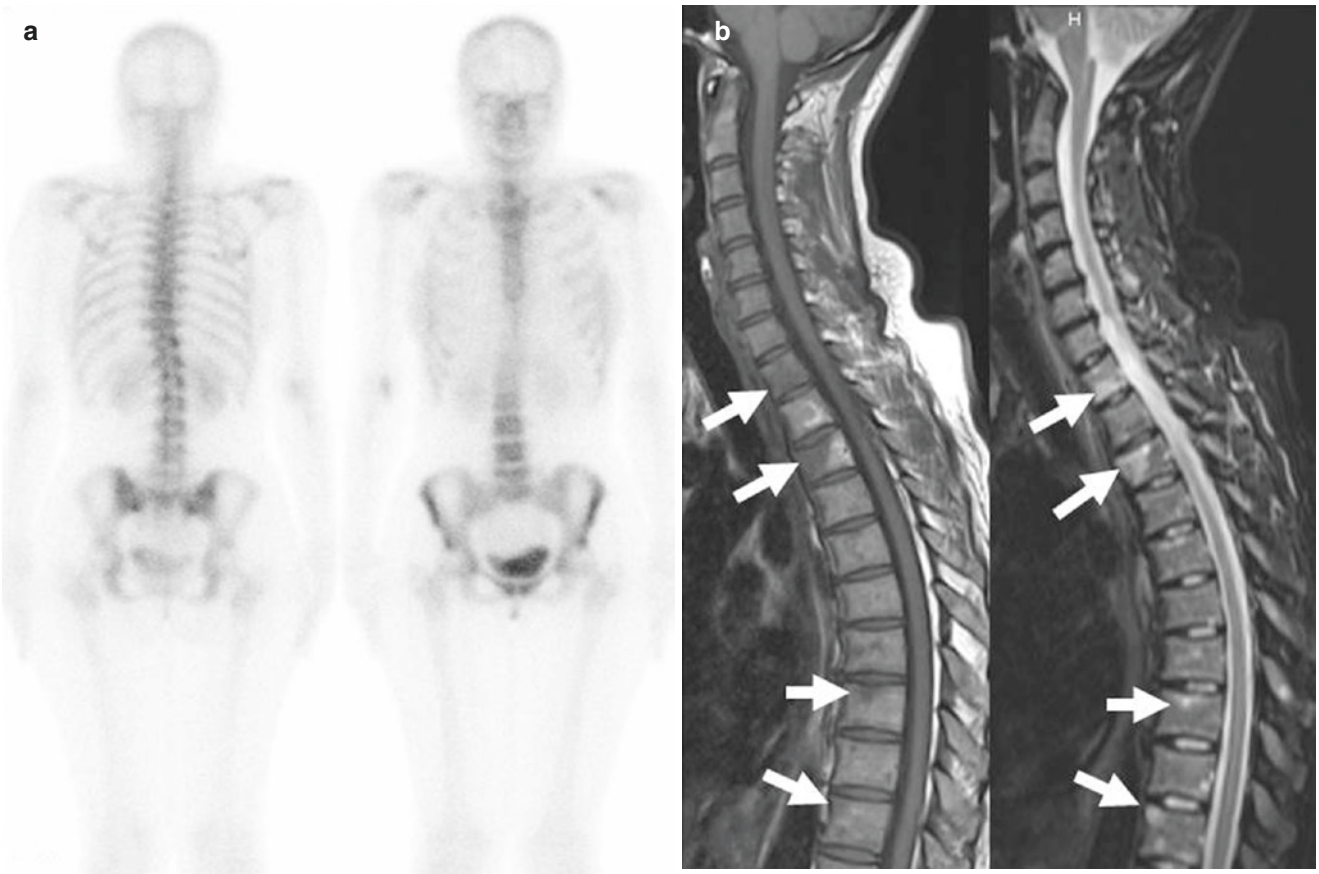

Fig. 20.1 Pure lytic bone metastases may not be apparent on bone scans. In this 43-year-old woman with nodal and liver metastases from breast cancer, 99mTc-MDP results were negative (**a**). In T1- and T2-weighted MRI of the spine performed 5 days later, multiple bone deposits can be seen (**b**—*arrows*). The large metastases in the thoracic spine show distinctive lytic features on MRI (*arrows*)

Anderson Cancer Centre criteria [24] have defined other CT features for defining response to treatment, which are based on the changes in bone structure and density within lesions. According to these criteria, an osteosclerotic reaction of a lytic/infiltrative lesion can be used as an indicator of response, as it can represent a healing process which again needs osteoblastic action (Fig. 20.2). Using the MDA criteria, the development of new osteosclerotic lesion(s) should not be classified as progression unless there is other evidence of disease progression. Unfortunately, these criteria have a significant limitation, as they are not applicable in breast cancer patients who receive anti-osteoclastic therapy (bisphosphonates), which are standard of care medicating in the metastatic setting.

20.4.3 Positron Emission Tomography (PET)

Positron emission tomography (PET) is an established technique for the diagnosis of distant metastases in breast cancer. It has potential advantages over anatomical imaging in that it demonstrates changes in metabolic activity that may occur prior to the changes in morphology depicted in CT. PET offers several different radiotracers for bone (^{18}F-NaF) and bone marrow imaging (^{18}F-FDG is the most commonly used marrow agent in breast cancer). ^{18}F-FDG PET has a strong role in evaluating metastatic disease that has accelerated glucose metabolism [25]. Unfortunately, in up to 42% of all oncological patients have FDG non-avid disease that is not appropriate for evaluation with ^{18}F-FDG PET [26]. In the setting of breast cancer, lobular cancer is oftentimes ^{18}F-FDG PET negative. ^{18}F-FDG PET data acquisition is usually coupled with CT for attenuation correction and anatomical correlation. The overall sensitivity and specificity for skeletal metastases detection of ^{18}F-FDG PET/CT are superior to those of CT and BS [27]. The role of PET/CT for monitoring bone response to therapy has been reported in a few, promising but small-scale studies [28]. Amongst the recognized limitations include the *flare* phenomenon; bone marrow "flare" reactions have been described for FDG PET/CT when bone marrow growth factors such as granulocyte colony-stimulating factor (G-CSF) are administered. In specific cases, the observation of a flare reaction could indicate therapy success, such as after the start of tamoxifen/fulvestrant therapy (usually after 7–10 days) in oestrogen receptor-positive breast cancers [29, 30].

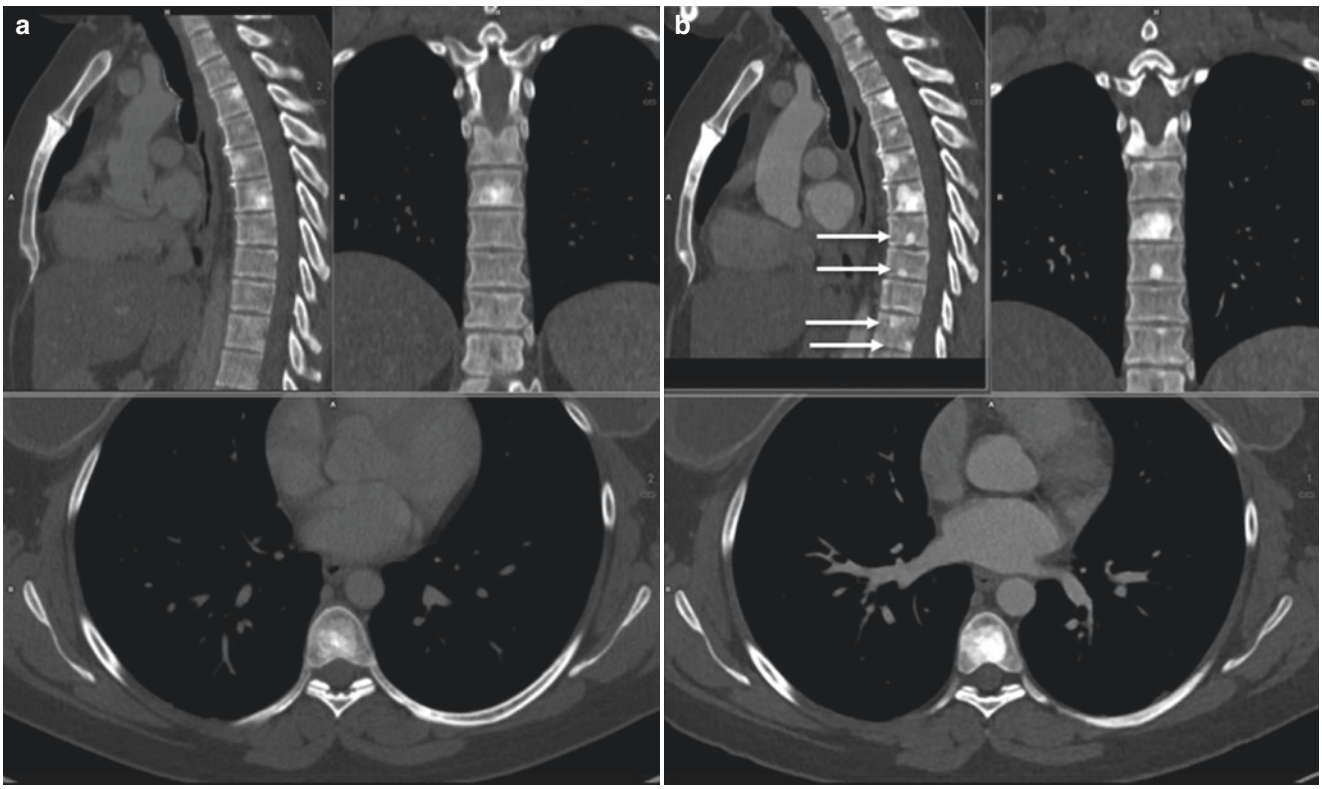

Fig. 20.2 Sclerotic response of bone metastases to therapy. A 35-year-old woman with BRCA-positive breast cancer and skeletal metastases has received prior, ineffective therapy with poly-ADP ribose polymerase (PARP) inhibitors. CT scans are acquired before and after new treatment with three cycles of carboplatin and bisphosphonates. Multiple metastases are visible in thoracic spine, some of them showing mixed sclerotic/lytic features (**a**). Dense sclerotic reaction can be seen in (**b**) in all lesions, likely indicating effective response to therapy. New, small sclerotic lesions have appeared in the second scan (*arrows*), suggesting response to therapy of smaller metastases that are not present/visible in (**a**)

20.4.4 Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging (MRI) has a growing role in the diagnosis and assessment of response of metastatic disease and in particular bony disease. The key advantage of MRI is that the bone marrow can be directly evaluated using a variety of sequences each sensitive to different aspects of bone and bone marrow, such as the marrow cellular density (diffusion-weighted imaging (DWI) MRI), vascularity (dynamic contrast-enhanced (DCE) MRI) (diffusion-weighted imaging (DWI)), trabecular bone density (ultrashort echo time MRI and susceptibility-weighted MRI) and bone marrow fat:water ratio (Dixon MRI, MR spectroscopy). Another advantage of MRI is the ability to perform multiregion examinations including whole-body studies. Furthermore, techniques can be combined thus enabling morphologic and functional (sometimes quantitative) assessments of tumour response, which can be repeated as required, as there is no radiation exposure penalty. Advantages of MRI include the fact that no ionizing radiation is administered, no injection of isotopes is necessary and whole-body examinations are possible.

Several meta-analyses show that the performance of MRI is comparable to ^{18}F-FDG PET, both being significantly more accurate than bone scintigraphy and CT for detecting bone metastases in many types of cancers, on a per patient and per lesion basis [27, 31, 32]. MRI also performs well for monitoring therapy response of metastatic breast cancer patients using bone-specific response criteria [33]. Progression criteria include increase in number/size of focal/diffuse areas of metastatic infiltration within normal marrow, evolution of focal lesions to a diffuse neoplastic pattern and the appearance of or increases in soft tissue components associated with bone disease. The appearance of new fractures (needing radiotherapy/surgical interventions) should be considered as progression only if the bone marrow MRI signal intensity in the affected area is indicative of malignancy.

Amongst the findings considered indicative of bone lesion response are the emergence of intra-/peritumoural fat within/around lesions (*fat dot* and *fat halo* signs), decreases in contrast enhancement and the development of dense lesion sclerosis on T2-weighted fat-suppressed MR images.

There is however limited evidence for the use of morphologic MRI criteria for the assessment of bone response to treatment. Instead, a few small studies have identified problems with the use of morphologic descriptors of response, including arrested resolution of abnormalities despite effective therapy (presumed to be due to bone sclerosis, due to marrow fibrosis or due to necrosis). Other limitations of morphologic imaging include the problem of evaluating disease activity against an already scarred background and the so-called "T1W image pseudoprogression" phenomenon that occurs due to intense bone oedema secondary to massive cell death and inflammation, which can lead to darkening of the bone marrow on T1-weighted sequences, mimicking metastatic spread through the affected segments. Ollivier and colleagues have described these technical bone marrow changes in some detail [34], but the clinical data for the use of morphological MRI in the routine assessment of metastatic bony disease response are still lacking.

20.4.4.1 Diffusion Whole-Body (DWB) MRI

Diffusion whole-body (DWB) MRI is emerging as a promising bone marrow assessment tool for detection and therapy monitoring of bone metastases [35–37]. DWB MRI continues to make use of anatomic T1 and T2 sequences for morphologic evaluation, but combines them with diffusion-weighted sequences, for the functional representation of cellular density within tissues (Fig. 20.3). Diffusion-weighted imaging evaluates the microscopic motions of tissue water and allows the calculation of water diffusivity (apparent diffusion coefficient (ADC)) that reflects the degree of freedom of water movement. Water diffusivity is determined by architectural tissue properties such as cellular density, cellular arrangements, vascularity, size of the extracellular space, tissue viscosity and nuclear:cytoplasmic ratio. Increased tumour cell proliferation tends to increase cell density while decreasing the volume of the extracellular space, resulting in reductions of ADC values [38]. Importantly, due to technological advances, DWB MRI can be performed in clinically acceptable examination times (20–30 min depending on scanner capabilities); actual scan times are longer when combined with morphologic sequences (generally 40–50 min) [35–37].

20.4.4.2 Detection of Metastases

DWB MRI is attractive for metastatic lesion detection because diffusion-weighted imaging permits at a glance assessments of the entire body, immediately drawing attention to potential abnormal skeletal and body regions and thus helping to reduce image interpretation times of anatomic MRI [36]. On diffusion-weighted imaging, lytic/infiltrative skeletal metastases appear as focal or diffuse areas of high-signal intensity on high b-values (such as b900 s/mm^2, i.e. strongly weighted diffusion images) on a background of lower signal intensity of the normal bone marrow. It is important to emphasize that metastasis detection on diffusion-weighted images should not be done in isolation but rather has to be considered as a potent adjunct to the anatomical MRI assessments, the combination of which form a complete DWB MRI assessment [39]. This assertion has been highlighted in a recent meta-analysis demonstrating that DWI alone is a sensitive but rather unspecific tool for the detection of bone metastases [40]. Thus, the pooled sensitivity/specificity of DWI alone has been reported as 87.7% (95% confidence interval [CI]: 76.3–94.9%) and 86.1% (95% CI: 79.2–91.4%), compared to 90.9% (95% CI: 84.3–95.4%) and 96.1% (95% CI: 92.2–98.4%) for whole-body MRI without DWI [40].

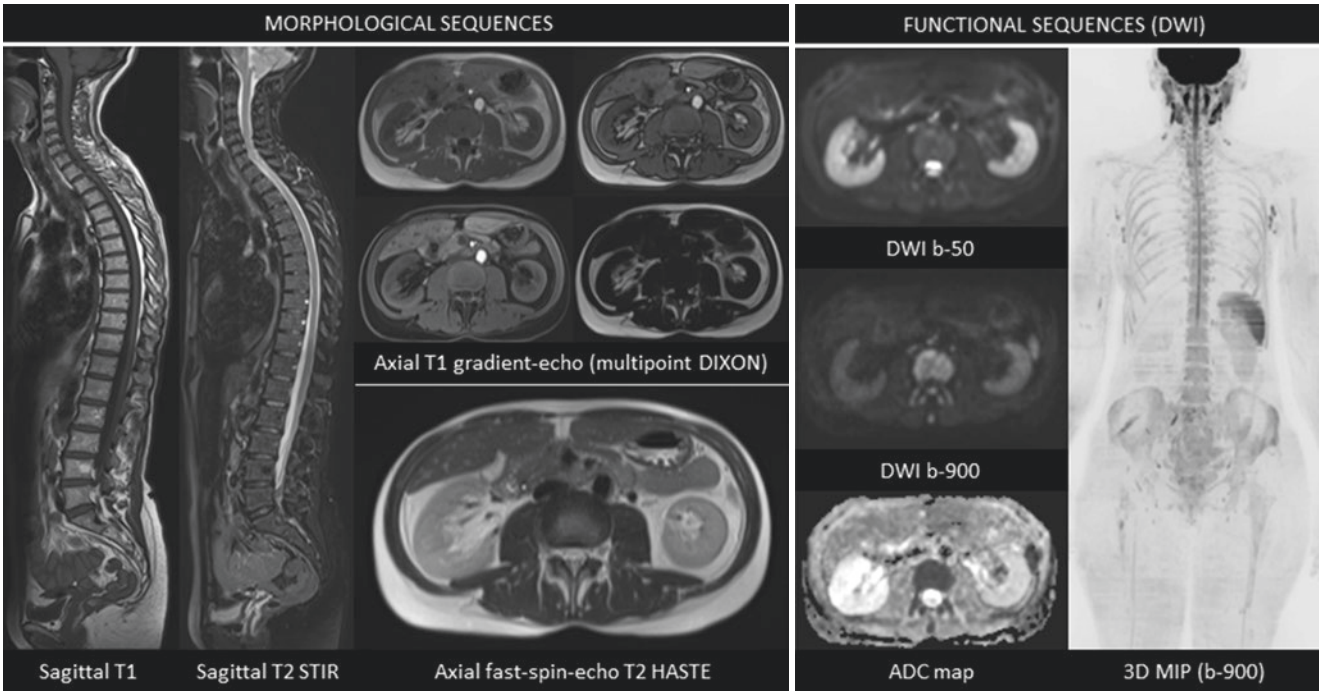

Fig. 20.3 Diffusion whole-body MRI consisting of sagittal T1-weighted and T2-weighted sequences on the whole spine, axial T1-weighted (multipoint DIXON), T2-weighted and diffusion-weighted images from head to mid-thigh, performed on a 1.5 T scanner (Magnetom Avanto, Siemens Healthcare Sector, Erlangen, Germany). Anatomy-specific phased-array surface coils are used for all body regions. The images are processed on a dedicated workstation (Leonardo, Siemens Healthcare Sector, Erlangen, Germany) to produce a unified axial series covering from head to mid-thigh and greyscale apparent diffusion coefficient (ADC) maps. Maximum intensity projections (MIPs) around the crania-caudal axis are generated from axial b900 s/mm^2 series and displayed in an inverted greyscale

Possible causes of increased skeletal signal intensity on high b-value images that lead to false-positive findings include bone marrow oedema caused by trauma [41], degenerative joint disease, bone infarction, infection and haemangiomas, isolated red bone marrow islands within yellow marrow and patchy bone marrow hyperplasia due to bone marrow growth factors. It should be noted, however, that a reader's experience, consideration of ADC values corresponding to hyperintensities on high b-value images and reference to the morphologic T1- and T2-weighted MR images can help reduce false-positive findings. Possible sources of false-negative findings include metastatic lesions in the anterior ribs and within the sternum that are sometimes relatively less conspicuous than lesions found in the spine and paraspinal regions; at these sites, respiratory motion contributes to signal losses on high b-value images. Other causes of false-negative results in bone marrow tumour detection include low levels of tumour infiltration (myeloma or densely sclerotic metastases), location of metastases in the skull vault and skull base (due to the adjacent high signal intensity of the brain) and the development of metastases within hypercellular bone marrow. As a general rule, lytic bony metastases are better seen than pure sclerotic metastases because of the lower water and cellular content of sclerotic and treated lesions [42, 43].

A recent review showed that DWB MRI has overall equal performance to FDG-PET for detecting primary tumours and soft tissue metastases [44]. In addition, it has been established that the diagnostic performance of DWI in combination with conventional non-contrast T1- and T2-weighted imaging in detecting liver metastases (the second most common site of metastases) is high, comparable with contrast-enhanced MRI [45]. DWI has also shown good performance for lymph node assessment, as well as for detecting peritoneal/GI involvement, which are other common sites of metastases for breast cancer patients [46]. Thus, DWB MRI is indicated in all breast cancer patients, who need accurate staging of the entire body, including those at high risk of metastases at presentation (inoperable locally advanced breast cancer (T3/T4) patients and those with inflammatory cancer) or with early locoregional relapse. Another emerging application is the use of DWB MRI in pregnant women with breast cancer [47]. Due to their lowered immunity, diagnosis of advanced stage disease is 2.5 times more likely in these patients than in the general population [48], demanding for an accurate bone and liver staging. It is obvious that the absence of contrast agent and radiation exposure makes a DWB MRI the technique of choice in such patients. Finally, DWB MRI is increasingly used in breast cancer women below 35 years of age, to replace bone scan and abdominal-

pelvic CT scan, to avoid radiation exposure. It is well known that the estimated lifetime attributable risk of death from cancer dramatically increases in patients undergoing CT examinations prior to 35 years of age [49]. DWB MRI is often used when equivocal findings are observed with other techniques where non-FDG avid metastases may be present. Moreover, the other most common sites of metastases (after bone) in lobular breast cancer patients are GI organs, peritoneum and pleura; these sites that are difficult to evaluate with PET/CT, CT or ultrasound. Due to the high tissue contrast between hyper-cellular metastases and the suppressed background tissue, DWB MRI may facilitate detection of metastases in these sites (Fig. 20.4).

20.4.4.3 Monitoring Therapy Response

In the context of therapy monitoring, the attractions of DWB MRI are largely those mentioned above in regard to the absence of radiation and contrast agent with the added consideration that in the course of serial imaging, multiple episodes of radiation exposure are avoided. The absence of contrast agent administration in the majority of applications makes DWB MRI extremely useful in patients with impaired renal function, as well as helping to prevent gadolinium accumulation in the brain [50].

Therapy assessments with DWB MRI are largely made by observing changes in the volume and symmetry of signal-intensity abnormalities on high b-value images, together with changes in ADC values. Nonetheless, correlating the diffusion-weighted imaging findings with morphological appearances on conventional MR images (T1W, fat-saturated T2W/STIR and Dixon) remains important. The lower spatial resolution of diffusion-weighted images is not a real issue in daily practice, as accurate measurements of soft tissue lesions can be easily performed in corresponding axial T1- and T2-weighted images using RECIST or WHO criteria [23, 24]. Although monitoring of bone and soft tissue metas-

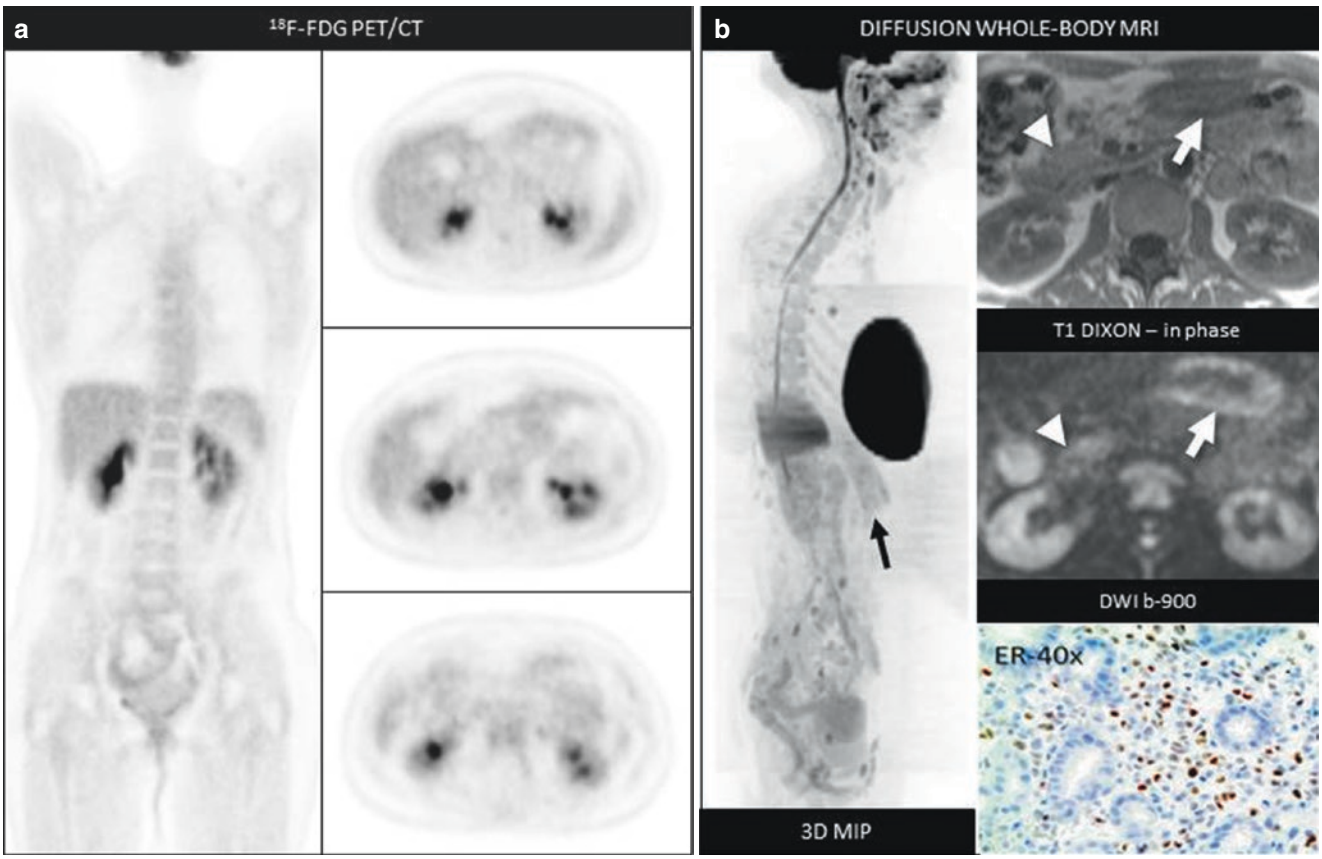

Fig. 20.4 Low sensitivity of 18F-FDG PET/CT for metastases from lobular breast cancer. A 44-year-old woman with operated lobular breast cancer is re-staged with 18F-FDG PET/CT due to suspicion of recurrence after progressive rise in CA 15.3. The FDG/PET examination was negative. After further rises in tumour markers, a second PET/CT (**a**) is performed 8 months later, confirming the absence of detectable disease. DWB MRI is performed at the same time point (**b**), with findings suspicious for the presence of abdominal metastases. Suspicious solid tissue on the right anterior renal fascia is visible both on the anatomical and diffusion-weighted sequences (*arrowheads*). In addition to this, in the DWI sequences abnormally high signal can be seen in the gastric walls (*arrows*): an anatomical site where signal is usually suppressed in b900 images. A second DWB MRI performed two months later confirms these findings. The patient undergoes gastroscopy and multiple punch biopsies of the gastric wall are taken, with positive results for the presence of infiltrating breast cancer (Image of the gastric infiltration for courtesy of Dr. G. Renne, IEO, Milan)

tases is generally based upon similar principles, the evaluation of changes in the bone is unique to DWB MRI, which involves a more detailed and specific process of image interpretation and analysis.

For the monitoring of bone metastases, the lesion-by-lesion signal intensity and ADC value changes can be interpreted using the guidance in Fig. 20.5 with several distinct patterns being recognized in the therapy assessment setting [51].

When bone metastases are treated successfully, the death of tumour cells results in cellular membrane destruction and liberation of intracellular water, which results in increases in water diffusivity, manifested as higher ADC values [52, 53] (generally above the threshold of 1400–1500 μm²/s). ADC increases may be greater for therapies that result in tumour cell death via necrosis rather than via apoptosis because of the associated inflammatory response [54], but this has not been definitively shown. As we have already noted, a prominent response mechanism is the development of dense osteoblastic lesions (osteoblastic scar), the sclerotic response category in Fig. 20.2. Regardless of the mechanism of tumour cell death, in the majority of lesions responding to therapy, high b-value images tend to show signal decreases (Fig. 20.6). Occasionally, however, a successful response to therapy with marked rise in ADC values may yield little change in high b-value signal intensity changes due to T2 shine-through (Fig. 20.7).

When bone metastases are not treated successfully, an increase in the volume of previously documented abnormal signal intensity on high b-value images is observed with new areas of abnormal signal intensity. Increases in the intensity of abnormalities on high b-value diffusion-weighted images can also indicate disease progression (Fig. 20.8).

Importantly, bony metastases that progress can have variable changes in ADC values, with modest increases, unchanged or slight decreases in ADC values compared to pre-therapy values that can occur [52, 55]. Reductions in

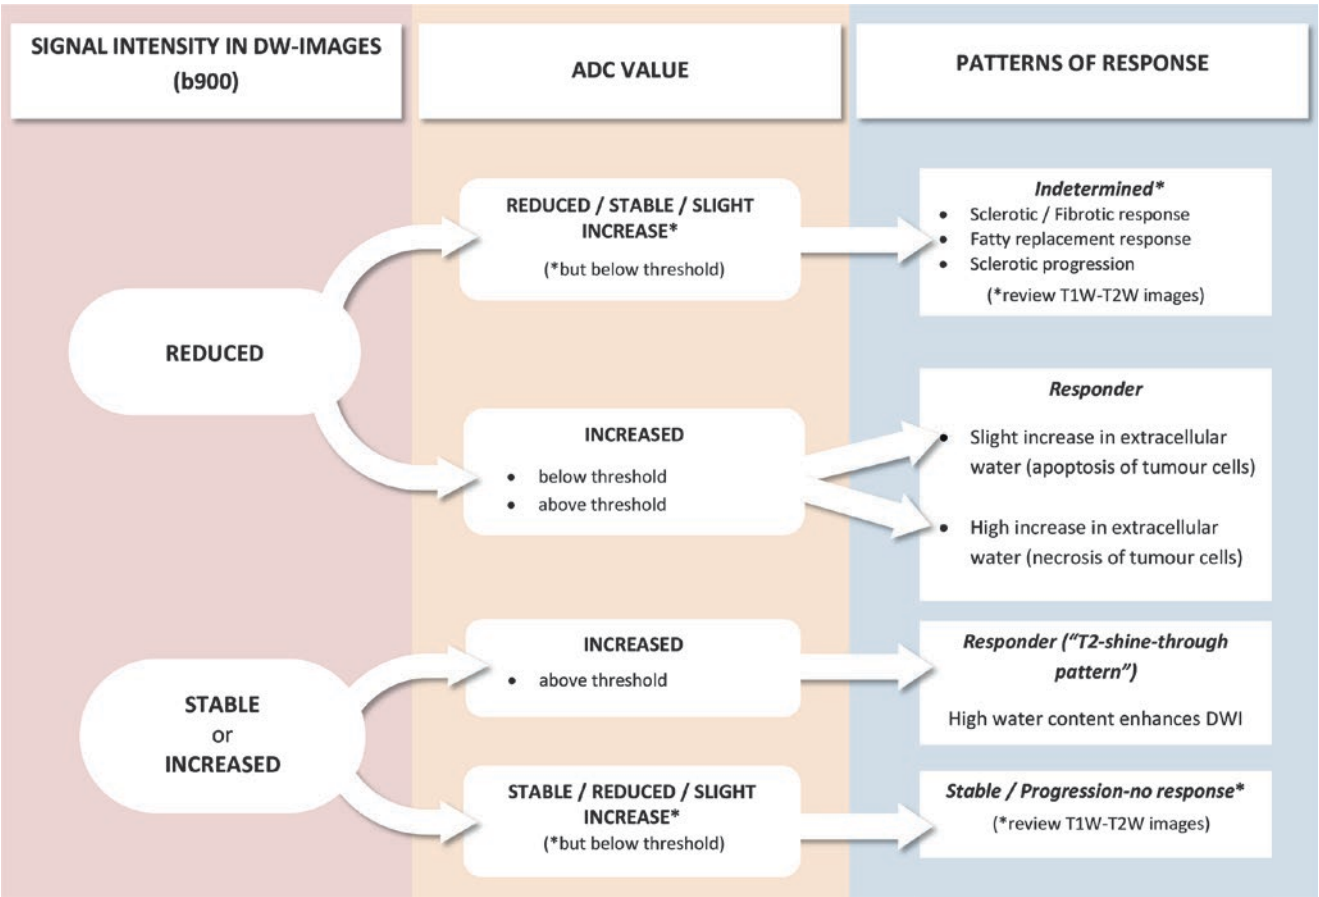

Fig. 20.5 Proposed scheme for assessing therapy response of bone metastases using diffusion-weighted MRI scans, ADC measurements and morphologic images [adapted from *Therapy Monitoring of Skeletal Metastases with Whole-Body Diffusion MRI*; Padhani AR et al. J Magn Reson Imaging 2014]

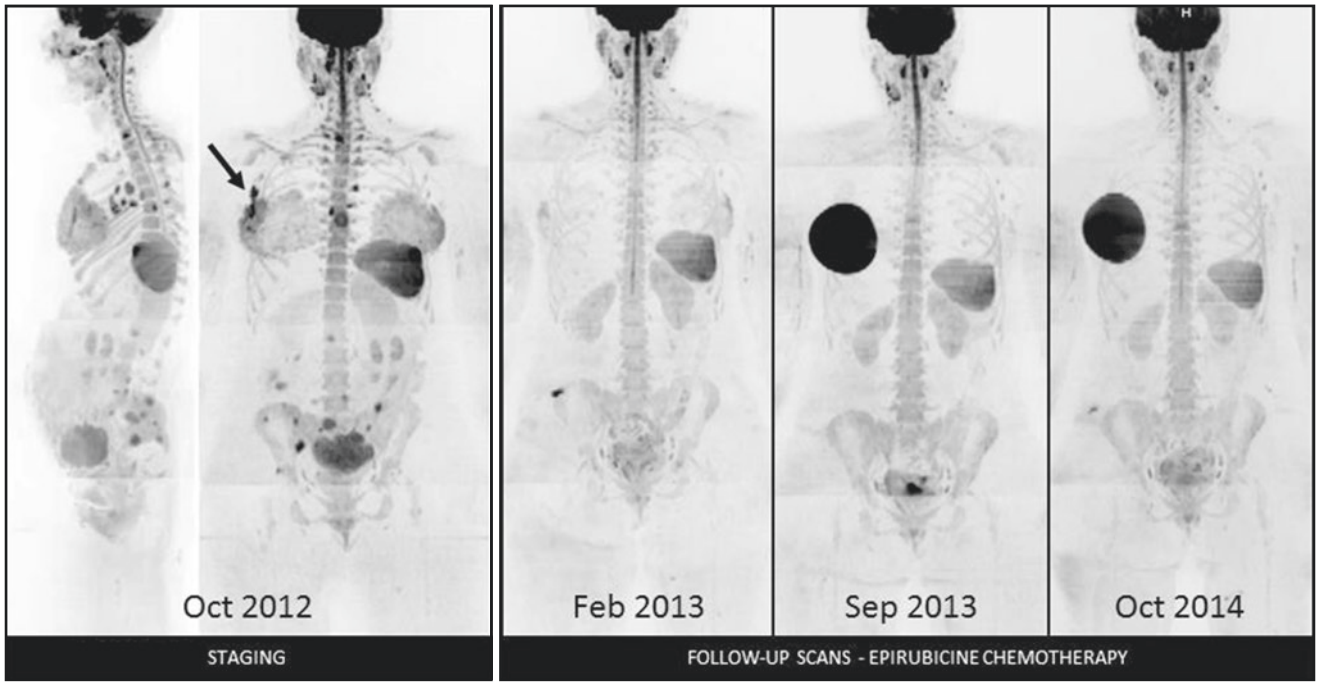

Fig. 20.6 Disease staging and follow-up in a 31-week-pregnant woman with newly diagnosed breast cancer. A pregnant 37-year-old woman is diagnosed with infiltrating breast cancer after fine-needle biopsy of a right breast solid lesion. DWB MRI at staging purpose (October 2012) revealed bone metastases in the dorsal and lumbar spine, in the pelvis and in the sternum. All of the lesions are visible in the rotational b900 MIP reconstruction. The brain, spinal cord and the kidneys of the foetus and mother are well visualized. The right primary tumour and right axillary lymph node enlargement can be seen (*arrow*). Chemotherapy was started after caesarean section. Follow-up scan on February 2013 after three cycles of chemotherapy shows complete response of the bone lesions, with loss of signal on b900 DWI images. All following DWB MRI follow-up scans confirmed a sustained, complete response to chemotherapy

ADC values are probably related to increasing cellularity within a fixed bone marrow space or due to bone sclerosis. Stable ADC values could occur with unchanged tumour cellularity accompanying increases in the geographic extent of disease. The causes for modest increases in ADC values with disease progression are related to increasing tumour infiltration, which displaces fat cells, increases bone marrow water (including water in the extracellular space) and increases tissue perfusion, thus returning higher ADC values compared to yellow or mixed bone marrow [42, 56–60]. ADC values in excess of 1400–1500 $\mu m^2/s$ are rarely seen with disease progression unless there is de novo tumour necrosis.

Further developments of DWB MRI include the quantitative tumour volume assessments that can be undertaken by segmenting high signal intensity regions on high b-value images. Corresponding whole-body ADC histograms can also be generated. Improved precision of response assessment can be undertaken by deriving "viable tumour volume" using threshold ADC cut-off values to exclude normal bone marrow (<600–650 $\mu m^2/s$) and non-viable necrotic tumour with ADC >1400–1500 $\mu m^2/s$ [42, 58]. The proportion of viable tumour can then be calculated and followed over time in the subsequent DWB MRI examinations.

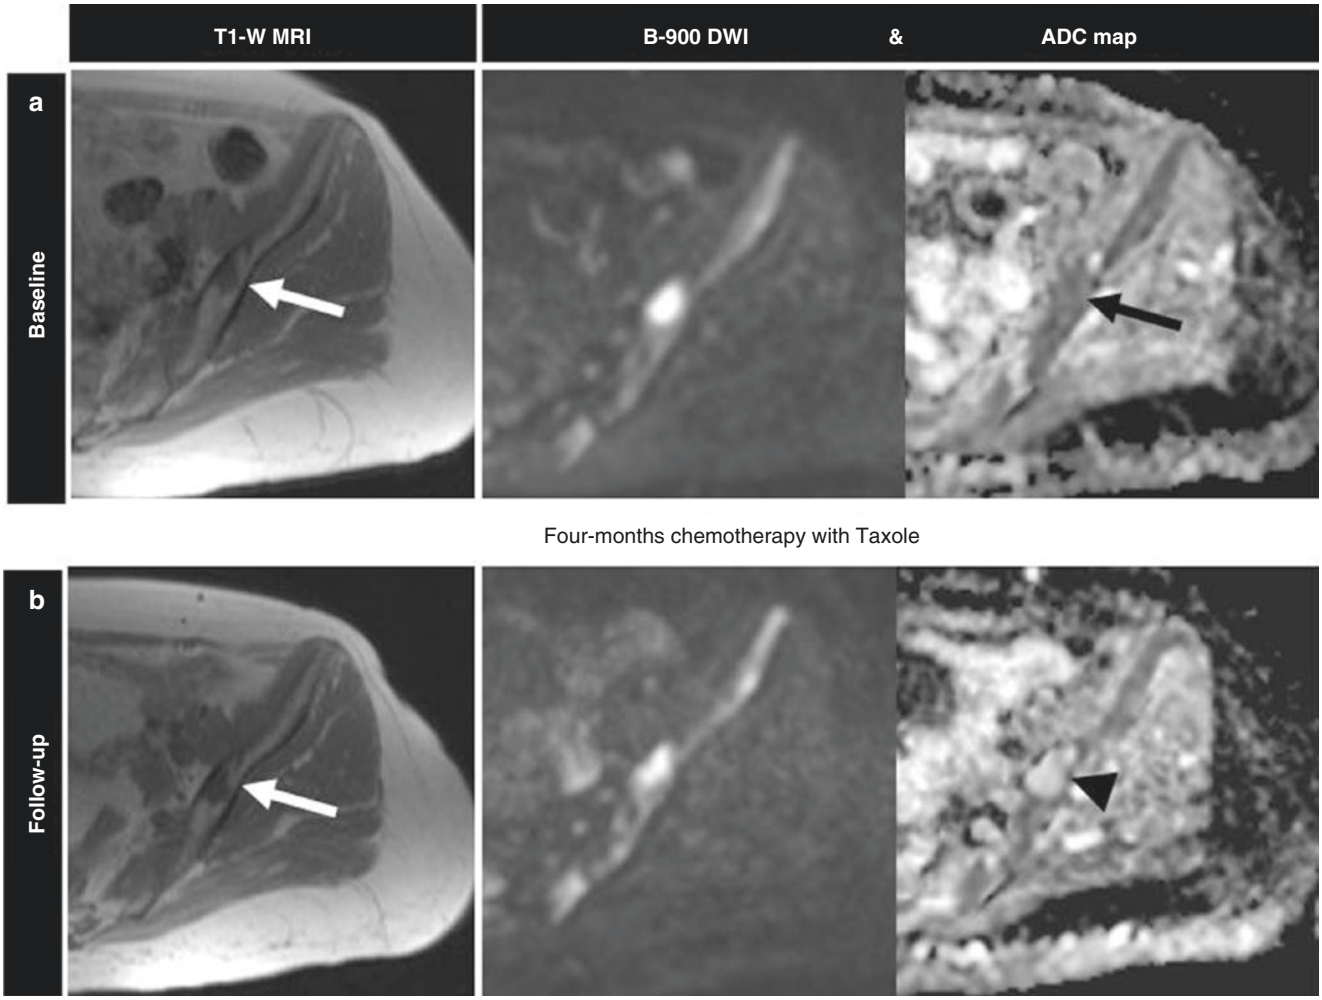

Fig. 20.7 T2 shine-through pattern indicating successful response to chemotherapy. A 51-year-old woman with bone-metastatic breast cancer undergoes DWB at baseline and after treatment with Taxol. (**a**) a metastatic lesion in the left iliac bone is shown as acquired in the baseline evaluation, on T1-weighted and b900 DWI images, as well as on the related ADC map. The lesion has a hypo-intense appearance on T1-weighted images (*white arrow* in **a**) and has a high signal on b900 images with corresponding low ADC values (*black arrow*), suggesting the presence of active disease. (**b**) A second evaluation with DWB after chemotherapy shows unchanged features of the metastasis in the T1-weighted images (*white arrow* in **b**). The lesion maintains high signal in b900 images. The ADC map of the lesion reveals a significant elevation in the mean ADC values (above 1500 $\mu m^2/s$, *black arrowhead*) indicating complete response to chemotherapy. The high signal in b900 images with accompanying high ADC values is termed "T2 shine-through"; the latter is strongly associated with cell necrosis and tumour response

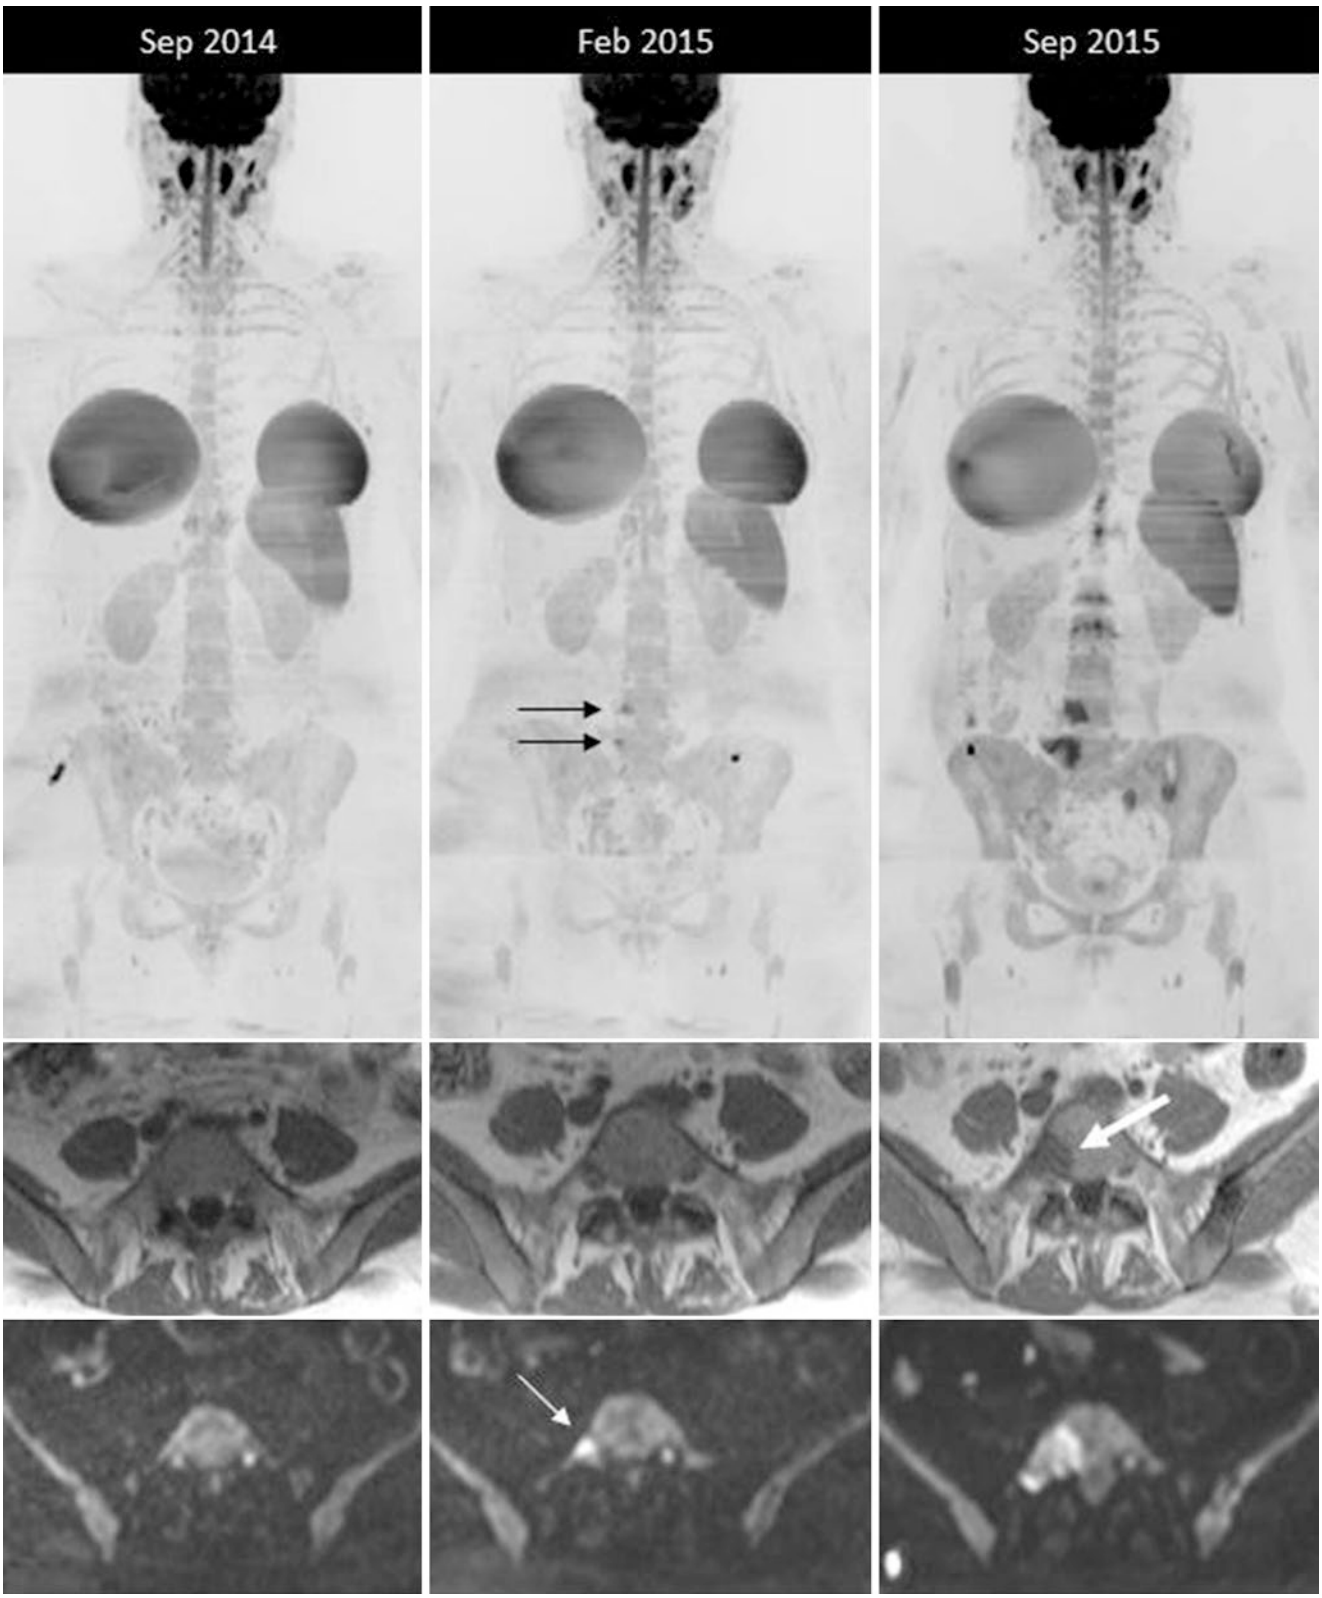

Fig. 20.8 Bone disease progression in anatomical and diffusion-weighted images. Serial changes in a 39-year-old woman with progressive metastatic breast cancer being treated with hormonal therapy and bisphosphonates. Axial anatomical (T1W) and DWI images (b900) and inverted coronal MIP images allow bone metastases to be evaluated over time. The second scan shows bone disease progression with re-activation of lesions not visible in examination 1 (*black arrows*). Increases in the number of lesions in the lumbosacral spine and pelvis are seen on examination 3. Axial images show re-activation and then growth of a bone metastasis located adjacent to the right sacroiliac joint despite therapy change in February 2015. Note the presence of a new lesion posteriorly in the left iliac bone adjacent to the left SI joint whose signal on high *b*-value images is being moderated by osteosclerosis

Conclusions

Whole-body MRI has the potential address the unmet clinical need for an accurate method to detect and monitoring response of all manifestations of metastatic breast cancer. There is a need to develop common measurements and analysis methods and to establish uniform data displays, to expand the use of quantitative analyses of DWB MRI in clinical practice. The technology is now mature enough to incorporate into clinical studies that define appropriate use of this technology.

Imaging Findings After Surgery

21

Silvia Pérez Rodrigo and Elizabeth A. Morris

21.1 Introduction

Breast cancer treatment has markedly improved in the last few decades. Radical mastectomy was initially considered the treatment of choice despite its associated morbidity. However, less aggressive surgeries such as modified radical mastectomy, simple mastectomy, skin-sparing mastectomy, and breast-conserving surgery have increasingly replaced radical mastectomy. Moreover, reconstructive surgeries such as oncoplastic surgery have entered the surgical scene, combining a safe oncological treatment approach with desirable aesthetic outcomes. Many women being treated for breast cancer have also undergone breast-enhancing procedures using exogenous material that are either heterologous or autologous. These procedures can be performed for purely aesthetic reasons or for reconstructive purposes in cases of breast cancer.

The greatest difficulty in assessing breast tissue postsurgery is to distinguish postsurgical changes from malignancy. Recurrence is possible despite the treatment of breast cancer, including in patients who have undergone mastectomy. Thus it is necessary to know the radiological techniques available to study recurrence in patients and to establish an appropriate follow-up.

Mammography can detect tumors which are then less likely to develop metastases during follow-up. However, mammography has limited sensitivity, from 55 to 68%. There are also difficulties in performing mammography correctly with adequate compression, and the radiologist does not always obtain good image quality with mammography. Mammography also presents difficulty in interpretation, for example, in differentiating spiculated scars from recurrence and differentiating edema (due to the RT) from lymphatic involvement. A clinical examination complements mammography in detecting recurrences, and a palpable lesion usually indicates worse prognosis.

Compared to clinical examination and mammography, MRI has high sensitivity, from 90 to 100%. It also has high specificity, from 83 to 93%. It is also able to reliably distinguish scar from recurrence 12 to 18 months posttreatment. Breast MRI allows both morphological and functional evaluation. Non-enhancement (absence of uptake) after intravenous contrast (IVC) suggests fibrosis rather than cancer. However, the presence of enhancement does not always indicate malignancy because there are many benign processes that can cause uptake, such as fat necrosis. Consequently, if the presence of fat inside the lesion cannot be determined with fat suppression sequences, a core biopsy is required.

Ultrasound has limited sensitivity for small or noninvasive lesions. Acoustic posterior shadowing on ultrasound presents difficulty in differentiating fibrous scar from recurrence.

21.2 Imaging Findings After Surgery Without Any Material or Reconstruction

21.2.1 Mastectomy

An estimated 10–15% of patients will develop locoregional recurrence after treatment. Nearly a third of them will present with synchronous metastases at diagnosis. The most common form of presentation (50–70%) is local recurrence (Fig. 21.1a–c), which tends to be symptomatic. The patient has a single mass or multiple masses in the bed of mastectomy (chest wall or under the scar), diffuse skin thickening, trabecular thickening, or ulceration of skin. Recurrence can manifest radiologically as masses with signs of suspicion and/or calcifications

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_21

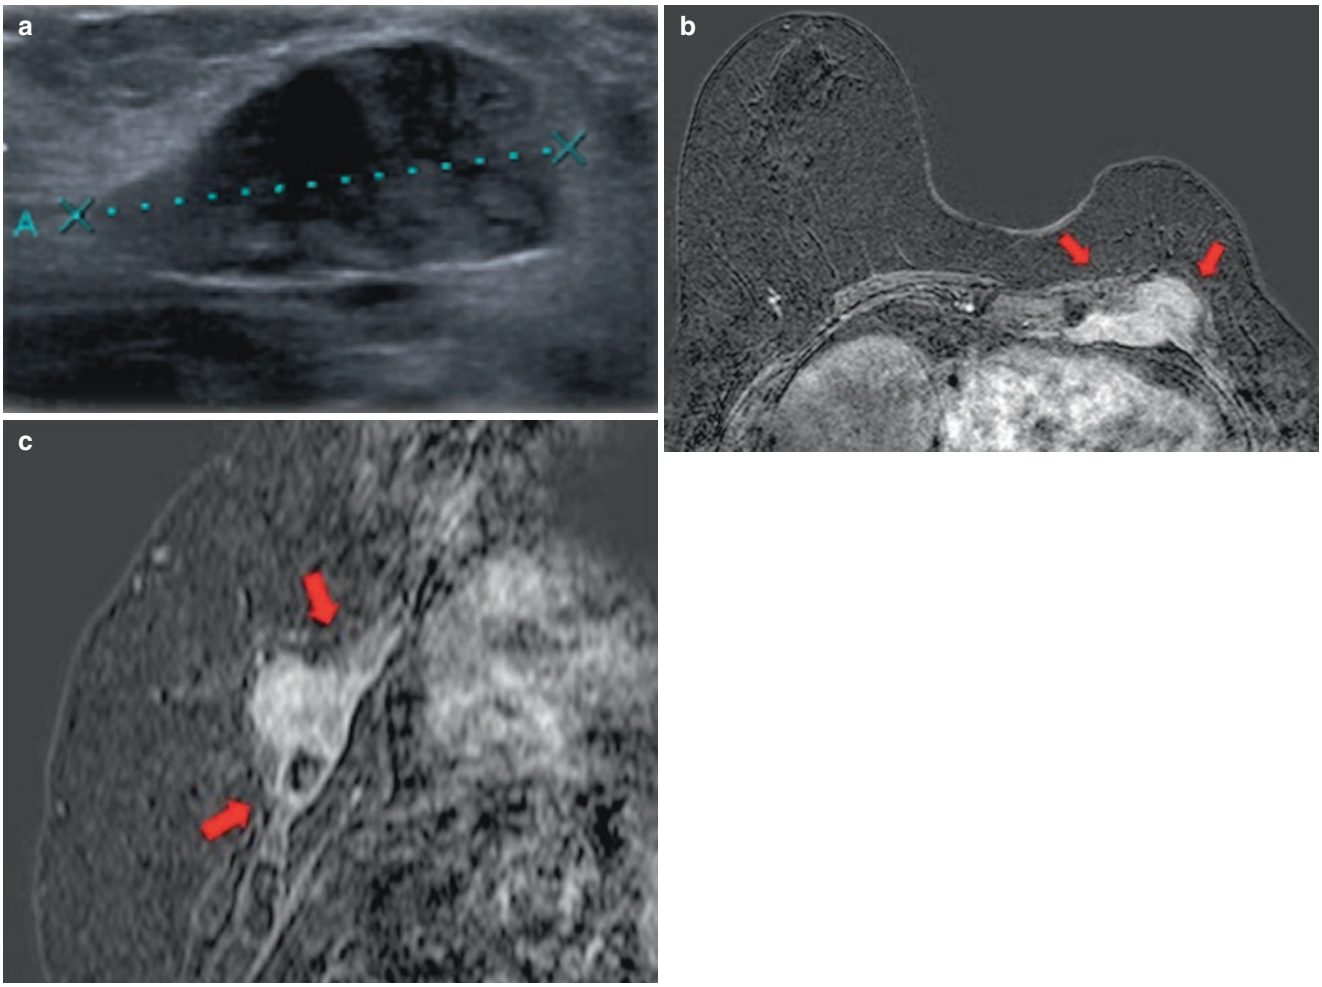

Fig. 21.1 Patient with history of left mastectomy noticed a palpable lump in the mastectomy site corresponding to recurrence. (**a**) Ultrasound: an anechoic and heterogeneous lesion, ill-defined in some margins and seeming to be in contact with the pectoral muscle, is seen. (**b**) Breast MRI (dynamic sequence, axial plan): a mass in the mastectomy site, involving the pectoral muscle, some ribs, and intercostal muscles and goes inside the thoracic cavity, is seen. (**c**) In the sagittal view, involvement is well seen in the costal and intercostal spaces

that in some cases can be difficult to distinguish from dystrophic calcifications or fat necrosis. Recurrence can also present in regional or distant lymph nodes (30–40%), which are usually asymptomatic (Fig. 21.2) and may not be palpable, at least initially. Some common locations are the supraclavicular, axillar, and internal mammary regions, where they can cause pain, brachial plexopathy, or arm lymphedema. Any new onset lymphedema after treatment should be evaluated to rule out regional recurrence.

21.2.1.1 Radiological Tests and Findings

1. *Mammography*: Mammography is not routinely performed for patients who have undergone mastectomy. However, it can be performed, and the mammogram can be examined for the presence of residual breast tissue, especially in cases of subcutaneous or incomplete mastectomy.

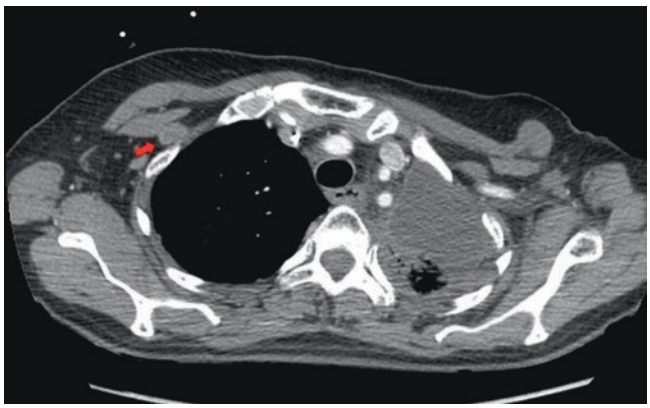

Fig. 21.2 Patient with history of left mastectomy. CT axial plane shows an enlarged and round retropectoral lymph node, suggesting recurrence. Despite retropectoral involvement, the axillary lymph nodes were negative and asymptomatic

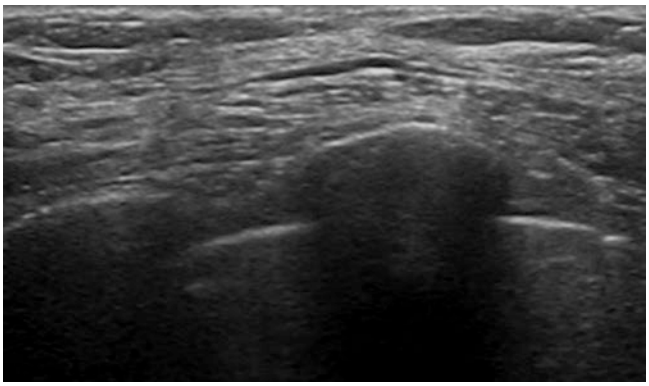

Fig. 21.3 Sonographic appearance of a mastectomy. The skin, subcutaneous tissue, and the pectoral muscle on the chest wall can be appreciated

2. *Ultrasound*: Patients who have undergone mastectomy may be examined by bed ultrasound. Ultrasound allows the physician to observe subcutaneous fat, postsurgical scarring, and fibrosis (Fig. 21.3). Nodular lesions on ultrasound suggest recurrence (Fig. 21.1a), and as patients undergoing mastectomy do not routinely undergo mammography, these should be evaluated carefully. Possible complications or benign findings such as seromas or hematomas should also be assessed.
3. *CT or MRI*: Postsurgical changes in the axillary level and the presence of residual breast tissue should be evaluated. The type of surgery and the presence or absence of the pectoral muscle should also be noted before the interpretation of findings.

21.2.1.2 Follow-Up Protocol

In the follow-up of patients, physical examination and ultrasound are usually performed. Mammography is performed only in cases where incomplete mastectomy or residual breast tissue is suspected and when technically feasible (Fig. 21.4). Breast MRI can be performed to show the absence of residual glandular tissue (Fig. 21.5). It has shown greater sensitivity and specificity than other techniques; however, it is rarely used routinely due to its availability and cost.

21.2.2 Breast-Conserving Surgery

There is a risk of recurrence in about 1–2% patients post-breast-conserving treatment per year. Early detection is crucial because it is associated with improved survival. Presentation of recurrence can manifest early or late. Early recurrence usually occurs at the site of the original tumor and represents failure in the eradication of the primary tumor (Fig. 21.6a, c, and d). Late recurrence (after 10 years of

Fig. 21.4 Patient with left mastectomy. Mammography (oblique view) was performed to rule out the presence of residual fibroglandular tissue

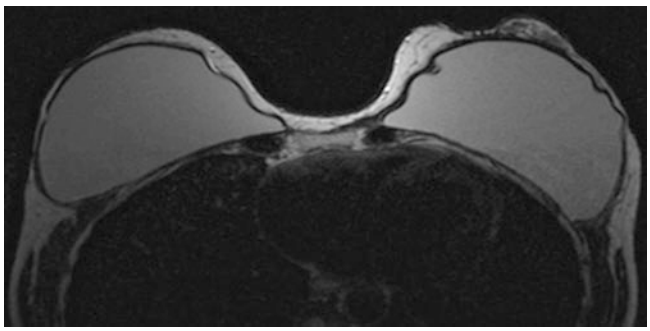

Fig. 21.5 35-year-old patient with a history of right breast cancer and positive BRCA1. Right mastectomy and prophylactic left mastectomy were performed. The patient was not a candidate for mammography. Breast MRI was performed to check whether there was residual fibroglandular tissue. T2 sequence shows the presence of residual fibroglandular tissue with slight enhancement on the left breast. A follow-up MRI was recommended

finishing the treatment) usually occurs in another quadrant or away from the treated area and usually represents new tumors.

Interpretation of imaging post-breast-conserving surgery can be complicated because postsurgical benign changes can simulate recurrence and make the follow-up overwhelming. Early recurrence usually occurs after 2 years following

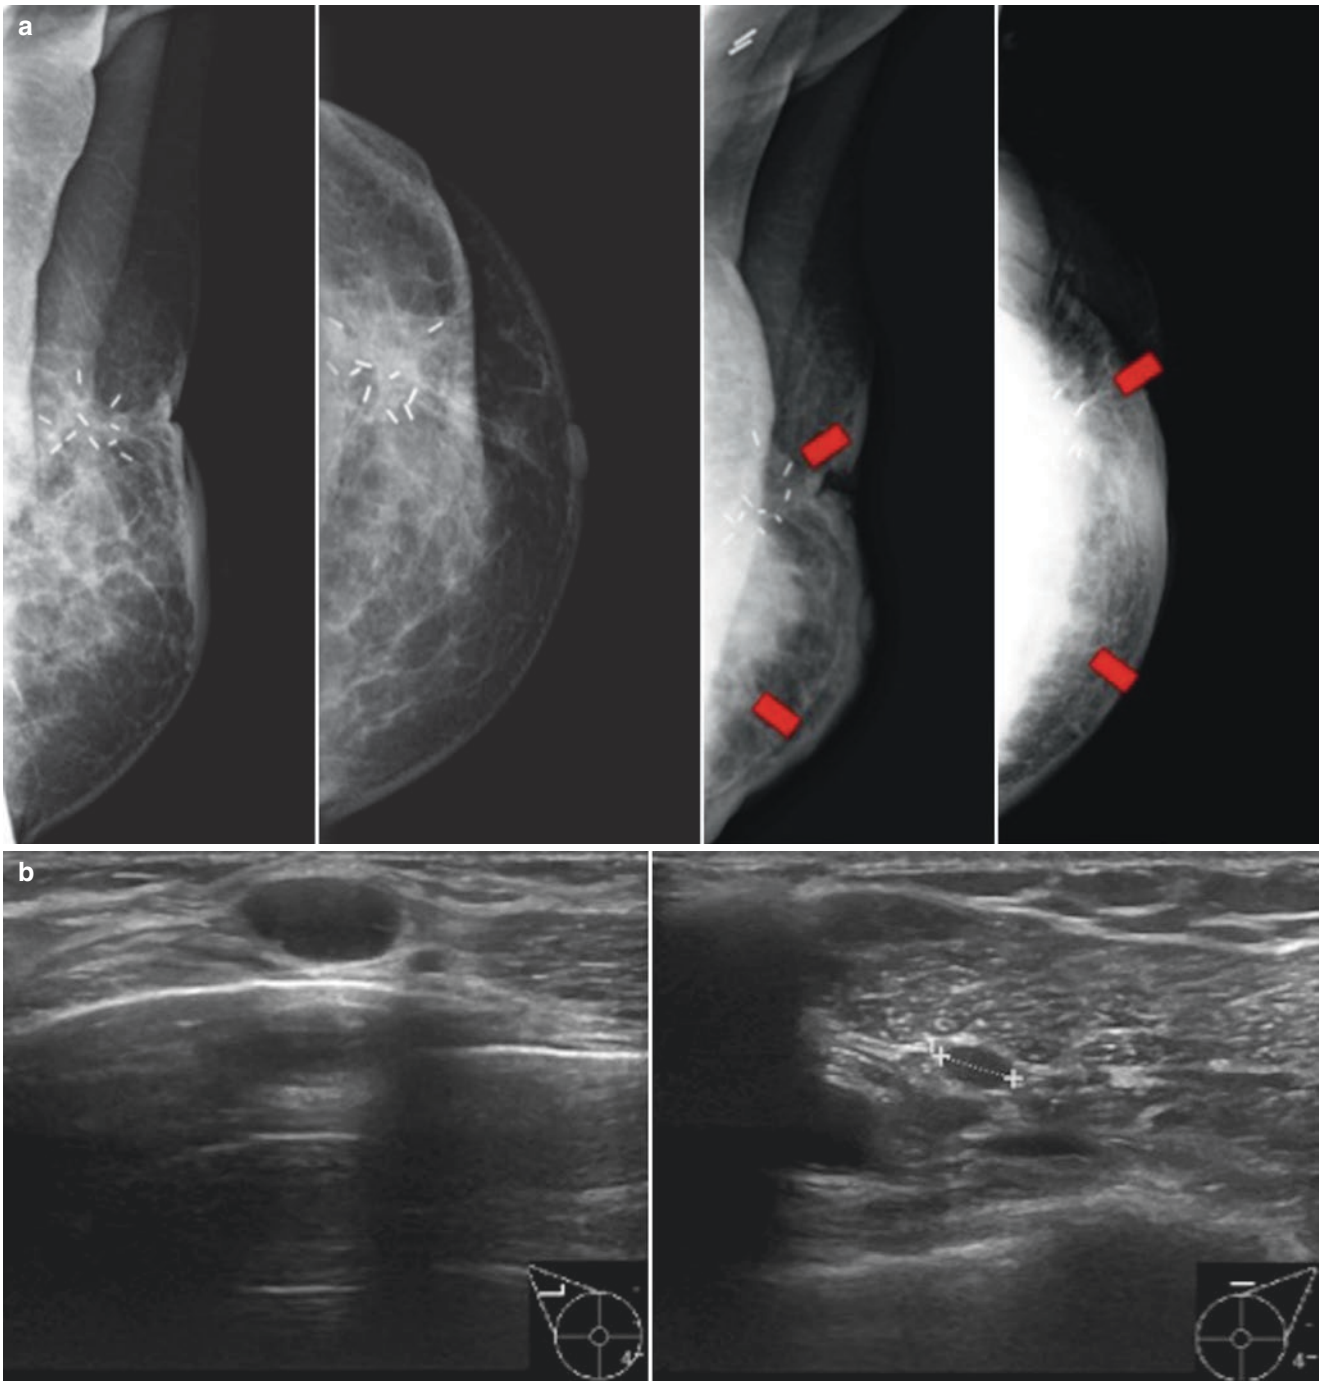

Fig. 21.6 Patient with triple negative breast carcinoma in the right UOQ and axillary involvement. The patient received neoadjuvant chemotherapy. MRI showed a complete response. Therefore, breast-conserving surgery was performed. After the surgery, the pathologist reported positive margins, and the patient received radiotherapy but was not reoperated. (**a**) Mammography with CC and oblique views: On the left, first mammogram after surgery shows a distortion relating to post-surgical changes adjacent to the clips. On the right, second follow-up mammogram shows a diffuse increase of density involving the pectoral muscle, in comparison with the previous mammogram, suggesting recurrence (*red lines*). Skin thickening was also noted. (**b**) Ultrasound confirmed these findings where new involvement of axillary and infraclavicular lymph nodes as well as contralateral axillary lymph nodes is also seen

treatment, whereas during the first 2 years, most radiological changes are due to benign changes. To distinguish recurrence-related and benign changes, radiologists need to be aware of the following expectations. Benign changes should decrease or remain stable over time. Stability is usually achieved 2–3 years after RT. After this, any postsurgical changes, density or new onset suspicious calcification, should rule out recurrence (Fig. 21.7).

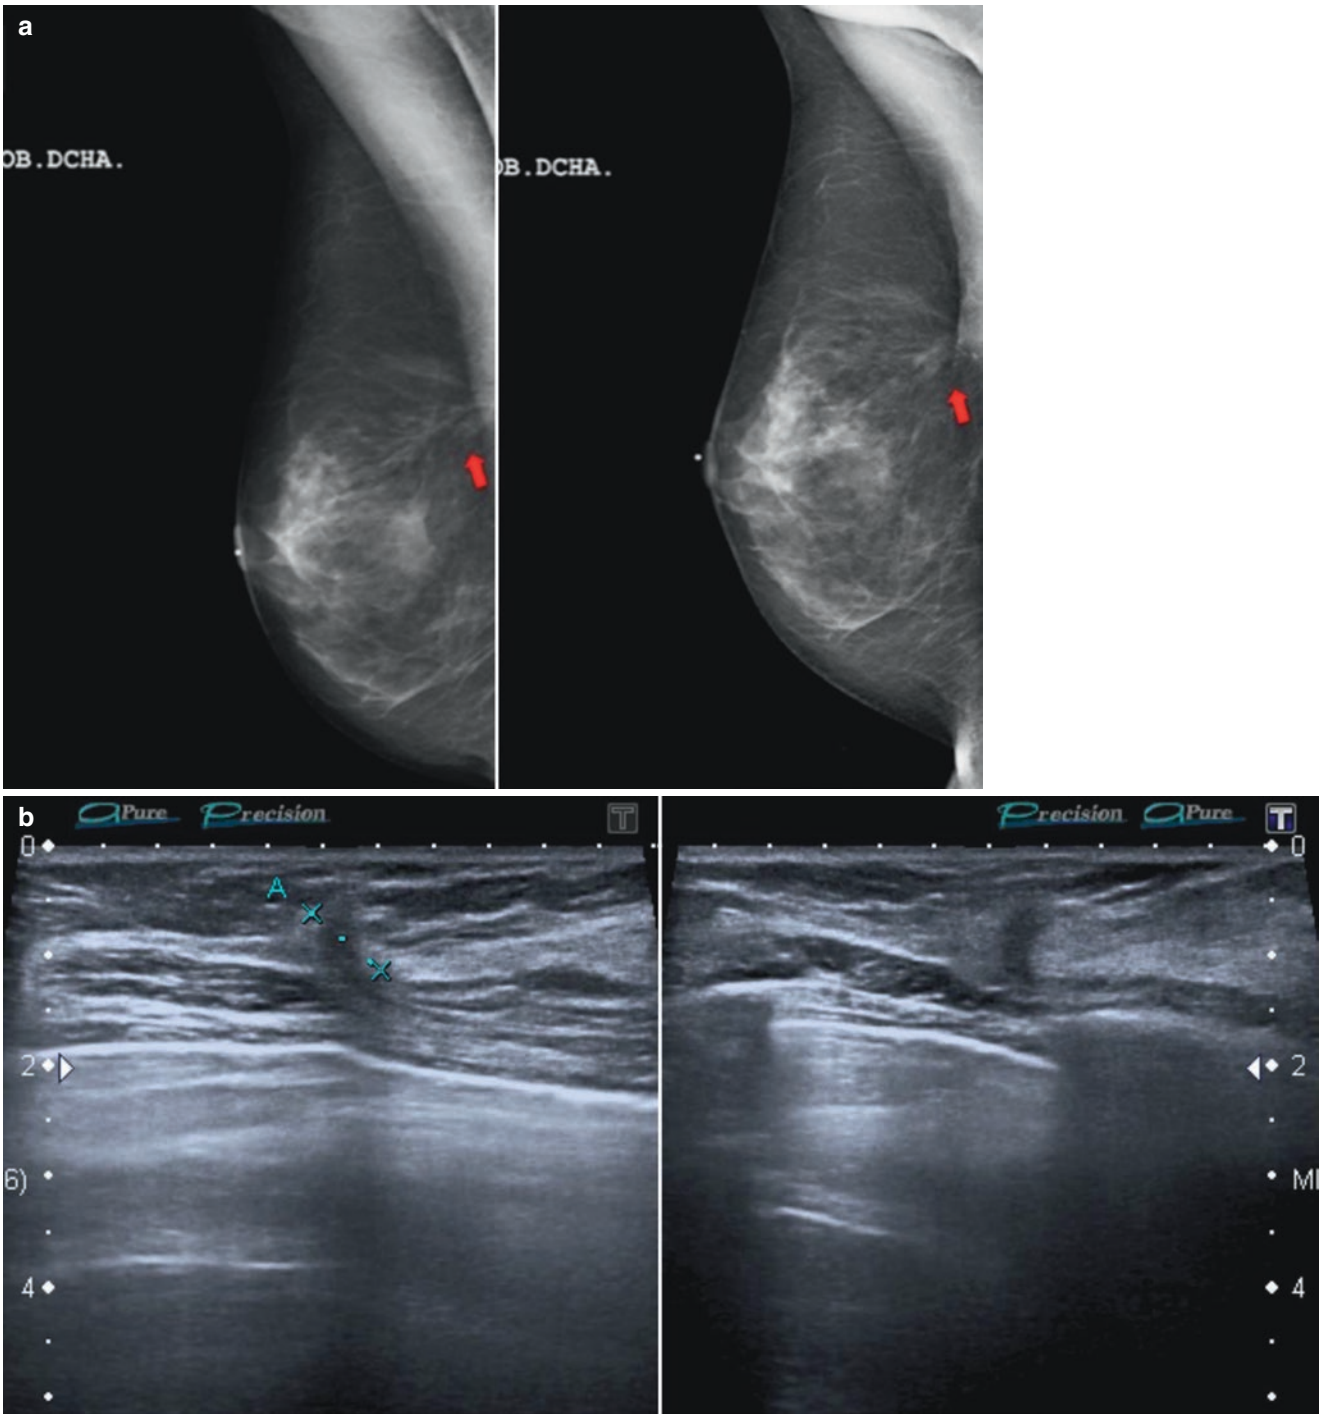

Fig. 21.7 Patient with breast-conserving treatment in the UOQ of the right breast. (**a**) Mammography oblique views: On the left, a follow-up mammogram a few years after surgery demonstrates subtle and stable distortion in the postsurgical area (*red arrow*). On the right, another mammogram a year after shows the distortion presenting a slight increase in density. An ultrasound was recommended. (**b**) A hypoechoic, ill-defined and irregular lesion can be seen with an antiparallel orientation suggesting malignancy that was confirmed with a core needle biopsy

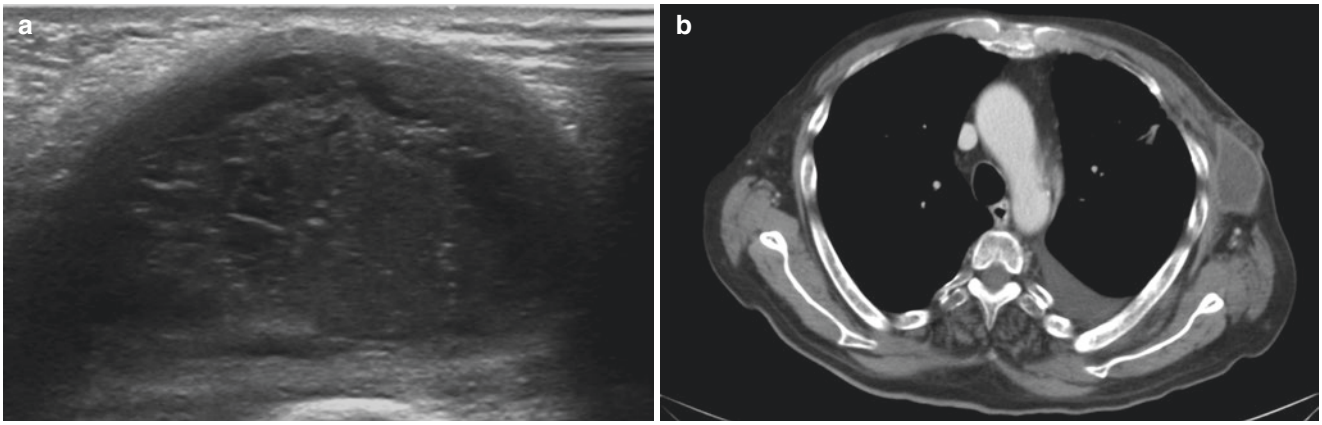

Fig. 21.8 Patient with a personal history of left mastectomy and axillary dissection. The patient showed a palpable lump in the axillary region corresponding to an evolved seroma/hematoma without changes in follow-up. In normal conditions, the seroma or hematoma is reabsorbed a few times after surgery. In this case, it did not happen although it was stable. (**a**) Ultrasound of the axillary region shows a complex lesion with internal septa and a thick wall relating to the palpable lesion. (**b**) CT shows fluid collection with different densities and thin enhancement of the wall

21.2.2.1 Radiological Tests and Findings

The following are considered benign findings after breast-conserving surgery:

Seroma/hematoma is present when there is fluid collection in the surgical area. In most cases, over time, seroma/hematoma will be reabsorbed and replaced by fibrosis and scarring. Fifty percent of the cases will last a month after surgery, 25% will last 6 months after surgery, and most of them will disappear within 12–18 months after surgery. Sometimes seroma/hematoma may persist over time (Fig. 21.8):

- *On mammogram*: Seroma/hematoma will appear as a highly dense, oval, or round mass. It can have well-defined margins or obscured margins when it lies within the distortion produced by benign postsurgical changes.
- *On ultrasound*: Seroma/hematoma will appear as an anechoic collection normally seen as a simple cystic lesion. Over time, seroma/hematoma will decrease in size and have increased echogenicity showing a complicated or complex appearance (septa, loculations, and/or thickening of the wall).
- *On CT and MRI*: Fluid collection will be seen in the surgical site. Water density and signal intensity will vary over time according to cancer stage.

Edema and skin thickening will be most highly expressed 6 months after RT and later evolve and regress in a similar way. The edema may be focal in the area of the lumpectomy (reflecting postsurgical changes) or be distributed diffusely (reflecting changes post-RT). If there is an increase of edema, the physician should perform differential diagnosis regarding tumor to lymph vessels, obstruction of venous drainage, or congestive heart failure and infection. Skin thickening is secondary to the damage produced on small vessels and can measure up to 1 cm in thickness. It is more evident when the treated breast is compared to imaging of the contralateral breast or to its appearance on the pretreatment mammogram (Fig. 21.9). On MRI these findings are well observed, especially on T1 sequence (where we can observe the skin thickening) and T2 sequence (where edema is clearly hyperintense) (Fig. 21.10).

Architectural distortion occurs as a result of changes in scarring and fat necrosis. It reaches its highest expression at 2 years. Thereafter, it will remain stable or decrease. Architectural distortion can have spiculated or irregular density as well as poorly defined margins and may be accompanied by skin retraction; these can resemble recurrence. A number of mammographic findings such as central radiolucency, appearance changes in different projections, and thick and curvaceous spiculations may suggest that the findings are more likely of postsurgical origin. Note that findings are not always reliable; for example, there are some lobular carcinomas that may also present central radiolucency. For this reason, it is essential to perform magnified and spot compressed views (Fig. 21.11) as well as a comparative study with previous mammograms (to verify the stability or progressive reduction in size and density) (Fig. 21.7), and if there is still some doubt, biopsy should be performed (Fig. 21.12).

Benign calcifications usually appear in the first 6–12 months in 28% of cases. They can usually be distinguished from pleomorphic calcifications associated with malignancy, but when there is uncertainty, additional views, tests, or biopsy are required. Benign calcifications can be dystrophic calcifications, which usually originate in areas of fat necrosis. These are irregular in shape, and they are

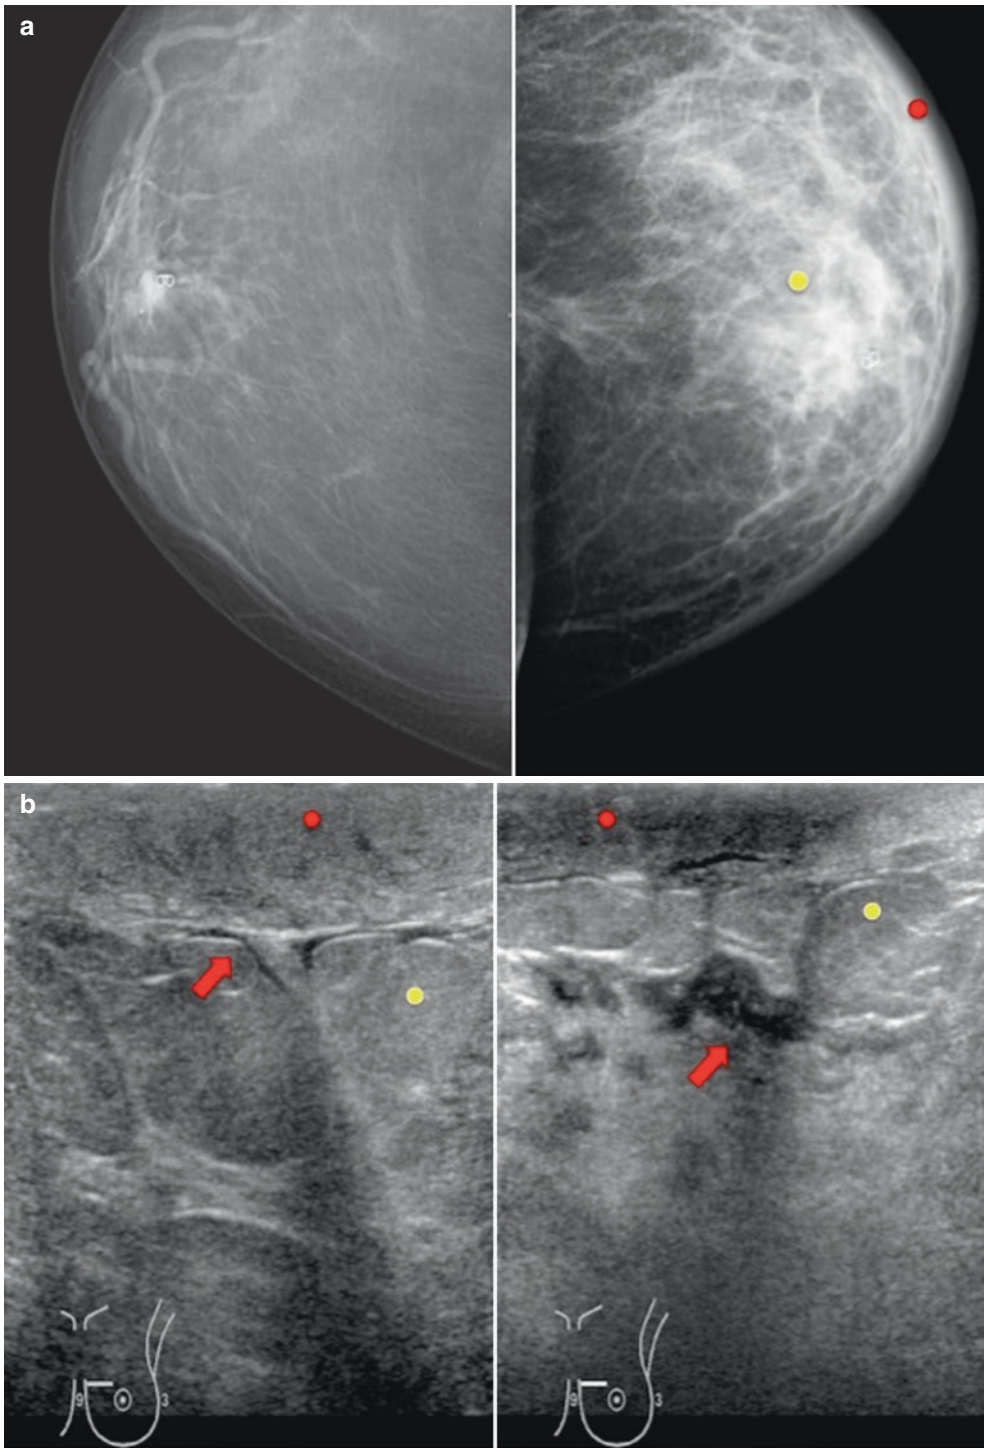

Fig. 21.9 Patient with breast-conserving treatment in the left breast with surgery in LIQ and RT. The patient presented with marked skin thickening with diffuse subcutaneous tissue edema at 6 months after finishing treatment as well as hot, red, and induration in the breast. (**a**) Bilateral mammography CC views show skin thickening (*red dot*), trabecular thickening, and increased density (*yellow dot*) relating to edema and post-radiotherapy changes. (**b**) Ultrasound shows skin thickening (*red dot*), diffuse increased echogenicity relating to edema (*yellow dot*), anechoic linear images between fatty islets relating to distended lymphatic vessels, and an anechoic nodular imaging relating to emerging abscess (*red arrows*). The patient was diagnosed with mastitis. The clinical context is always key because radiological findings of noncancerous entities may mimic breast carcinoma

usually larger than 1 cm. They often have a lucent center. Sometimes they show the typical appearance of rim or eggshell calcification. Benign calcifications can also be suture material, which represent calcium deposited on suture material. They are less common than dystrophic calcifications. They are typically linear or tubular in appearance, and when present, knots are frequently visible.

There is no universal agreement about when to perform the first mammography after finishing RT. In most cases, the first mammography is performed 6 months after RT. In some cases where tumors initially present with calcifications, the initial mammography is performed just before the beginning of RT to verify the absence of residual calcifications.

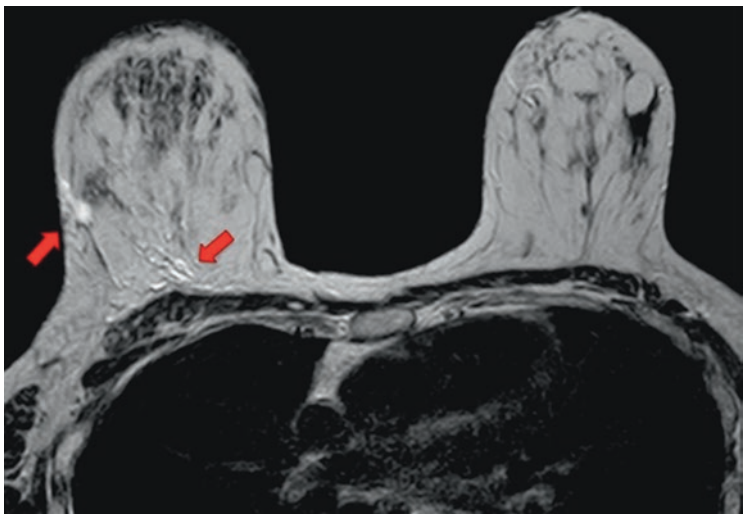

Fig. 21.10 Patient with breast-conserving surgery and subsequent RT treatment in the right breast presented with redness, skin thickening, and fever during her RT treatment. T2 sequence shows hyperintensities regarding the liquid and edema (*red arrow*)

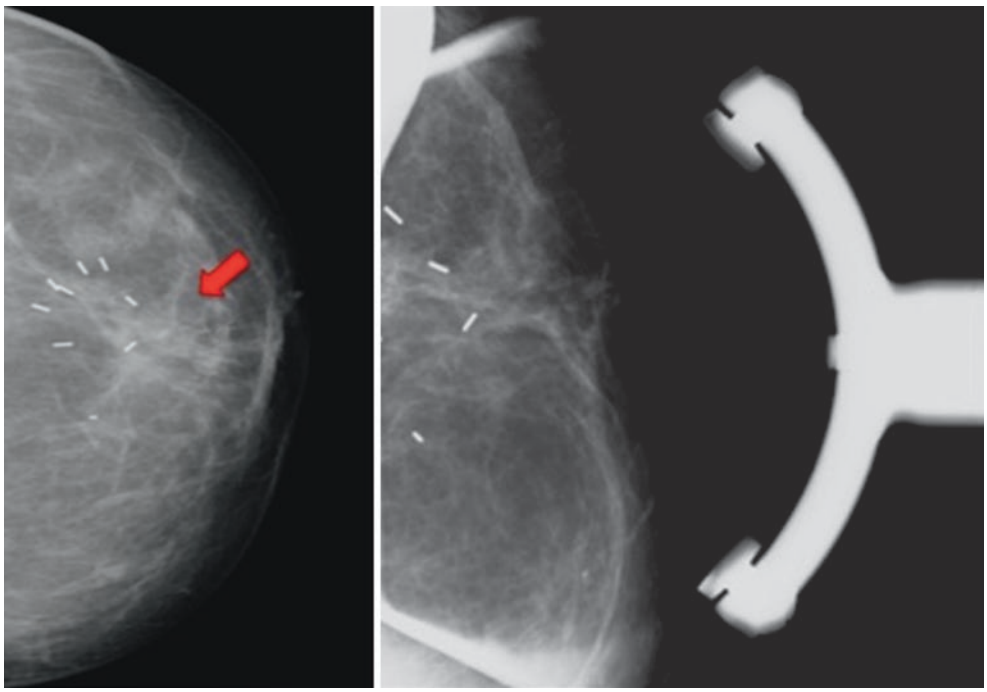

Fig. 21.11 Patient with personal history of breast-conserving surgery in the OUQ of left breast. A distortion image is seen in the area relating to scar tissue. CC view mammography (on the *left*) shows a distortion in the area of the surgical changes. A spot compression view (on the *right*) shows a fat center and dissociation

21.2.2.2 Follow-Up Protocol

A follow-up protocol could be:

- Initial mammography 6 months post-RT (in cases of tumors with calcifications, mammography could be performed just before RT to confirm complete removal of them).
- Annual mammography (± magnified and/or compressed projections) 2 years after RT. This should be considered as baseline as thereafter the posttreatment changes should remain stable or decrease.
- Annual ultrasound with mammography: Optional.

If available, breast MRI is the most useful imaging technique in evaluating cases after breast-conserving surgery because of its high negative predictive value. Nevertheless, if there is any doubt concerning its findings, a histological examination should be conducted.

21.2.3 Mastopexy

For patients who have undergone mastopexy, a new architectural pattern is established which can modify the normal radiological appearance of the breast. These modifications

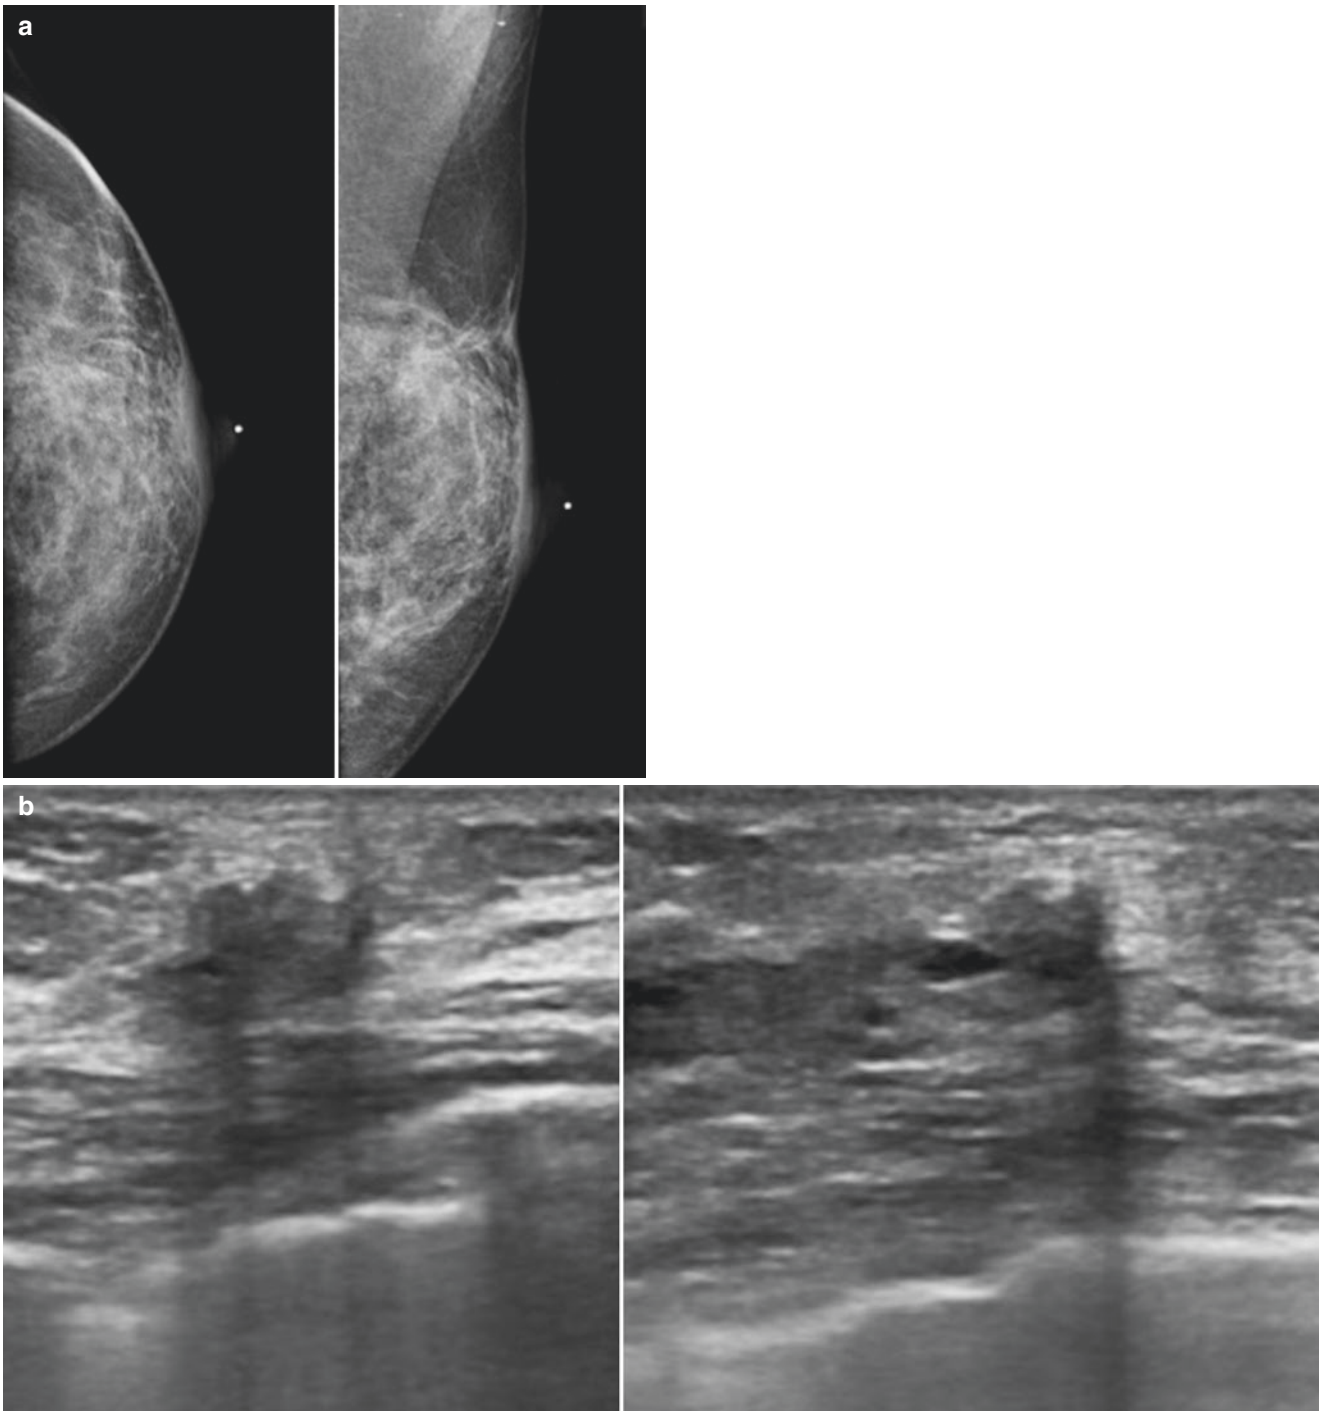

Fig. 21.12 Patient with a personal history of breast-conserving surgery in OUQ left breast. (**a**) Mammography shows architectural distortion in the area of the scar. (**b**) Ultrasound shows a nodular lesion corresponding to the surgical area. Although that image changed with probe position, it was suspicious so a core needle biopsy BAG was performed with result of scarring changes

are due especially to the presence of scars, remodeling and reorientation of breast tissue, and repositioning of the NAC. When mastopexy is performed for cosmetic purposes, postsurgical changes are usually bilateral; therefore, radiological findings are often in both breasts and can be compared. In cases where mastopexy is performed for symmetrization/contralateral reconstruction after mastectomy, radiological findings are asymmetrical and can seem suspicious especially if the patient's imaging history is unknown.

Imaging history should be reviewed to assess possible changes over time. Sometimes important radiological

findings after mastopexy can go unnoticed if the patient's previous history is unknown. Postsurgical findings should decrease over time, and any new or more evident findings should be investigated.

21.2.3.1 Radiological Tests and Findings

1. Mammography:
   - Distortions or focal asymmetries
   - Skin thickening or a dense periareolar line and sometimes in the vertical line that joins the periareolar region with the inframammary fold
   - Benign calcifications—usually skin calcifications, oil cysts predominantly of periareolar location, or coarse calcifications
   - Fibrous bands extending from the repositioned NAC
   - Reorientation of the breast tissue, with higher amount of tissue in the lower quadrants
2. Ultrasound:
   - Shadowing, usually related to scars
   - Heterogeneous areas of breast tissue relating to the repositioning of the gland
   - Ill-defined and heterogeneous lesions when there are fat necrosis changes
3. MRI:
   - New architectural pattern.
   - Cutaneous and subcutaneous postoperative changes, especially in the periareolar region, the vertical scar and the inframammary fold. Sometimes these changes cannot be noticed on mammogram and they can only be detected on MRI. They are more evident on gradient echo and black silicone sequences (Fig. 21.13).
   - If irregular enhancement is seen, differential diagnosis should be done to distinguish fibrosis, fat necrosis, or malignancy, and then, biopsy should be done.

21.2.4 Complications and Sequelae

Complications and sequelae should be considered when interpreting imaging and managing the follow-up of the patient. Seroma/hematoma will disappear in most cases but may persist and be clinically significant in some. In the latter scenario, both increased risk of infection and delayed healing have been shown, so seroma/hematoma may require aspiration or drainage. With cellulitis, skin and subcutaneous thickening and trabecular thickening can be seen. Sonographically they correspond to a diffuse increased echogenicity with hypoechoic septa regarding distended lymph vessels. An abscess (Fig. 21.9b) can occur as a late complication (approximately 5 months after surgery), because of a superinfection of a previous collection. The radiological appearance could be a complex lesion and on MRI could show a peripheral enhancement that sometimes can show a rude aspect. Sequelae include increased risk of infection, especially if there is axillary dissection. Radiation-induced cancer is unusual. The most common are lung cancer, breast cancer, leukemia, and radiation-induced sarcoma. There is cumulative incidence of radiation-induced sarcoma, from 0.07% 5 years after the radiotherapy to 0.48% 15 years after radiotherapy, with a latency period of 5–7 years after radiotherapy. The clinical presentation often mimics benign pathology (usually skin thickening that can be confused with normal posttreatment changes), which explains the delay in diagnosis and thus advanced staging with worse prognosis.

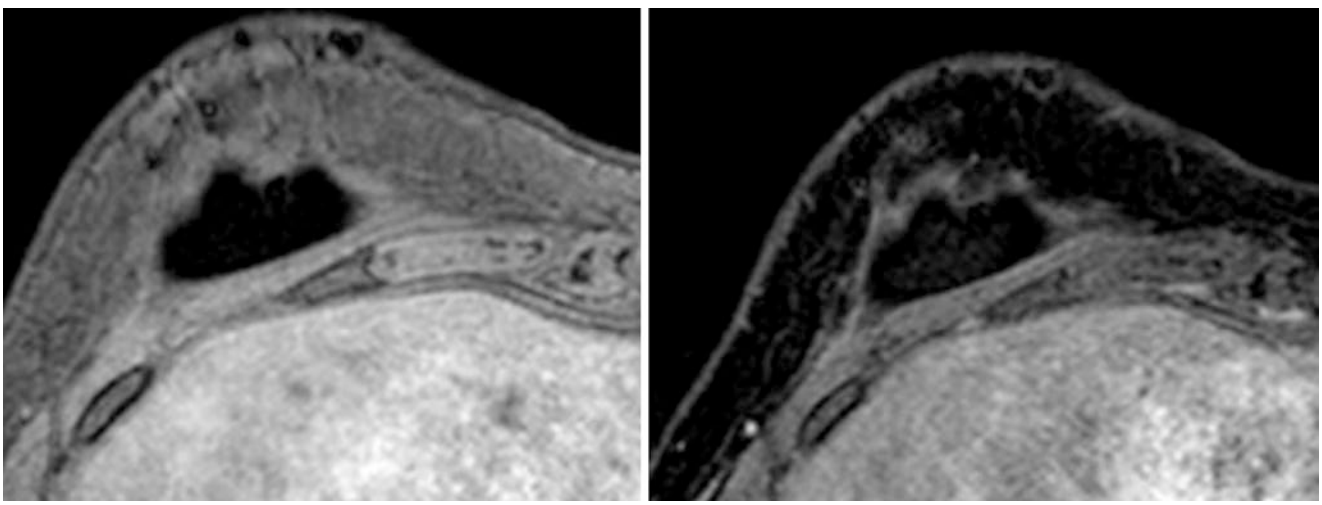

Fig. 21.13 Black silicone (on the *left*) and thrive postcontrast (on the *right*) sequences in a patient with previous history of left mastectomy and right symmetrization with mastopexy surgery unnoticed on other sequences. Postoperative changes on skin are seen

21.3 Imaging Findings After Surgery with Heterologous Material

Heterologous reconstruction is the most common type of reconstruction of an operated breast. The surgeon makes an incision in the skin usually including the NAC and removes the breast parenchyma through it. A pocket covered by a piece of skin is created where an implant will be placed (usually under the pectoralis major to prevent movement). The procedure may involve biological mesh and acellular dermal matrix to assist with the implant. It is advantageous over autologous reconstruction in several respects, including lower morbidity rates because there is no donor site, higher simplicity as it requires the shortest surgical time and recovery time, similar aesthetic presentation in color, texture, and sensitivity of the reconstruction to the adjacent tissue, and fewer scars. However, disadvantages include a very large and/or hypertrophic contralateral breast (usually ptotic) and a lack of a natural-looking breast causing patient refusal of the procedure. It is also contraindicated when there is poor skin quality due to RT or previous scars and insufficiency of the skin or pectoralis major to cover the implant.

More recently, free injection methods of different types of substances into the mammary gland have been also developed with a similar aim to that of implants, which is to increase breast size and to rebuild after surgery. They are especially useful in cases of partial defects. However, they remain controversial due to safety concerns including the possibility of migration of the injected substance to other parts of the body, their ability to promote the development of breast cancer, and the difficulty in assessing normal breast parenchyma after the procedure due to radiological findings and complications. Heterologous substances used in free injection techniques include free silicone, paraffin (no longer used), or hyaluronic acid (banned in some countries). These substances remain located in the mammary gland or in or under the pectoral muscle.

21.3.1 Implants

Clinical examinations are limited in their ability to evaluate implants and have low sensitivity for detecting ruptures. Thus, imaging techniques such as mammography, ultrasound, and MRI are clinically important.

21.3.1.1 Radiological Tests

The use of mammography is limited to evaluating the integrity of implants: extracapsular rupture, evident deformities, and capsular contractures, sometimes with calcifications. Silicone gel and saline implants will show a hyperdense appearance on mammogram (Fig. 21.14). The filling valve may be seen in the case of saline implants (Fig. 21.15). When there is a double lumen implant, both chambers can be distinguished; the inner chamber (saline) appears less dense than the outer chamber (silicone) (Fig. 21.16). Breast cancer screening in patients with implants will be affected since implants decrease the parenchymal visibility by 30–50%. Therefore, a full mammographic exploration should include:

- Oblique projection (both breasts).
- Cranio-caudal projection (both breasts).
- Eklund-modified compression technique, which is used in addition to the routine two-projection mammogram. It consists of posterosuperior displacement of the implants simultaneous to an anterior traction of the breast, pushing the implants toward the chest wall up to flatten. It provides significant improvement in image quality and displays a greater amount of breast tissue (Figs. 21.14 and 21.15).

Both silicone and saline implants have an anechoic appearance on ultrasound. Therefore, it is often not possible to distinguish sonographically between both if the patient's clinical history is not available (Fig. 21.17). Sometimes, however, it is possible to make a distinction if the filling valve of the saline implant is apparent (Fig. 21.18). The presence of a reverberation artifact and some subcapsular folds are normal findings. The main advantages of ultrasound are that it is a safe and noninvasive test, allows the integrity of the implant to be analyzed, allows the detection of extracapsular rupture (highly specific) and intracapsular rupture (where ultrasound's usefulness is more limited), and is the imaging technique of choice in guiding fine needle aspiration (FNA) or core needle biopsy to clarify suspicious lesions. Ultrasound provides a direct view of the breast in real time without risk of damage to the implant. The main limitations of ultrasound are that it is less capable for assessing the posterior aspect of the implant, it is highly dependent on the operator, and there are pitfalls when there is a lack of clinical history of the patient. For example, a hyperechoic line corresponding to the elastomer of the inner chamber in a double-lumen implant may be misinterpreted as a subcapsular line, leading to an incorrect diagnosis of an intracapsular rupture (Fig. 21.23a). Additionally, especially in very old implants with capsular contracture and with clinically suspected rupture, it is very common to find calcifications in the implant as well as ill-defined margins of the external capsule in the implant which may be misinterpreted as extracapsular rupture when there is no previous mammogram or CT for comparison.

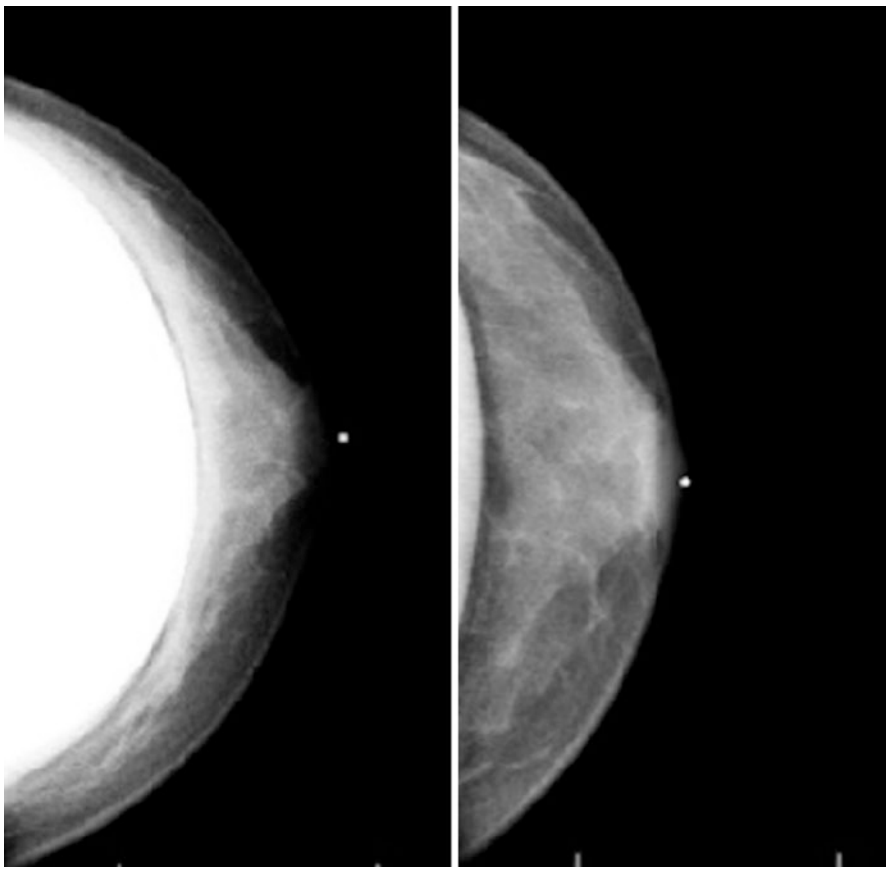

Fig. 21.14 Left breast mammography with CC projections in a patient with silicone gel implant. The silicone gel implant shows a hyperdense appearance on mammogram. The breast parenchyma is partially seen due to the implant (on the *left*), but with Eklund projection (on the *right*), the silicone gel implant can be displaced posteriorly (while the technician pushes the parenchyma to the anterior) to show most of it. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

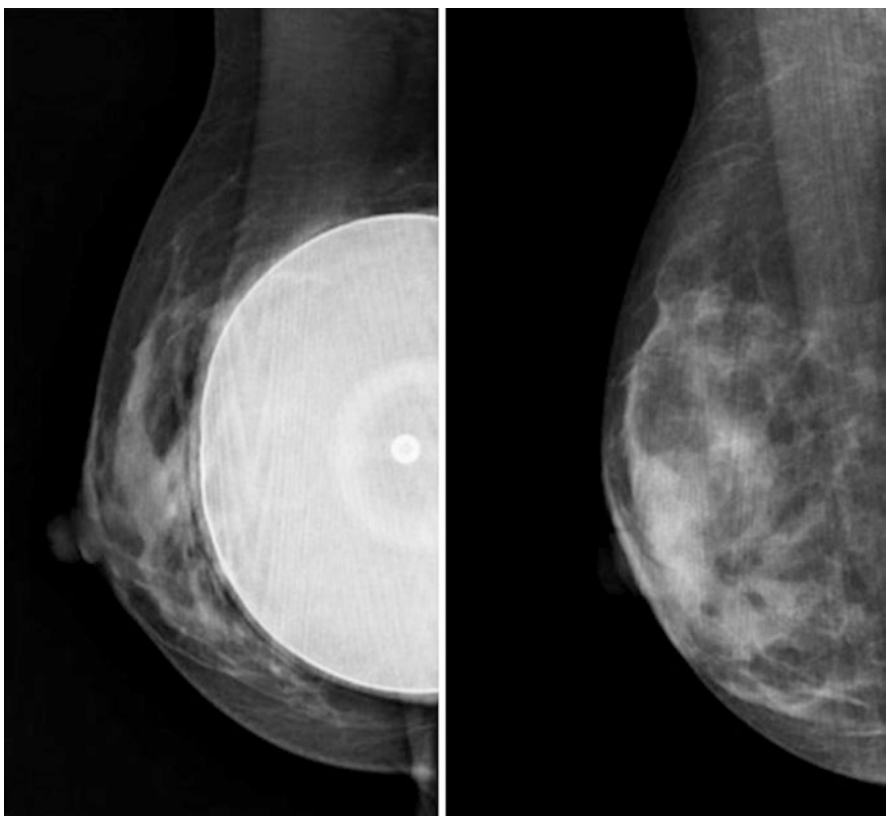

Fig. 21.15 Right breast mammogram with oblique projection in a patient with saline solution implant. The saline solution implant has a hyperdense appearance on mammogram, and the filling valve is seen at the center of the implant. The breast parenchyma is partially seen due to the implant (on the *left*). With Eklund projection (on the *right*), the saline solution implant is displaced to the posterior (while the technician pushes the parenchyma to the anterior) to show most of the parenchyma. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

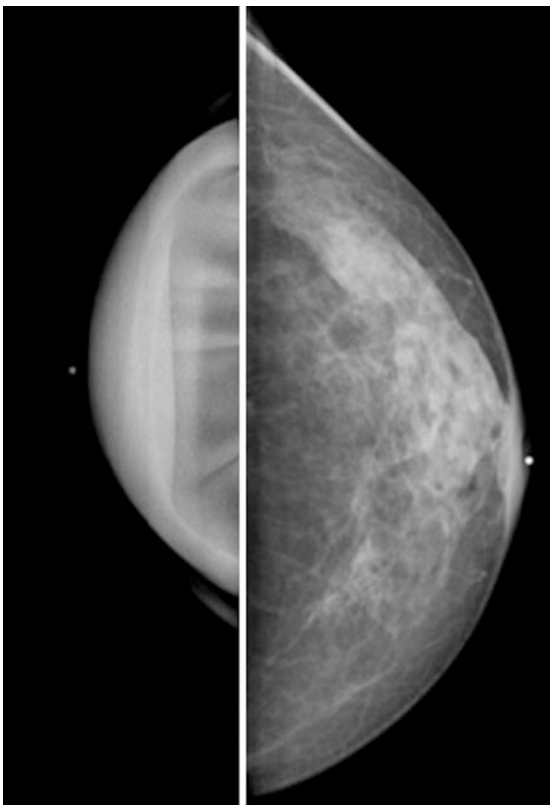

Fig. 21.16 Right breast mastectomy with a double-lumen expander. On mammography both chambers are identified. The inner chamber presents less density due to the saline solution

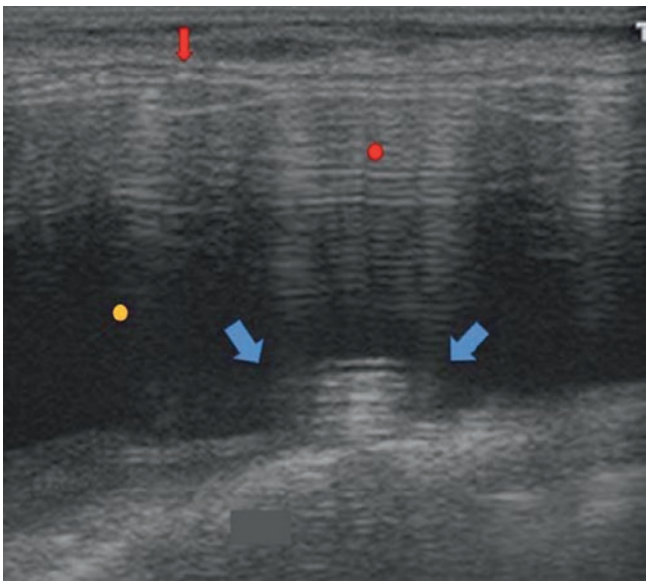

Fig. 21.18 Ultrasound appearance of a saline solution implant: Oval and anechoic mass identical to the silicone implant in Fig. 21.17 with a double hyperechoic line corresponding to the elastomer (*red arrow*) and reverberation artifact (*red dot*). The saline solution inside the implant presents an anechoic appearance (*yellow dot*). The only way to differentiate this implant from the silicone implant is to appreciate the filling valve in its posterior aspect (*blue arrows*). Sometimes it is not well seen with ultrasound because of the depth of the posterior margin of the implant. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica.

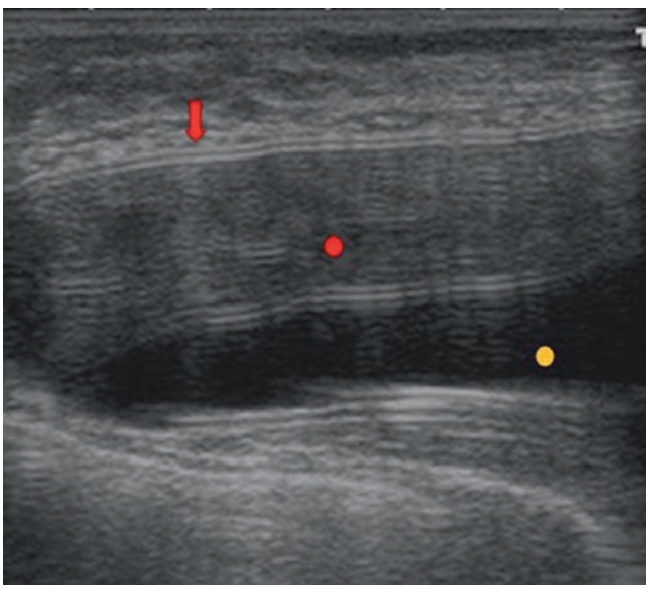

Fig. 21.17 Ultrasound appearance of a silicone gel implant: Oval and anechoic mass where the elastomer appears as double hyperechoic line (*red arrow*) with reverberation artifact below (*red dot*), and the silicone gel shows an anechoic appearance (*yellow dot*). There is no filling valve. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica.

Breast MRI is the most sensitive and reliable imaging technique available to assess implants and their associated complications. To obtain high-quality images, the use of high-field MRI machines with a breast-specific coil is required. MRI is performed when the patient is in a prone position to avoid respiratory movements that can affect the quality of the images. To examine silicone gel implants (Fig. 21.19), the protocol should include specific sequences for silicone, for example, white and black silicone sequences. The white silicone sequence is especially useful as the image will show only the white silicone, either intra- or extracapsular. Sagittal sequences should also be included so sutile intracapsular ruptures can be appreciated and the inferior edge of the implant can be better analyzed. One option is to perform the T2 sagittal sequence without fat suppression or to perform fine-slice imaging in the axial plane and sagittal reconstruction posteriorly. The use of an intravenous contrast agent is not necessary if MRI is only intended to evaluate the implant. However, it is useful if the patient has a history of breast cancer or a high-risk lesion. Silicone implants will have the following

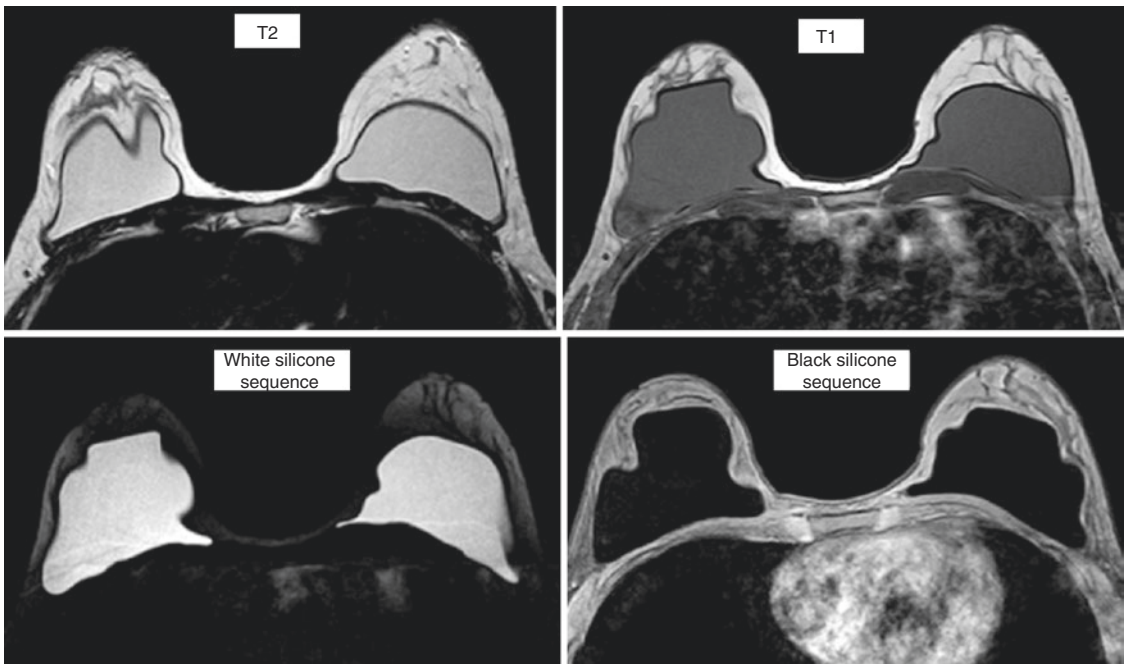

Fig. 21.19 Patient with silicone implants. Normal appearance of the silicone in different sequences

appearance on the different MRI sequences (Figs. 21.19 and 21.23):

- T1 sequence: Hypointensity.
- T2 sequence: Hyperintensity but not as intense as in a white silicone sequence or compared with a saline implant.
- STIR/SPAIR sequence: Hypointensity although sometimes this can vary depending on the composition of the implant.
- White silicone sequence: Marked hyperintensity, which contrasts with the rest of the breast.
- Black silicone sequence: Marked hypointensity.

Specific sequences for silicone make no sense if the implant is a single-lumen saline implant, since the implant will look exactly like liquid in all sequences (Fig. 21.20).

MRI is not useful to assess expanders with an anterior valve, since this has a metallic component (that can be seen on X-ray and on CT) (Fig. 21.21), and so an artifact is produced on that hemithorax (Fig. 21.22). However, it is possible to perform the MRI to assess the contralateral breast; although the valve can move a little because of the magnetic field, the surgeon, posteriorly, is able to locate the filling valve over a magnet. The only obstacle to MRI is if the patient notes a warm or burning sensation on the skin.

In cases of a bicameral implant, the filling valve is made of titanium and usually located adjacent to the chest wall, lateral to the implant and connected with it through a connector. Then, the patient may be subjected to breast MRI to assess both the breast with implant and the contralateral breast because there is no artifact on that hemithorax. Besides, there is no risk of implant movement or warmth on the skin. It is advisable to visualize all the connector routes and the valve to detect possible complications and ruptures. For that purpose, black silicone and thrive postcontrast sequences are useful (Fig. 21.23).

The main advantages of MRI are that it is a noninvasive technique, is useful in breast cancer screening as it achieves a better assessment of parenchymal lesions with the administration of intravenous contrast, and allows the assessment of the implant in three projections and the evaluation of intracapsular and extracapsular ruptures. It may show migration of silicone to lymph nodes (axillary and internal mammary) as well as soft tissue when there is an extracapsular rupture.

However, it is not free of disadvantages, such as cost, availability, motion and breathing artifacts, and false-positive cases.

21.3.1.2 Radiological Findings

Some findings are considered as normal on MRI, for example, a small amount of periprosthestic fluid; rippling, subcapsular folds (these can be differentiated from an intracapsular rupture because most times they have fluid on one side); and fibrous bands.

Complications include intracapsular rupture, extracapsular rupture, migration of the silicone gel to lymph nodes and

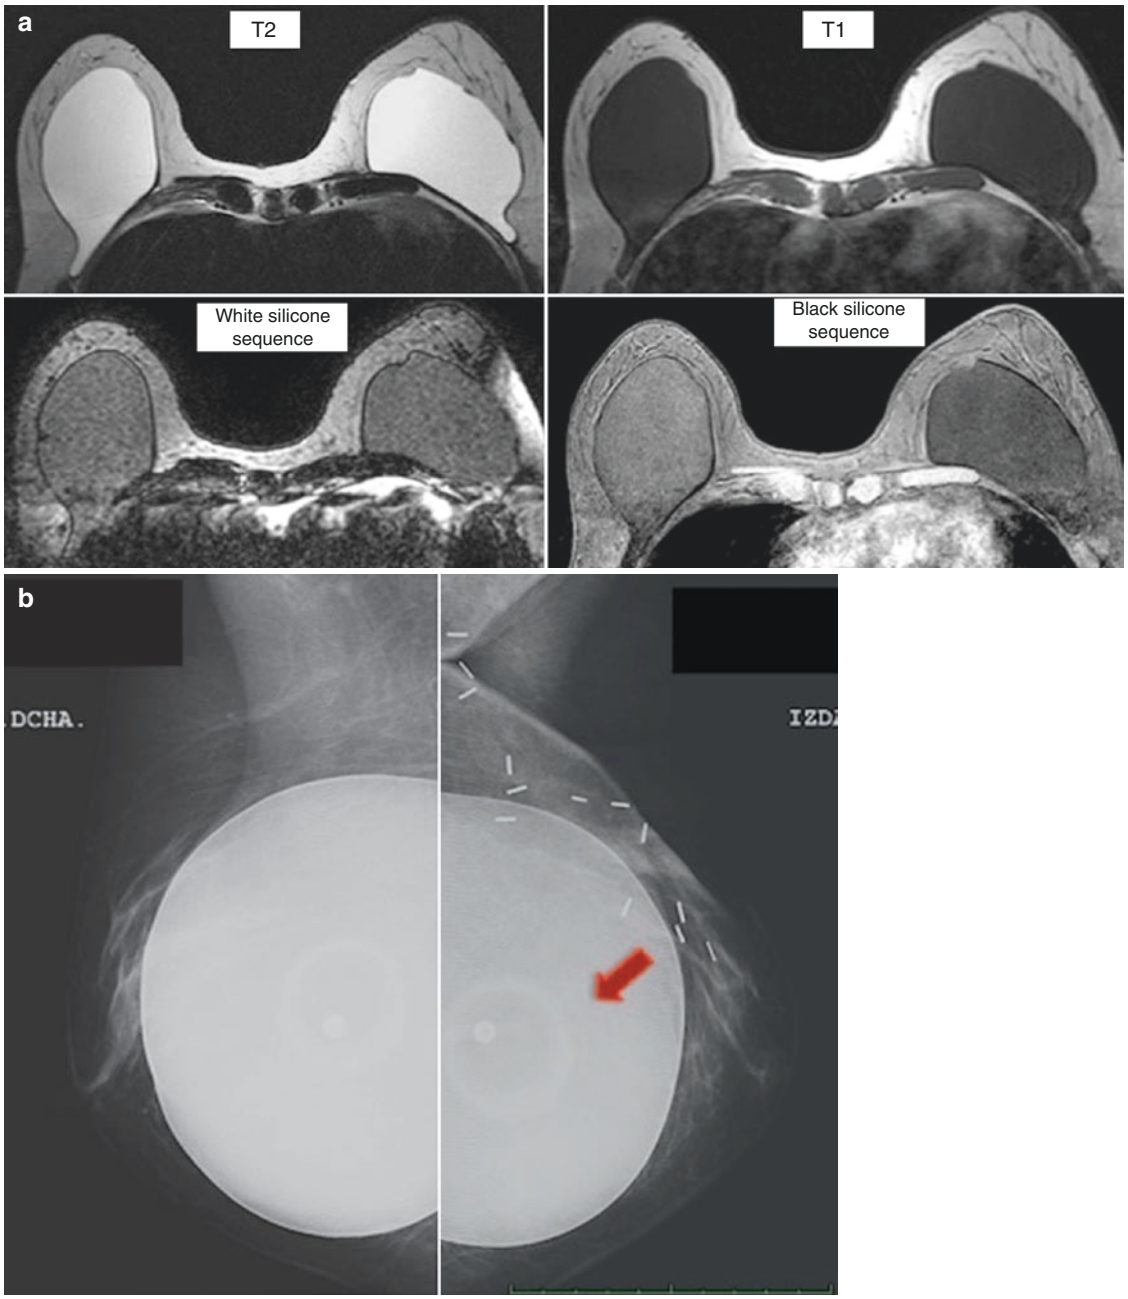

Fig. 21.20 Patient with breast-conserving surgery in UOQ of the left breast and reconstruction with saline solution implants. (**a**) MRI was performed without the presence of a radiologist, and the type of implants was unknown, so white silicone and black silicone sequences were made. The saline solution implants show identical signal intensity of the liquid which was hypointense on T1 and hyperintense on T2 (higher hyperintensity than silicone). On black and white silicone sequences, implants show similar signal intensity, slightly hypointense. This presentation may present a pitfall, suggesting a technical failure of the machine that is not able to suppress appropriately. (**b**) In this case and following a review of previous explorations, the patient had a mammogram where the filling valves could be seen in the posterior aspect of the implant (*red arrow*) supporting that these were saline implants

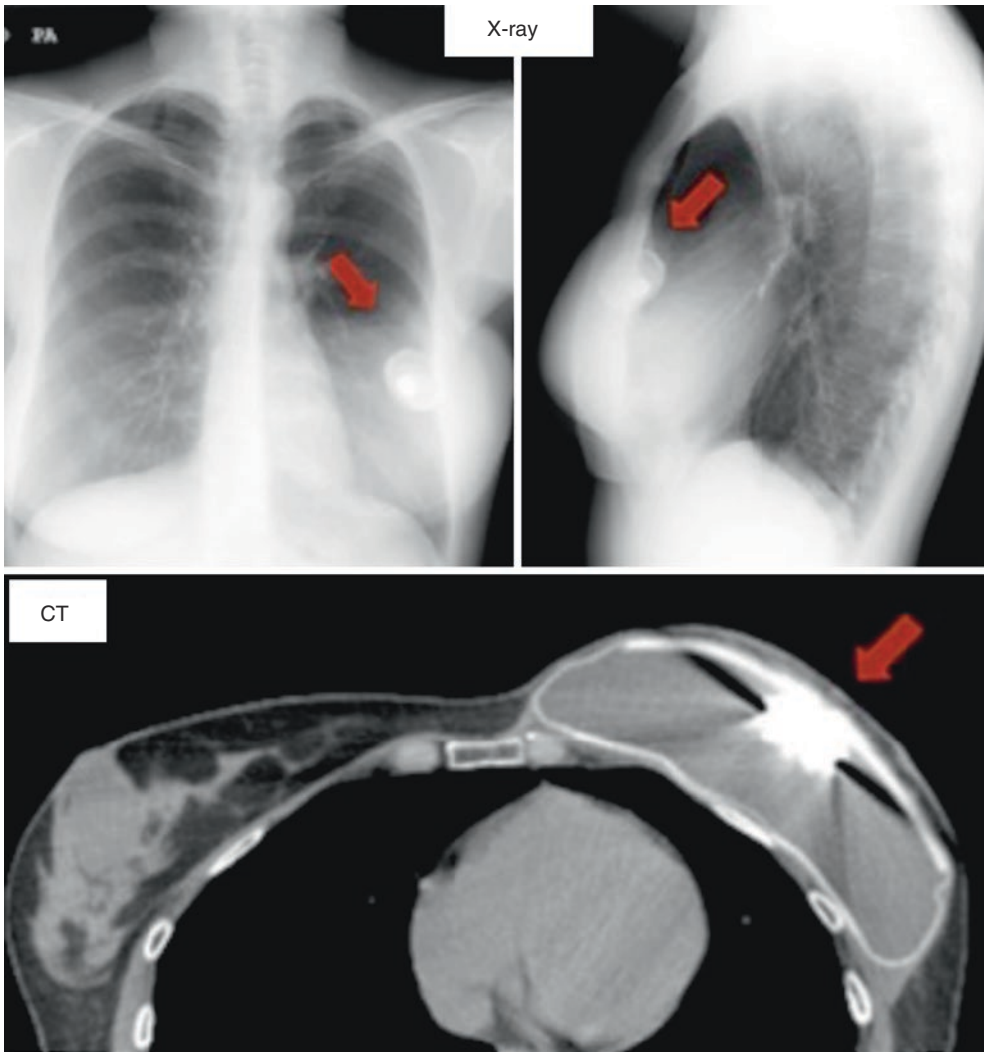

Fig. 21.21 Patient with left mastectomy and heterologous reconstruction with a unicameral saline solution expander with filling valve. The metallic component allows the expander to be seen on radiographs and on CT. The filling valve and the metallic artifact can be noticed (*red arrow*)

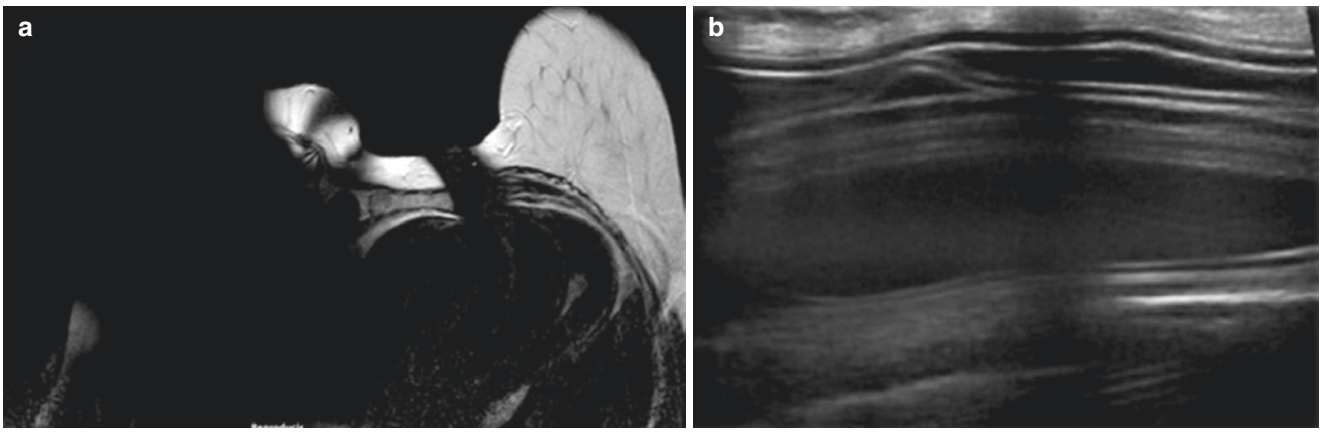

Fig. 21.22 Patient with personal history of right mastectomy and temporary reconstruction with an expander with a metallic valve. Breast MRI was performed due to surgeon request in the case of suspected rupture. There was no contraindication for the MRI except that it was not useful to evaluate either the operated breast or the expander, being able to only to assess the contralateral breast. (**a**) T2 sequence axial plane: The metallic component of the filling valve produces a magnetic artifact that prevents evaluation of the expander. However, the contralateral breast is clearly seen. (**b**) An ultrasound confirms collapse of the expander

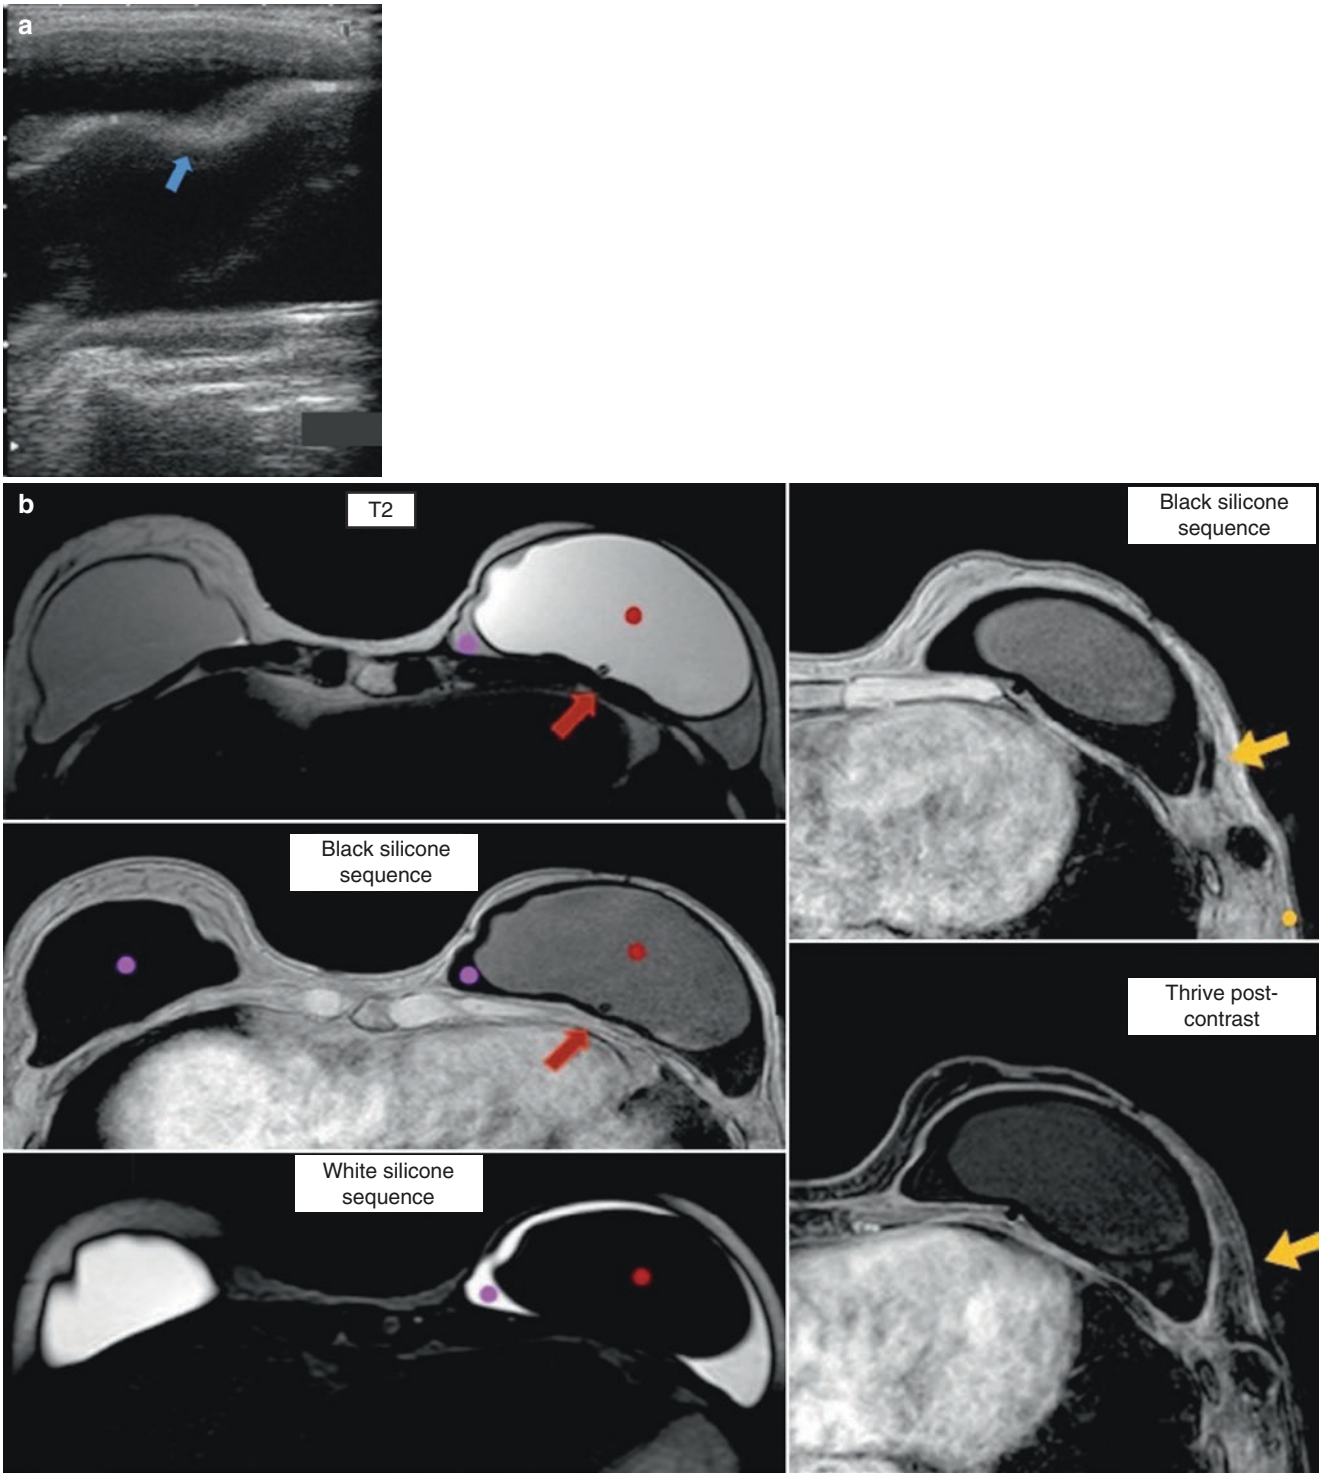

Fig. 21.23 Patient with bilateral mastectomy and left reconstruction with bicameral expander and right reconstruction with silicone implant. (**a**) Ultrasound: Two chambers separated by a hyperechoic line can be seen. It is a very common pitfall to misunderstand that line as the subcapsular line seen in intracapsular ruptures. (**b**) MRI with different sequences: Two chambers with different signal intensities can be seen. *Red dot*: internal chamber of saline solution. *Violet dot*: external chamber of silicone on the left breast and silicone implant on right breast. *Red arrow*: connector going from the posterior part of the expander through the lateral margin of the implant to the chest wall where the filling valve is located. Black silicone and thrive postcontrast sequences were very suitable to assess the connector in its path out of the implant (*yellow arrow*) and the filling valve (*yellow dot*). The connector should be assessed over its entire route to ensure that there are no ruptures

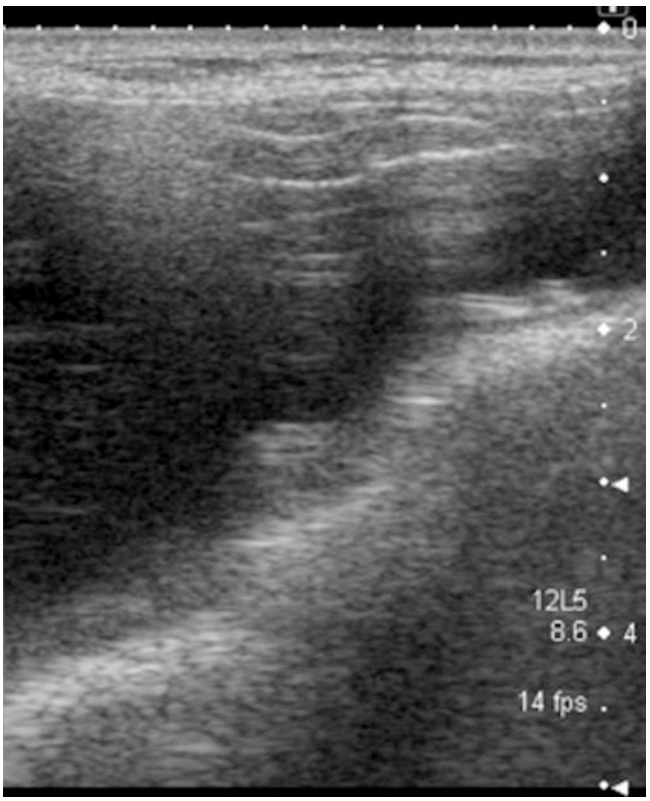

Fig. 21.24 Ultrasound showing an intracapsular rupture: stepladder sign. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

soft tissues, capsular contracture (where the diagnosis is usually clinical), and displacement/herniation (where the diagnosis is usually clinical) (Fig. 21.30).

1. Radiological signs of intracapsular rupture:

It is difficult to detect intracapsular rupture on clinical exam or mammography. This complication is better seen on ultrasound or MRI, with the latter as the best option:

- On ultrasound:
  - Overall sensitivity and specificity rates range between 59–85% and 55–79%, respectively.
  - "Stepladder sign": Hyperechoic lines parallel to the elastomer resembling a ladder or railway (Figs. 21.24 and 21.28a).
  - Subcapsular irregular and discontinuous hyperechoic lines inside the implant (Figs. 21.25 and 21.29).
  - Hyperechoic content inside the implant (Figs. 21.25 and 21.29).
- On MRI:
  - Unicameral implant:

    Without collapse: "*Keyhole*," "*teardrop*," "*inverted loop*," or "*noose*" signs (Figs. 21.26 and 21.27). An implant without collapse appears as silicone on both sides of a radial fold. These signs indicate focal extravasation of silicone, which is confined to the fibrous capsule without extending cir-

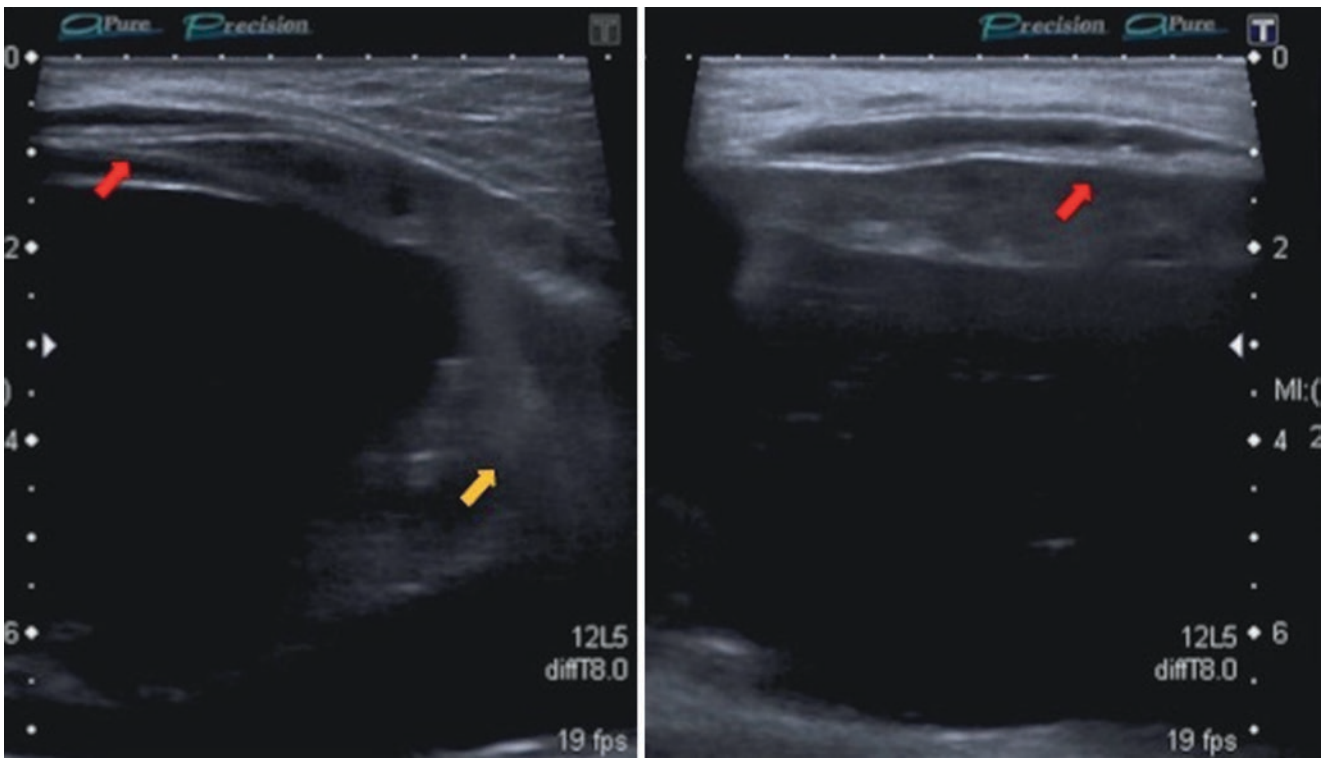

Fig. 21.25 Ultrasound showing an intracapsular rupture: Irregular subcapsular line under the shell (*red arrow*) and hyperechoic content and lines inside the implant (*yellow arrow*)

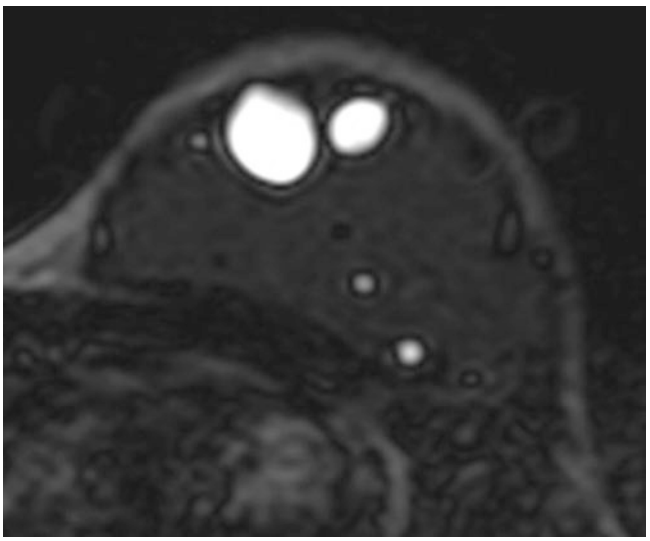

Fig. 21.26 Breast MRI with black silicone sequence: teardrop sign. The silicone appears completely black, and inside there are some white images due to water

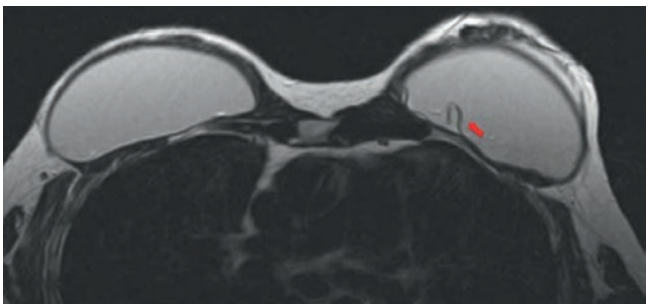

Fig. 21.27 Breast MRI with T2 sequence: inverted loop sign. There is a loop originating from the shell that goes inside the implant, with silicone on both sides

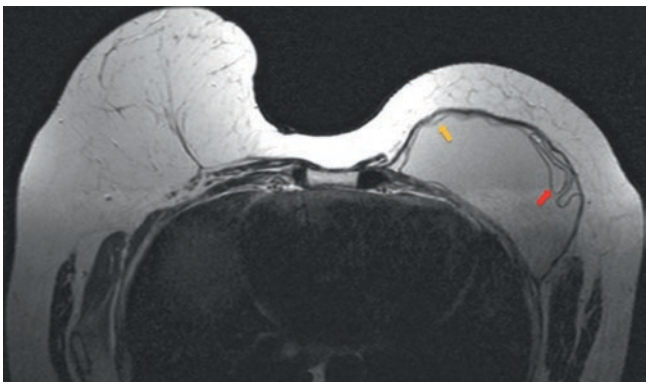

Fig. 21.28 Breast MRI with T2 sequence without fat suppression showing an intracapsular rupture: Linguini sign (*red arrow*) and a subcapsular line (*yellow arrow*)

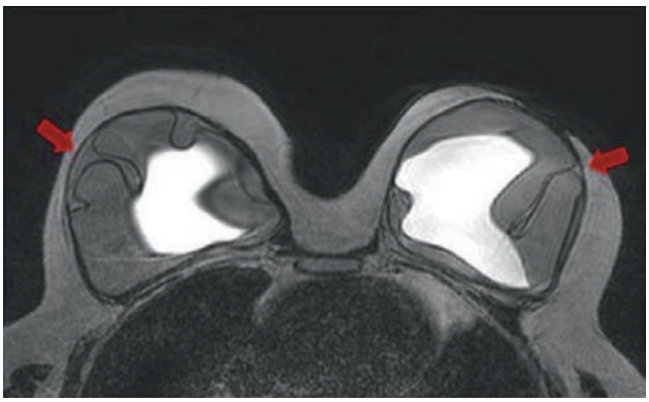

Fig. 21.29 Patient with bilateral mastectomy with heterologous reconstruction involving double-lumen expanders with definitive intention. Breast MRI (T2 sequence, axial plane): Both chambers can be seen in both breasts. The inner chamber is white because it consists of saline solution, and the outer one is gray because it consists of silicone gel. A subcapsular line (*red arrow*) is seen beside both outer chambers with silicone signal on both sides of the line indicating bilateral intracapsular rupture

cumferentially due to the presence of adhesions at their ends. However, none of these signs is a reliable sign of rupture on its own. Other imaging features, assessed in combination, may better suggest intracapsular rupture.

With minimal collapse: "*Subcapsular line*" (Fig. 21.28). There is presence of a parallel and hypointense line to the fibrous capsule with silicone on both sides. It represents an evolution of the previous stage, but in this case the base of the invagination of the elastomer is greater than in cases with no collapse.

With partial or total collapse: "*Linguini*" or "*wavy line*" signs (Fig. 21.28) due to a free-floating shell within the implant. Internal and hypointense curved lines are seen without a perpendicular orientation to the shell. It represents rupture of the elastomer and the presence of silicone between it and the fibrous capsule. It is the most reliable sign of an intracapsular rupture with a sensitivity and specificity of 96 and 76%, respectively.

– Bicameral implant or expander: If the rupture is in the outer chamber, findings are similar to that of an intracapsular rupture in a single-lumen implant (Fig. 21.29). If the rupture is in the inner chamber, a "*salad oil*" sign or "*mixed signal intensities*" between both chambers may be seen. Subcapsular lines inside the saline chamber may also be seen (Fig. 21.30). As the saline chamber is ruptured, a decrease in the volume of the implant is also noticed.

Fig. 21.30 Patient with conserving surgery in the right breast with reconstruction using a double-lumen expander. Follow-up breast MRI was performed every year. T2 sequences are shown each year. In year 1, the double-lumen implant is seen with both intact chambers. However, herniation signs and capsular contracture are noted. In year 2, the inner chamber (with saline solution) shows subcapsular lines with the same signal on both sides of the line indicating an intracapsular rupture. However, the patient did not replace the implant. In year 3, the subcapsular lines inside the inner chamber persisted, and additionally a mixed signal intensity is seen not showing the typical white appearance of fluid signal

2. Radiological signs of extracapsular rupture:

Extracapsular rupture is evident as the silicone, when separated from the implant, extends beyond the implant capsule into the breast or axilla. The silicone shows up as free silicone in the parenchyma, as granuloma (siliconoma) when the body encapsulates the silicone that may manifest as a lump or tumor, or as silicone migration in lymph nodes and soft tissues.

The presence of silicone outside the fibrous capsule without evidence of fibrous capsule or shell rupture can occur in two circumstances:

- Previous implant rupture and posterior replacement where there are remains of previous extracapsular silicone in the breast (Fig. 21.31).
- Leakage of silicone due to permeability of the shell and/or the fibrous capsule. The lymphatic vessels pick up this leakage and carry it to the lymph nodes. The lymph nodes can present a snowstorm sign or simply show enlargement without a fat center because of reactive lymphadenitis (Fig. 21.32). Differential diagnosis should be done with extracapsular rupture with silicone migration to the lymph nodes and with lymph node involvement because of tumor.

Radiological signs of extracapsular rupture are:

- On mammography:
  - Oval and well-defined hyperdense masses outside the implant.
  - Change of the contour of the implant that may be detected on clinical exam or mammography.
  - Enlarged and hyperdense axillary lymph nodes due to silicone migration.

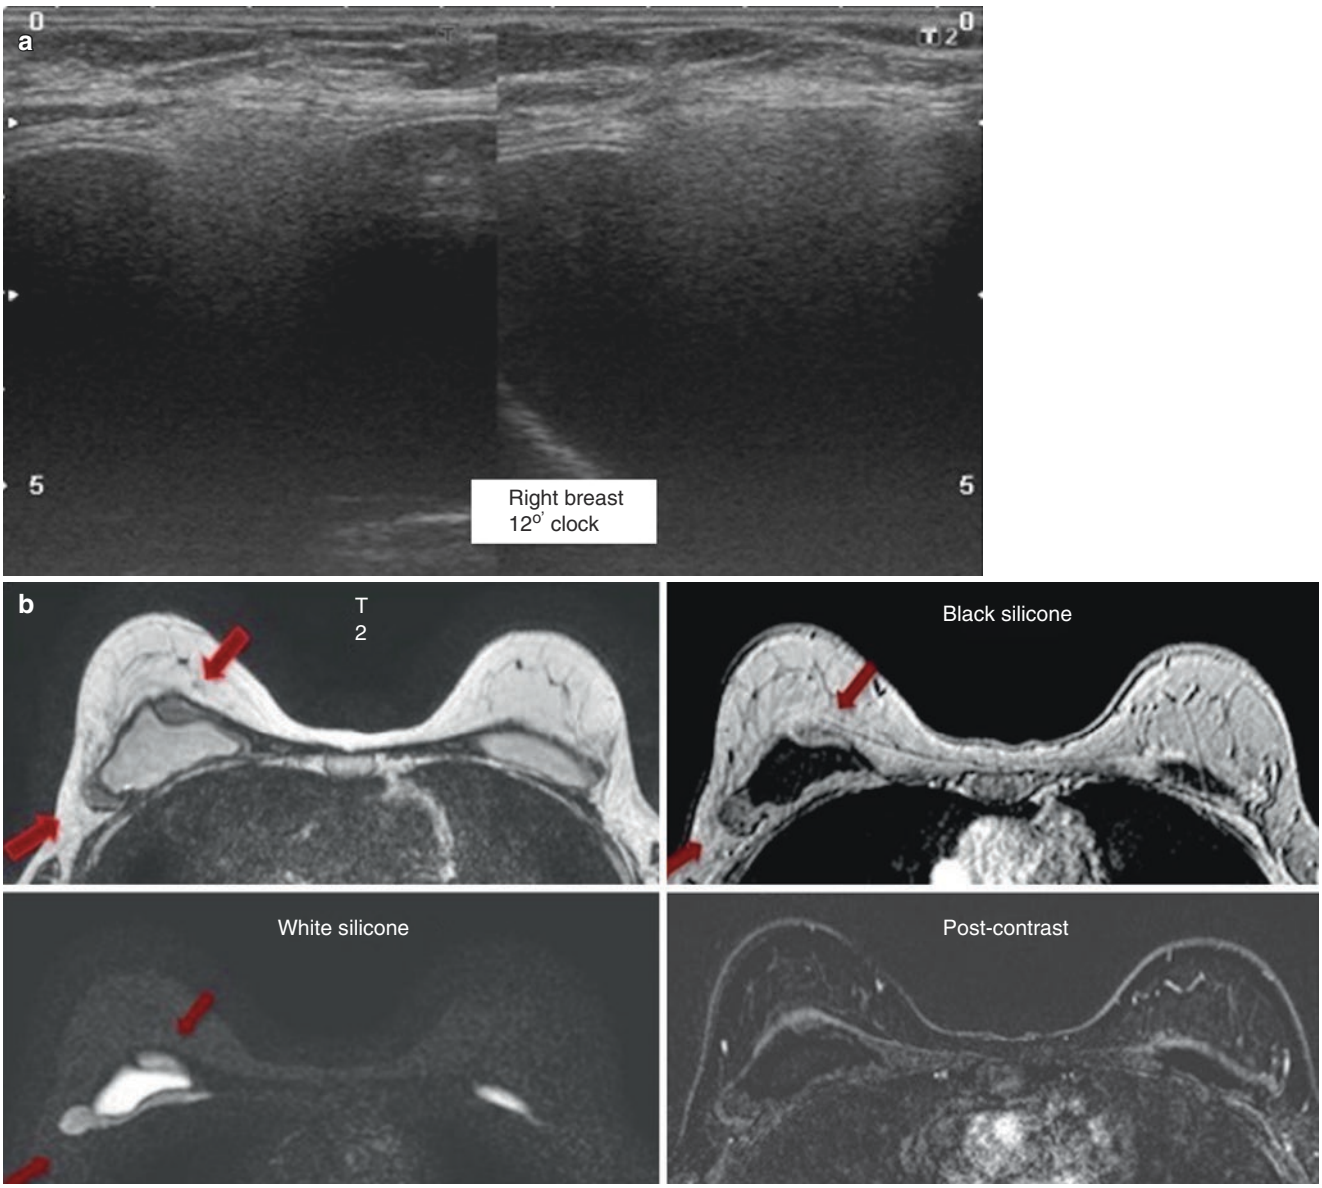

Fig. 21.31 Patient with personal history of extracapsular rupture with silicone extravasation. The surgeon referred the patient for replacement and cleaning. (**a**) Ultrasound was performed in a screening and a snowstorm sign was around some areas of the implant that prevented assessment of the capsule, suggesting extracapsular rupture. The patient wanted a definitive diagnosis before a new replacement surgery. (**b**) MRI was performed. An extracapsular material around the implant was seen, with signal intensity that did not correspond to free fluid but was similar to silicone (hyperintense) in silicone sequences (*red arrow*) and did not enhance after IVC. This could suggest a new extracapsular rupture; however, this signal intensity was not identical to intracapsular silicone on other sequences, and no evidence of discontinuity or rupture of the shell or fibrous capsule was seen. Therefore, these findings suggested remainders of the previous extracapsular rupture more than a new extracapsular rupture. That fact was confirmed with core needle biopsy with granulomatous reaction to foreign body result

- On ultrasound:
  - "*Snowstorm*" sign (Figs. 21.31 and 21.33): Highly specific. Extracapsular silicone appears as a hyperechoic image that prevents transmission of the ultrasound beam and the image resembles falling snowflakes.
  - Hypoechoic nodular lesions that are difficult to distinguish from solid nodules, usually due to a granulomatous reaction to a foreign body (silicone).
- On breast MRI:
  - Breast MRI is the most sensitive imaging technique for detecting small foci of migration.
  - In recent ruptures, free silicone shows a similar signal to the signal of the interior of the implant in all sequences, and there is no enhancement. However, over time, as granulation tissue builds up, the signal intensity changes and may present some enhancement after IVC administration.

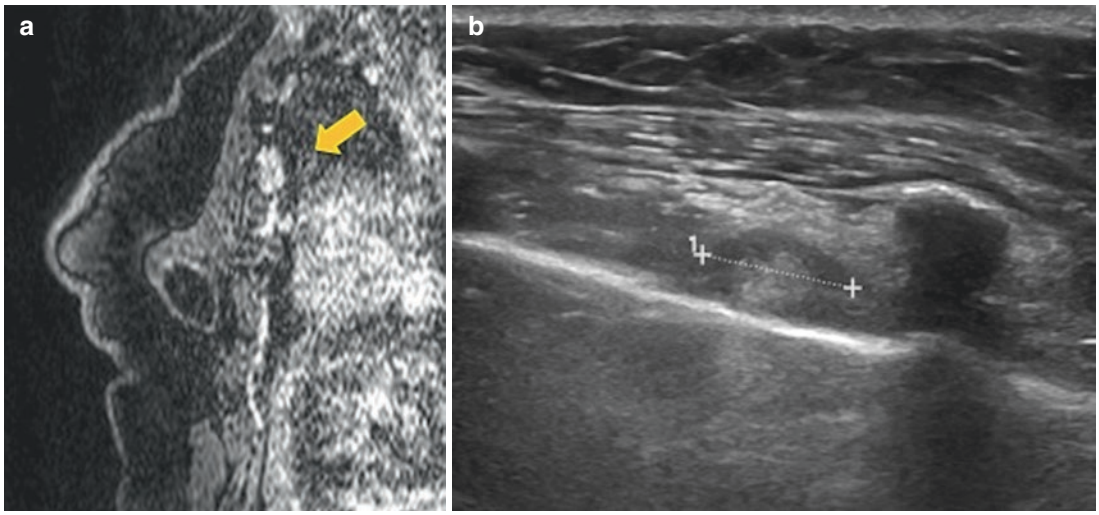

Fig. 21.32 Patient with bilateral mastectomy and heterologous reconstruction with an intracapsular rupture of the right implant. MRI showed an enlarged mammary internal lymph node that enhanced after IVC administration. (**a**) Dynamic sequence sagittal reconstruction shows an enlarged internal mammary lymph node without fat center (*yellow arrow*). Differential diagnosis should be done for an extracapsular rupture with silicone migration to lymph nodes, implant leakage with reactive lymphadenitis, or lymph node involvement due tumor as the patient had personal history of breast cancer. However, an extracapsular rupture was not seen and the external capsule was preserved. (**b**) Fine needle aspiration biopsy under ultrasound guidance was performed of that lymph node and the result was reactive lymphadenitis

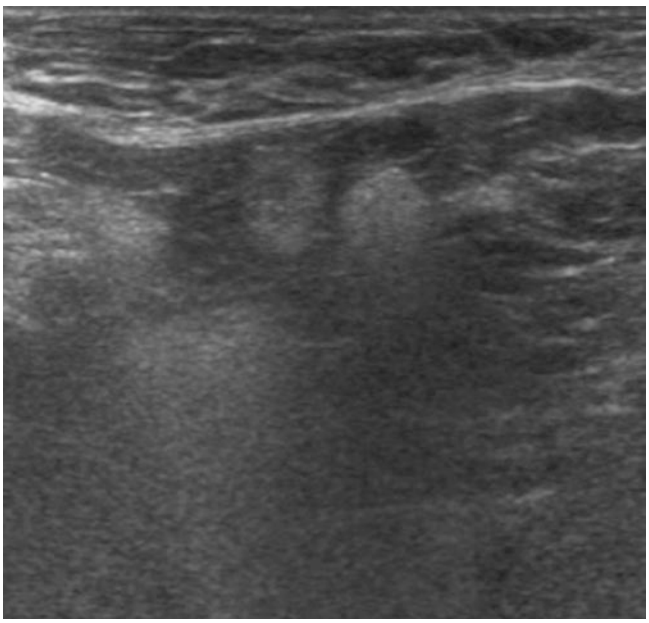

Fig. 21.33 Ultrasound showing hyperechoic lymph nodes with the snowstorm sign indicating extracapsular rupture and silicone migration to axilla. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica.

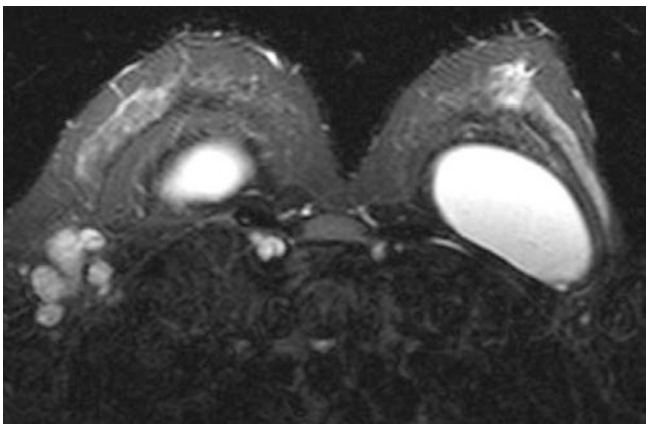

Fig. 21.34 Breast MRI, white silicone sequence, showing extracapsular silicone in the axilla and internal mammary lymph nodes. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica.

– Extracapsular silicone can be seen in the parenchyma, lymph nodes, or soft tissues (Fig. 21.34).

21.3.1.3 Follow-Up Protocol

1. Patients without a personal history of breast cancer:

Ruptures are frequently asymptomatic, and a clinical examination alone is not enough for diagnostic purposes. It is necessary to establish a diagnostic algorithm based on imaging in these patients.

Many studies show MRI as the technique of choice for evaluating the integrity of implants with a sensitivity of 72–94% and specificity of 85–100% and its superiority in detecting intracapsular rupture. This superiority of MRI, as well as the fact that the risk of rupture increases with implant longevity, has led the US FDA to recommend screening with MRI every 2 years from 3 years since the implant placement. However, due to its high cost and low availability, it is not routinely used as a screening method.

We recommend performing mammography as is performed for other patients without implants, according to age

and personal and family history but with the addition of Eklund projections and/or ultrasound.

This protocol could be:

- Mammography + Eklund projections ± Ultrasound
- Breast MRI when there are doubtful findings on mammography and ultrasound or when there are normal findings on mammography and ultrasound, but there is still a clinical suspicion of rupture.

2. Patients with a personal history of breast cancer:

Physical examination is more sensitive in operated patients. This is because over time the implant causes atrophy of the parenchyma and the implant shifts it to the skin (Fig. 21.35).

In addition, the sensitivity of mammography decreases over time. As such, we recommend that screening of these patients should include Eklund projections ± breast ultrasound. Breast MRI has the greatest sensitivity (Fig. 21.35), but it should be only used in doubtful cases of rupture. However, if the patient is younger than 50 years of age and has personal history of breast cancer and reconstructive surgery with implants, some protocols recommend an annual breast MRI as a screening method with the mammography and ultrasound.

Different options:

For symptomatic patients with suspected ruptures, ultrasound is the imaging technique of choice at the time of symptoms.

For asymptomatic patients, it is best to perform regular screening according to age but with the addition of Eklund projections and possibly ultrasound.

For patients with a history of breast cancer, specifically, if they have breast-conserving surgery and reconstructive surgery with an implant, it is best to perform a bilateral mammography along with Eklund projections and ultrasound annually. In patients who have had mastectomy and then reconstructive surgery with an implant, an annual ultrasound is recommended; mammography is not performed except in some cases where a single mammography is performed postsurgically to check for the absence of residual breast parenchyma.

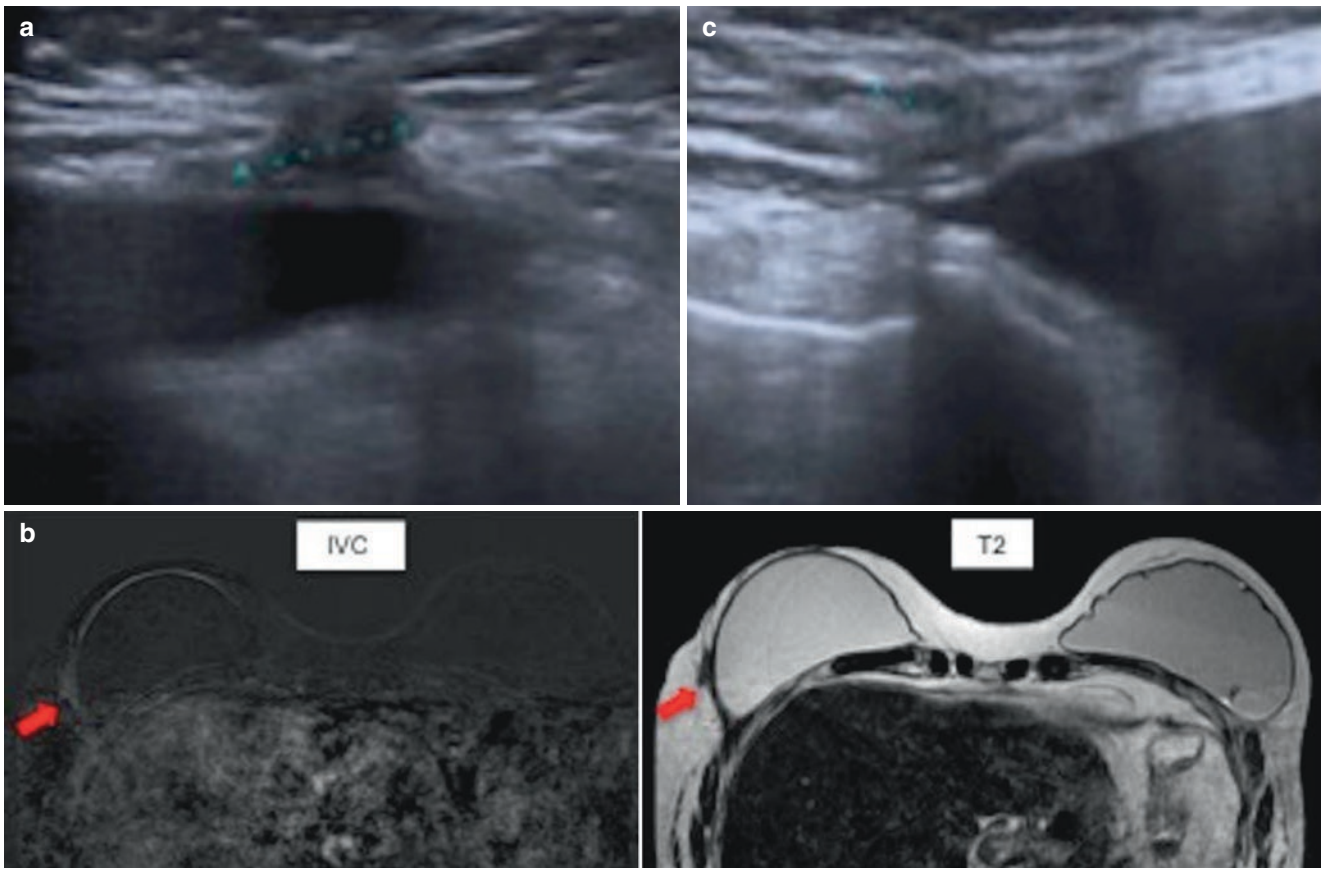

Fig. 21.35 Patient with a personal history of bilateral mastectomy. The patient noted a lump in the LOQ of right breast. (**a**) Ultrasound showing an ill-defined margin lesion in that location, adjacent to the implant, highly suggestive of malignancy. A breast MRI was performed due to difficulty in differentiating the suspicious finding from scar. (**b**) The lesion seen on ultrasound shows slight enhancement but irregular and ill-defined margins. (**c**) In a superior slice, another lesion is observed in the right UOQ with similar characteristics as the main lesion. (**d**) Second look ultrasound shows another ill-defined lesion in the UOQ, corresponding to the lesion observed on MRI. Both lesions were invasive ductal carcinoma confirming a multicentric recurrence after a bilateral mastectomy

Breast MRI is performed only in cases where conventional tests (mammography and ultrasound) are doubtful or inconclusive for rupture, when there are clinical suspicions of possible complications of the implants and as a screening method in patients with personal history of breast cancer younger than 50 years old.

21.3.2 Biological Mesh and Acellular Dermal Matrix

21.3.2.1 Radiological Tests and Findings

1. *Mammography*: Mammography is not usually performed in patients who have undergone mastectomy.
2. *Ultrasound*: Ultrasound is prone to pitfalls if it is unknown whether the patient has a biological mesh. Nodular or pseudo-nodular lesions are seen where the mesh is attached to the implant or the pectoral or serratus muscles (Fig. 21.36). They may present uncircumscribed margins and may lead to a core needle biopsy damaging the biological mesh.
3. *MRI* (Fig. 21.36) *and CT*: These tests help differentiate those images as they are usually bilateral and symmetrical (when the mastectomy and reconstruction are bilateral), show benign characteristics, and do not show enhancement after IVC administration.

21.3.3 Free Silicone Injection (Silicone Mastopathy)

21.3.3.1 Radiological Tests and Findings

Radiological features of free silicone are similar to that of an extracapsular rupture, although without an implant:

1. Mammography (Fig. 21.37):
   - Extremely dense masses ± rim calcification
   - Distortions
   - Breast asymmetries
   - Diffuse increase of parenchymal density complicating the display and assessment of suspicious lesions
   - Extremely dense lymph nodes
2. Ultrasound:
   - Nodular lesions with snowstorm sign
   - Nodular lesions with benign characteristics (oval and well defined, without shadowing)
   - Hypoechoic and/or heterogeneous nodules
   - Nodular lesions or areas with shadowing obscuring the posterior breast
3. MRI:
   - It is especially useful in clarifying clinical suspicions and/or uncertain diagnosis with ultrasound or mammography.

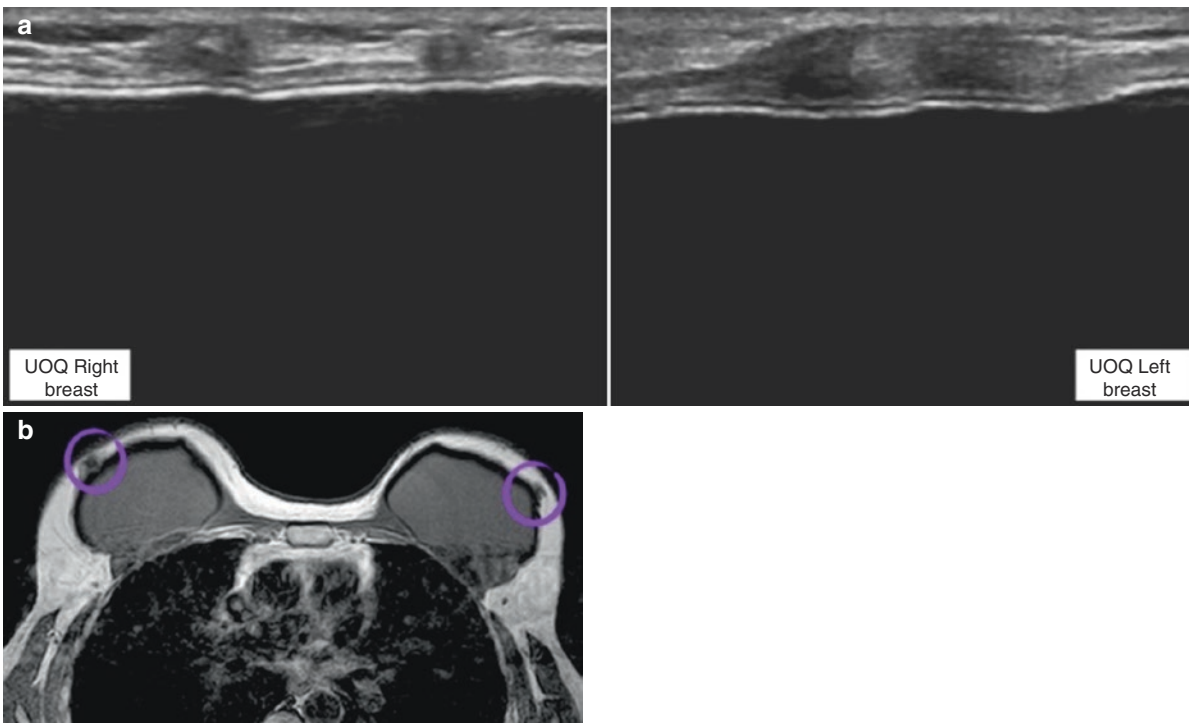

Fig. 21.36 Patient with bilateral mastectomy and heterologous reconstruction in a single surgical procedure with silicone implants and biological mesh. (**a**) First follow-up ultrasound shows nodular and solid appearance images, with ill-defined margins located in some locations. A core biopsy was recommended but as the patient had a recent bilateral mastectomy without complications and free margins, and an MRI was requested. (**b**) Breast MRI T1 sequence shows bilateral, symmetrical and hypointense nodular lesions in the junction areas of the mesh with the implant and the chest wall that had produced the sonographic pitfall

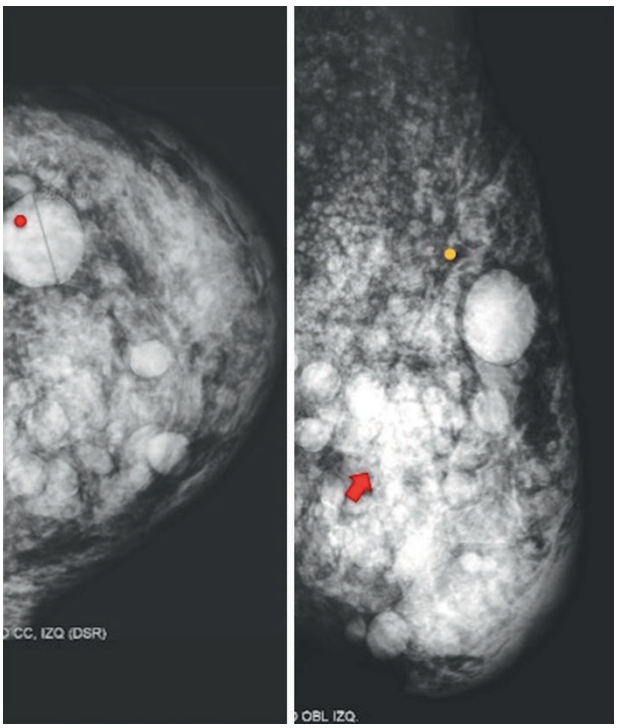

Fig. 21.37 Patient with free silicone injection in the thickness of the breast parenchyma. Right breast mammogram (oblique and craniocaudal views): There is a diffuse increase of breast density (*red arrow*), some distortion image (*yellow dot*), and some circumscribed and dense nodules (*red dot*). Some of these findings may be suspicious only with mammogram, preventing the dismissal of malignancy in the breast cancer screening. This image appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

- Nodules with benign characteristics, with the same signal as silicone, without enhancement after IVC.
- Nodules with peripheral enhancement after IVC administration due to granulomatous reaction. If there is some doubt, a cytohistological exploration should be done.

21.3.4 Hyaluronic Acid

21.3.4.1 Radiological Tests and Findings (Fig. 21.38)

On mammography and ultrasound, findings are similar to those for free silicone injection. On MRI, nodules are similar to fluid nodules except when there is a granulomatous reaction:

1. *Mammography*: Usually dense and well-defined masses
2. *Ultrasound*:
   - Solid appearance lesion.
   - Simple, complicated, and complex cystic lesion. Over time the lesions usually evolve to a more solid appearance.
   - Septate and interconnected collections.
3. *Breast MRI*:
   - Lesions with identical signal intensity as fluid on T1 and T2 sequences, without enhancement after IVC administration.
   - Lesions with peripheral enhancement when granulomatous reaction is produced.

In any case, sometimes hyaluronic acid can produce images mimicking solid lesions that may show enhancement. It can also hinder the display of remaining breast parenchyma and consequently the diagnosis of breast cancer if it occurs.

21.4 Imaging Findings After Surgery with Autologous Material

In breast surgery using autologous material, the surgeon uses autologous or endogenous material from the body of the patient.

Autologous reconstruction, where the surgeon uses flaps from the body of the patient, is the technique of choice of all reconstructions using autologous material. It is less commonly performed compared to heterologous reconstruction, but its use has dramatically increased over the years. Among other factors, the number of mastectomies has increased, and autologous reconstruction offers several advantages over heterologous reconstruction, for example, better aesthetic outcomes, more natural-looking reconstructions, durability, better results over a radiated skin, and moreover, the technique is not limited by the amount of available skin after surgery. However, it also has several disadvantages. It is surgically more complex than heterologous reconstructions using implants. It is associated with a higher rate of complications such as in donor site as in neobreast and higher morbidity.

Free injection techniques using different autologous substances have also been developed. Lipofilling is a free injection technique similar to the injection of free silicone and hyaluronic acid; however, the fat used in lipofilling is autologous, and the technique is completely accepted worldwide. Lipofilling has several advantages over other free injection techniques, for example, the autologous fat avoids the possibility of rejection and granulomas, increased risk of breast cancer has not been demonstrated, and the free fat will have a similar appearance than breast fat, so it should not interfere with radiological interpretation on imaging and consequently with cancer diagnosis. For all those reasons, it is commonly used as a reconstructive technique and aesthetic procedure. However, sometimes new palpable lumps may appear mimicking cancer on imaging, requiring breast MRI or biopsy.

NAC reconstruction is also possible using autologous material. It is the final step after breast reconstruction in

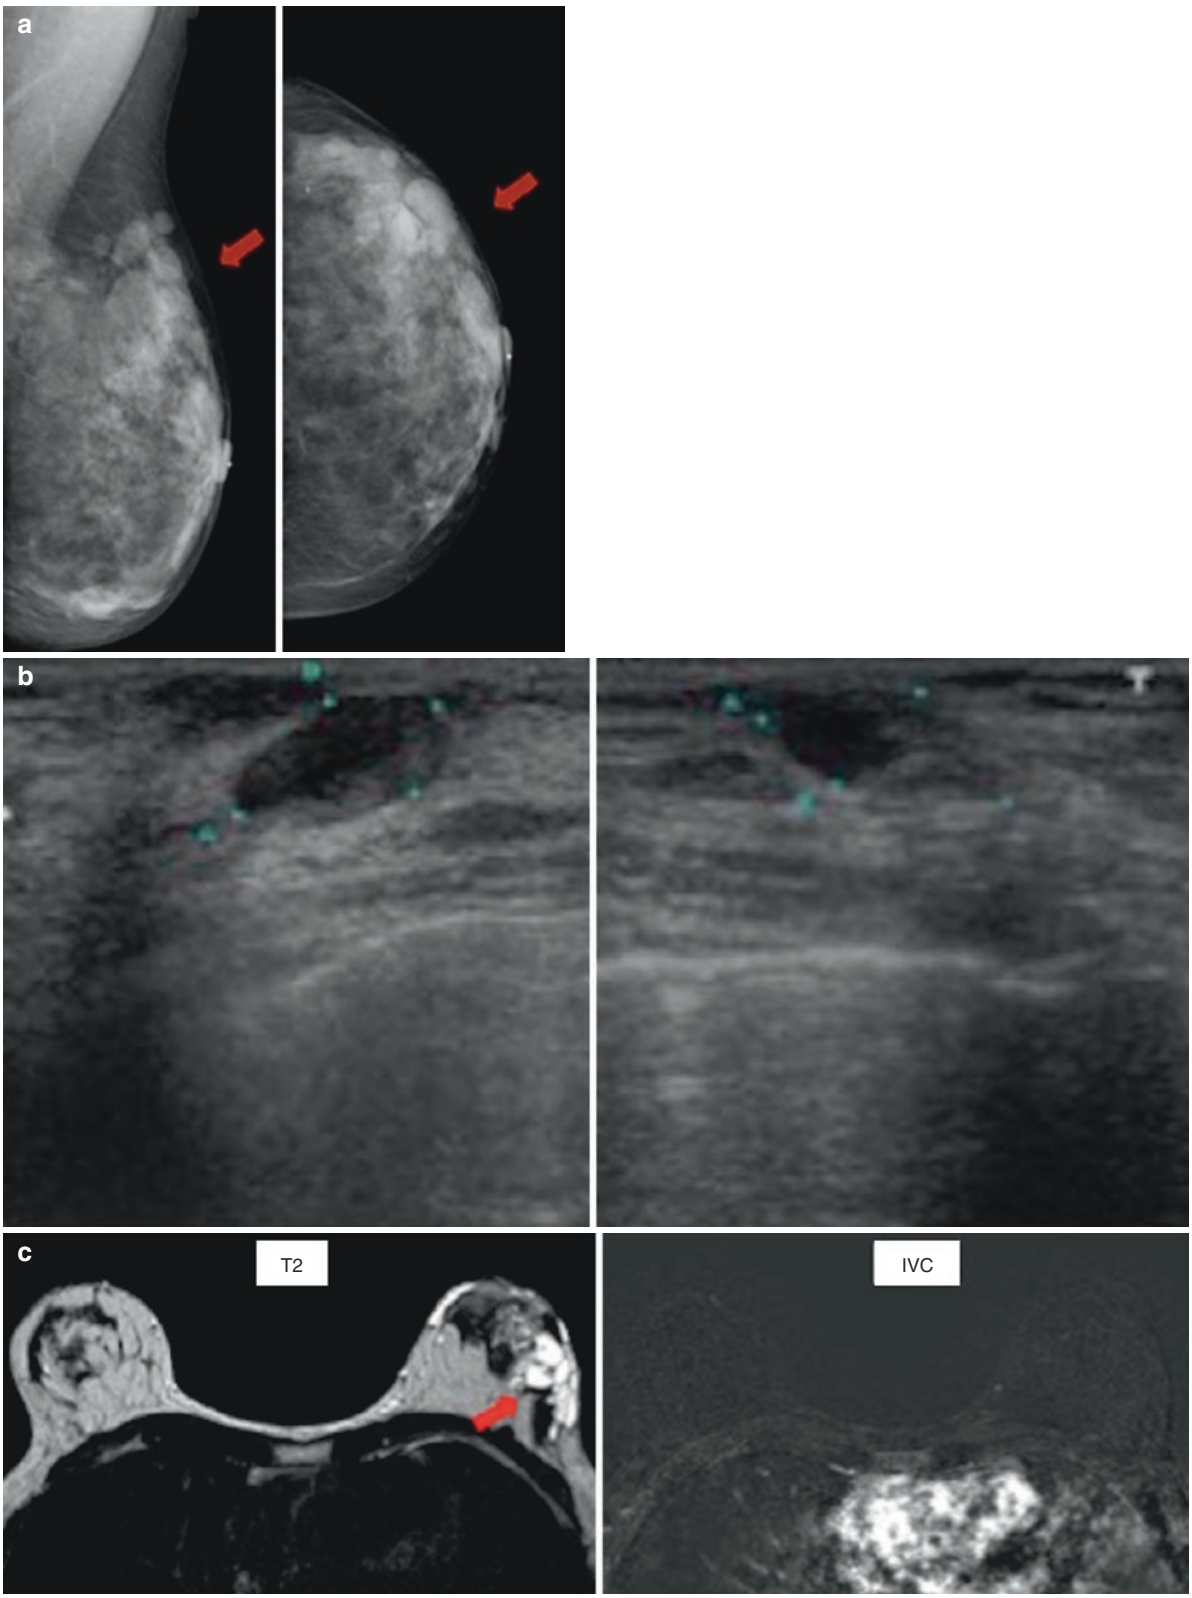

Fig. 21.38 Patient with free hyaluronic acid injection who had multiple palpable lumps at follow-up. (**a**) Mammogram of left breast (oblique and craniocaudal views): multiple nodular radiodense images, mostly located in the UOQ (*red arrow*), with some ill-defined margins and diffuse increased parenchymal density in the area. (**b**) Sonographic images: the mammographic nodules correspond to multiple nodular lesions (with complicated cystic and solid appearance) with uncircumscribed margins. (**c**) Breast MRI shows multiple nodules with an identical signal intensity of the liquid, different from the silicone and showing no enhancement in dynamic sequences. In this case, breast MRI allowed doubtful findings on mammogram and ultrasound to be solved. Figure 21.38b appeared in the European Aesthetic Plastic Surgery Journal (number 12). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

cases where the nipple is not preserved. The aim is to achieve greater symmetry and similarity in texture and color with the contralateral NAC. It is usually performed as a separate step after breast reconstruction when postoperative changes have stabilized (usually 6–8 weeks). Skin and subcutaneous tissue flaps are used (usually labia minora and the contralateral NAC when a mastopexy is also performed). Sometimes, only the nipple is reconstructed while the areolar area is tattooed.

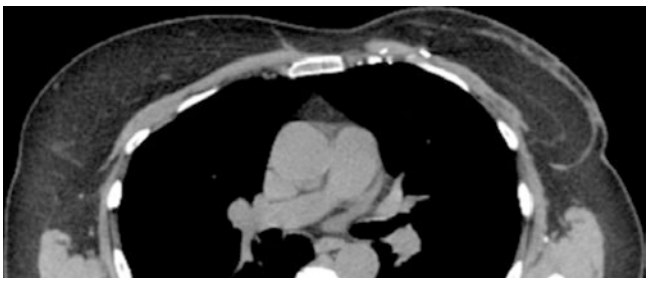

Fig. 21.39 Patient with left mastectomy and autologous reconstruction with DIEP flap. There is a contact line between the subcutaneous fat of the original breast and the flap fat. On CT there is a hyperdense line with variable thickness

21.4.1 Autologous Reconstruction

21.4.1.1 Radiological Tests

Physical examination and ultrasound are useful in the follow-up of patients who have undergone mastectomy without reconstruction. Nevertheless, they are less sensitive in patients who have undergone autologous reconstruction. Many tumor recurrences are located deep in the flap so they are not palpable. Reconstruction also decreases the contrast between the lesion (hypoechoic) and fat surrounding (hypoechoic too), rendering ultrasound ineffective. Frequent scars and fat necrosis often make it difficult to assess possible lesions with ultrasound and can produce hard palpable lumps that complicate the physical examination.

Mammography is useful in evaluating calcifications or microcalcifications by fat necrosis. It is also useful in detecting recurrence as it will increase the contrast between the flap (hypodense or fat) and possible recurrence (hyperdense).

Although breast MRI requires IVC administration, it allows the physician to distinguish benign tissue from recurrence in many cases because it can demonstrate fat inside the lesion (fat necrosis) or absence of enhancement after administration of IVC.

21.4.1.2 Radiological Findings

1. Distinguishing different types of flaps on imaging:

It is important to be able to differentiate different types of flaps on imaging, since clinical information often does not specify what type the patient has. Fat is key to recognizing an autologous flap in general. All flaps have in common the transfer of skin and fat and therefore, a fatty breast will be seen in all radiological tests. Muscle indicates a myocutaneous flap. The muscle is seen as a soft tissue density although there are atrophic changes over time and its appearance becomes more fatty. Vascularization is key to recognizing a muscle-sparing free flap with vascular anastomosis. Vascularization is assessed on breast MRI. The internal mammary region must be observed since this is the place where anastomosis was done and is sometimes the only sign of the presence of a flap or previous failed flap. It is important to note if there is IVC in the transferred vessels as this is a sign of viability.

There is a contact line formed between subcutaneous fat of the native breast and the fat transferred (Fig. 21.39). It is possible to distinguish three types of lines depending on its thickness: type 1, thickness smaller than 1 mm (almost not visible); type 2, thickness from 1 to 3 mm; and type 3, thicker than 3 mm. If the line increases in thickness after a month of surgery, then a recurrence, infection, or inflammation should be considered.

Characteristics of the main flaps:

- *Pedicled TRAM flap* (Fig. 21.40): Fatty breast is seen. Muscle density is seen anteriorly to the chest wall in a triangular shape. On breast MRI, the muscle density can be followed distally going to the abdomen (usually contralateral hemi-abdomen). In abdominal slices (CT or MRI), the absence of one rectus abdominis muscle and signs of postsurgical changes (metallic clips) can be seen.
- *Free TRAM flap* (Fig. 21.41): Fatty breast is seen. As in the pedicled TRAM flap, a muscle density is seen anteriorly to the chest although when there is atrophy this is not possible. The muscular density does not continue to the abdomen. In abdominal slices (CT or MRI), only a partial defect of the rectus muscle is seen. Postsurgical changes in the mammary internal region are seen because of vascular anastomosis in that area.
- *DIEP flap* (Fig. 21.42): Fatty breast is seen. There is no muscle density because there is no muscle transferred. In abdominal slices, the rectus muscle is complete although postsurgical changes can be seen as there are metallic clips inside it due to the harvesting of perforating branches of deep epigastric artery. Postsurgical changes are also seen in the internal mammary chain because of vascular anastomosis.
- *SIEA flap*: Fatty breast is seen. There is no muscle density because there is no muscle transferred. In abdominal slices, a complete and intact rectus muscle is seen, without any postsurgical change.

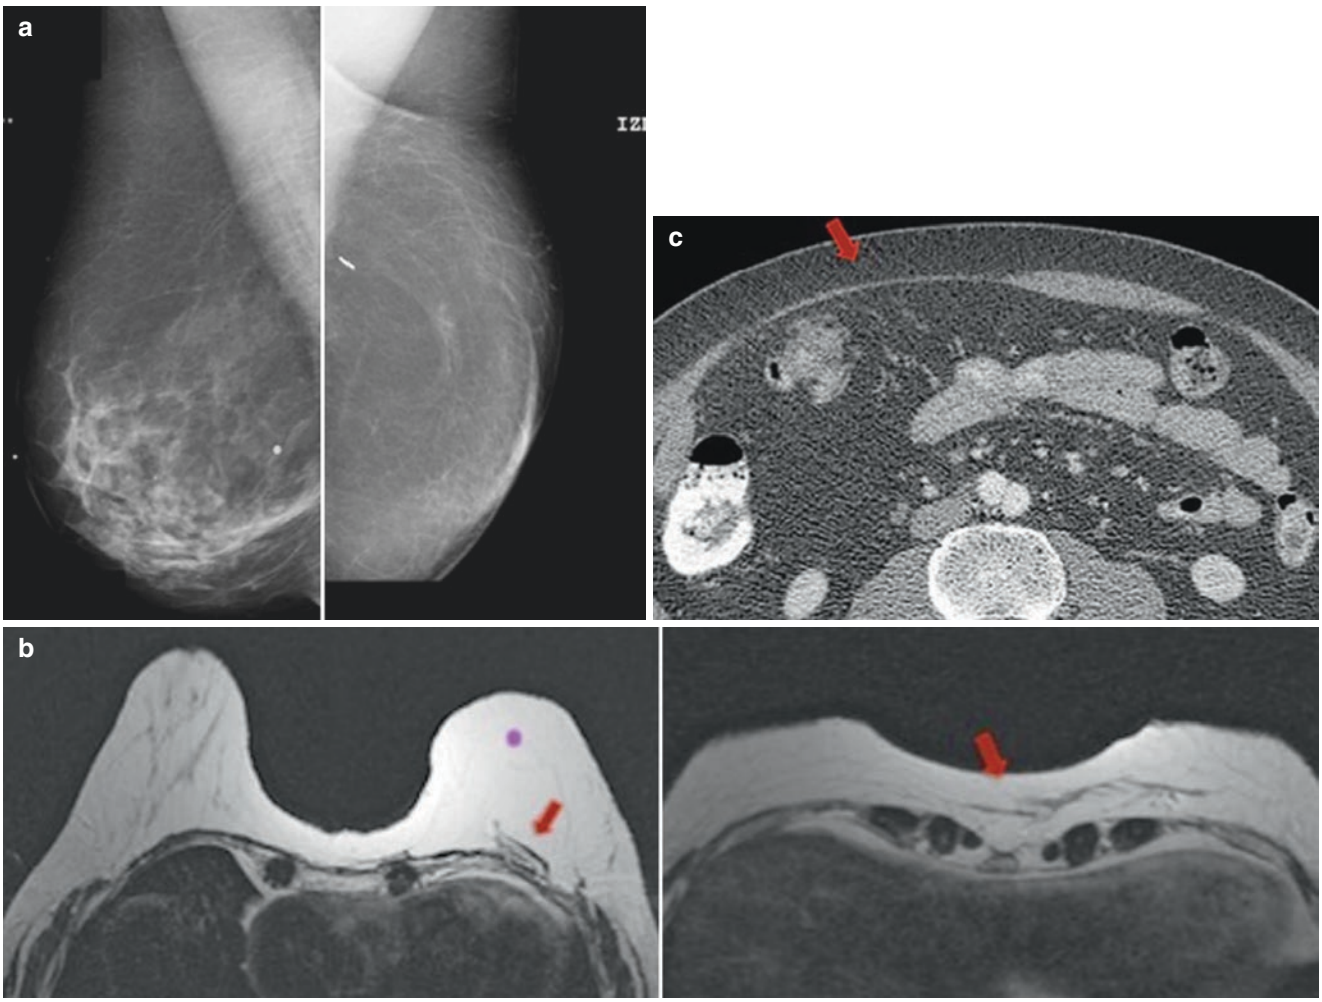

Fig. 21.40 Patient with left mastectomy and autologous reconstruction with pedicled TRAM. (**a**) On mammogram, a left fatty breast and the presence of metallic clips are indicating the presence of an autologous reconstruction. (**b**) Breast MRI with axial T2 sequence in two different slices: In the more superior slice, a left fatty breast (*purple dot*) is confirmed, and there is a muscle structure (*red arrow*) just beside to the anterior chest and the pectoralis muscle wall corresponding to a muscle with some hyperechoic lines inside relating to fatty atrophy. In the lower slice, the muscular density crosses the midline going to the abdomen. That is the key to knowing it is a pedicled TRAM flap. (**c**) Abdominal CT with IVC administration shows the absence of the right rectus abdominis muscle confirming the pedicled TRAM

- *LDM flap* (Fig. 21.43): Fatty breast is seen. The muscle density is seen as a band that comes from the back and parallel to the chest wall. When it is combined with an implant, it is usually seen posterior to the muscle band and is easily recognized on mammogram and the other tests. However, when there is only a partial defect or when it is not combined with an implant, it may be more difficult to recognize it on mammogram if the type of reconstruction is unknown. MRI will be useful (Fig. 21.13).
- *TDAP flap* (Fig. 21.44): Fatty breast is seen. There is no muscle density because there is no muscle transferred. Some vessels can be identified going to the back, related to the thoracodorsal pedicle.

It is important to examine all slices (from the most proximal to the most distal or superior abdominal slices). Special emphasis should be placed on these areas: the internal mammary chain (if there are postoperative changes, then there was microsurgery followed by a free TRAM, DIEP, SIEA, TUG, SGAP, or IGAP flap), the neobreast (if there is a muscle density, then there is a TRAM or LDM flap), the lateral chest wall looking at the latissimus dorsi muscle or its vascular pedicle (which indicates a LDM or TDAP flap), and finally the lower slices (if there is a muscle band, then there is a TRAM flap). All these are important especially in cases where a second flap has to be done because of a previous failure of another flap. It is possible to see a transferred LDM flap and postsurgical changes in the internal mammary chain, which means a previously failed DIEP or free TRAM flap. Another possibility is seeing a transferred LDM flap without an implant and asymmetry in relation to the contralateral breast suggesting complication and removal of the implant

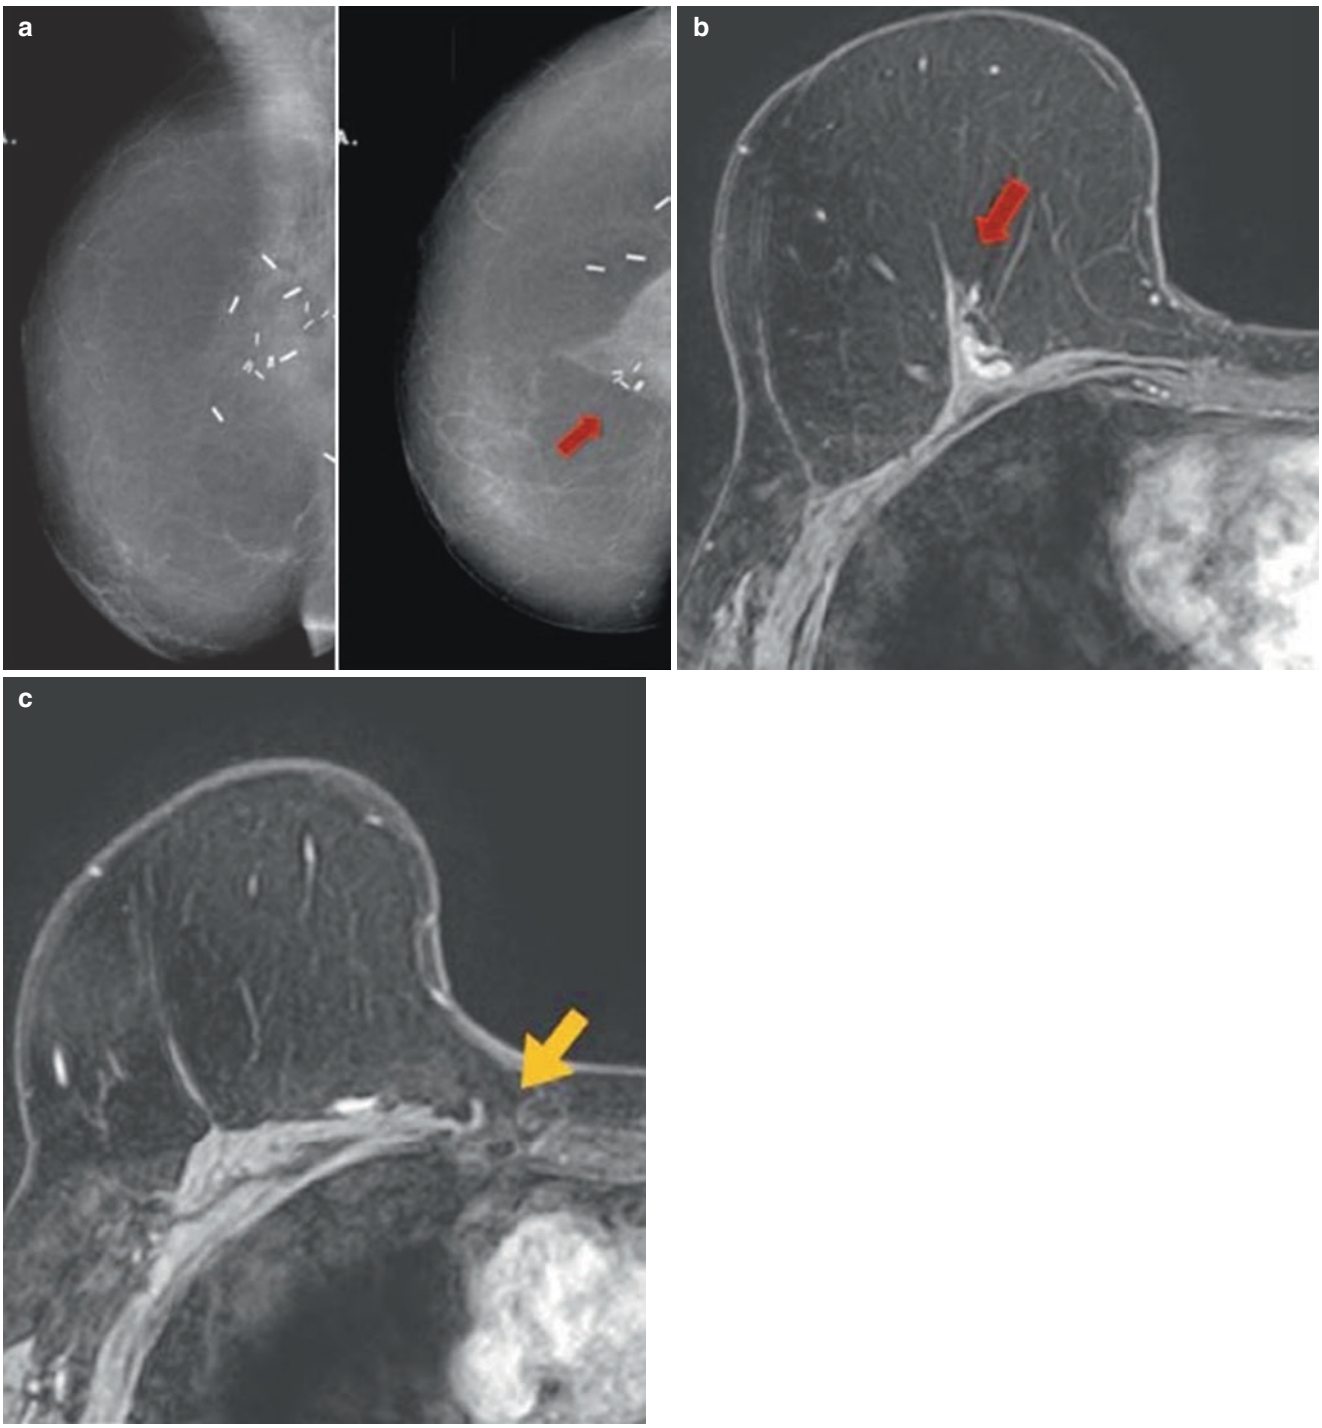

Fig. 21.41 Patient with right mastectomy and autologous reconstruction with free TRAM flap. (**a**) On mammogram, a muscular density is seen anteriorly to the chest wall and the pectoral muscle (*red arrow*). (**b**) Breast MRI with dynamic sequences showing the muscle transferred anteriorly to the pectoral muscle, with metallic clips and some vessels indicating good viability of the flap. (**c**) Breast MRI with dynamic sequences in an upper slice, at the level of the internal mammary vessels. The postoperative changes in the internal mammary vessels (*yellow arrow*) indicate the presence of vascular anastomosis and the presence of a free TRAM flap

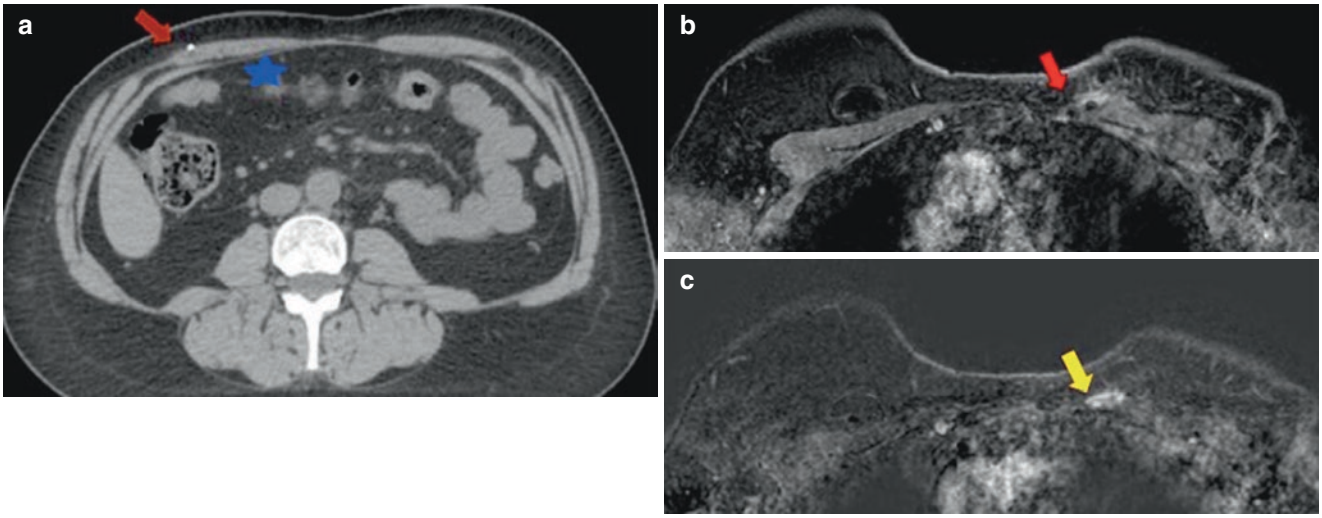

Fig. 21.42 Patient with left mastectomy and autologous reconstruction with DIEP flap. (**a**) Abdominal CT shows metallic clips (*red arrow*) on the rectus abdominis muscle indicating postoperative changes. However, the muscle is complete so it is not a free TRAM flap but a DIEP flap (*blue star*). (**b**) Dynamic sequence breast MRI shows metallic clips (*red arrow*) in the area of the internal mammary chain indicating the presence of vascular anastomosis. (**c**) Axial first subtraction sequence shows good vessel enhancement (*yellow arrow*) in the anastomosis, indicating good viability of the flap

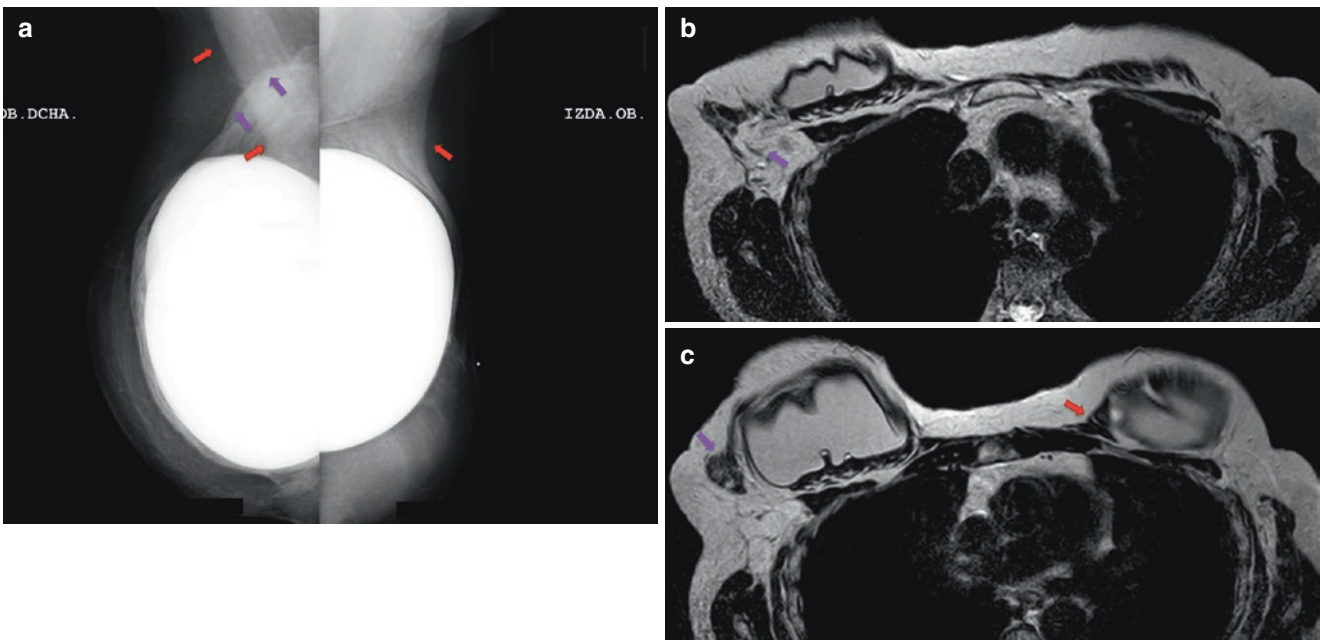

Fig. 21.43 Patient with bilateral mastectomy who had autologous reconstruction with an implant and LDM flap in the right breast and heterologous reconstruction in the left breast. The patient presented with a right axillary palpable lesion. (**a**) Mammography with oblique projections of both breasts: Both implants can be seen. In the left breast, the implant is located posteriorly to the pectoralis muscle (*red arrow*). In the right breast, the implant is located anteriorly; soft tissue visualized corresponds to the LD muscle (*purple arrow*) and the palpable area corresponds to the prominent and thick LD muscle containing fat just below. (**b**) and (**c**) Breast MRI T2 sequences confirm the presence of the pectoral muscle (*red arrow*) (posteriorly to the implant in the right breast and anteriorly in the left breast) and the LD muscle coming from the back and located anteriorly to the implant in the right breast making a prominence in the axillary region

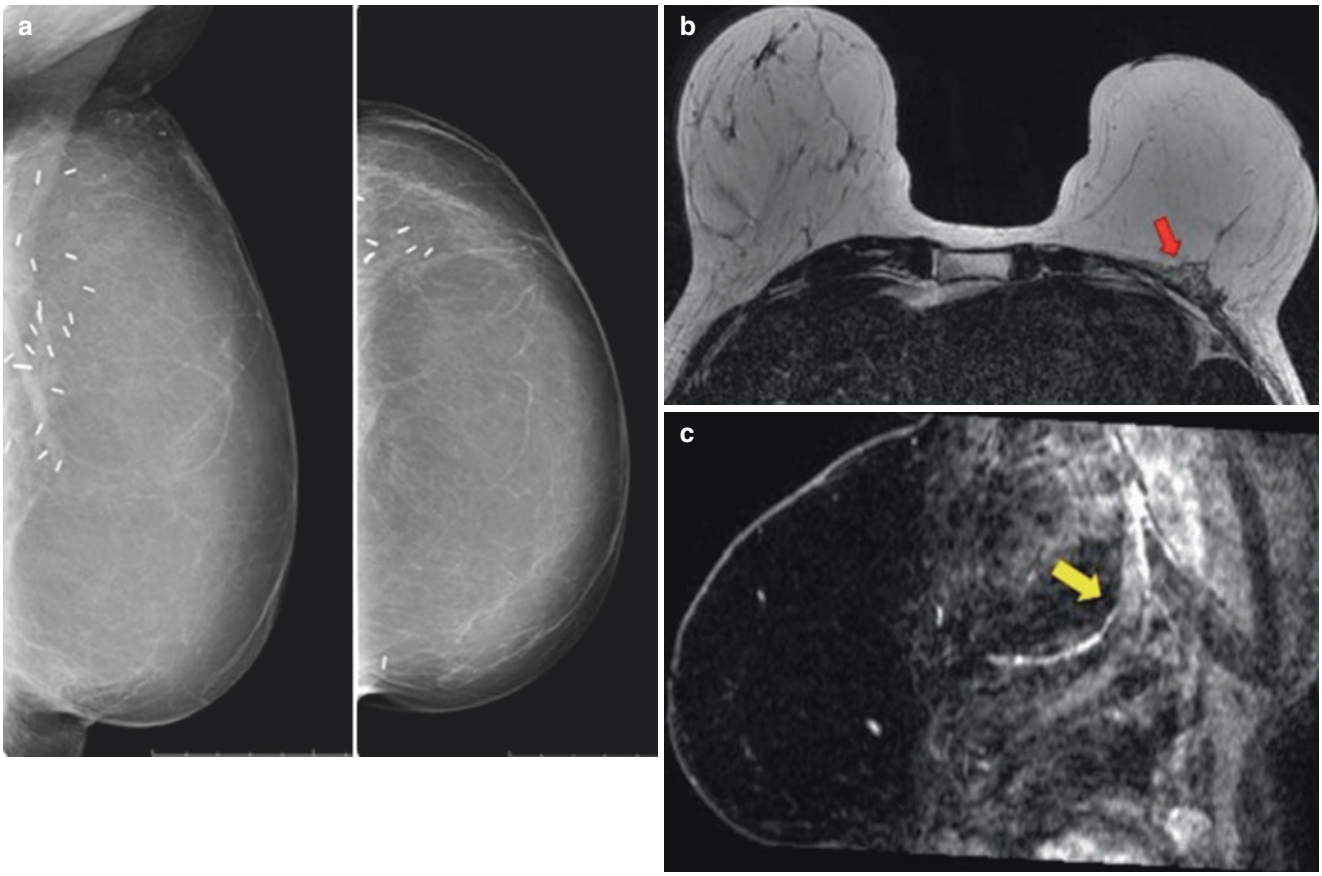

Fig. 21.44 Patient with left mastectomy. The patient had a failed autologous reconstruction with pedicle TRAM flap and later underwent a new autologous reconstruction with TDAP flap. (**a**) Mammogram shows a fatty breast with metallic clips that suggested a reconstructed breast. (**b**) Breast MRI with T2 sequence confirms the presence of a fatty and reconstructed breast with a muscular structure anteriorly to the pectoral muscle suggesting a TRAM flap (*red arrow*). (**c**) However, on a sagittal reconstruction of a dynamic sequence, a vascular structure (*yellow arrow*) is seen coming from the back corresponding to a perforating branch of the thoracodorsal artery and without any accompanying muscle, indicating a TDAP flap

(Fig. 21.45). An LDM or TDAP flap with perforating vessels going to the back and a muscle density in the deep of the neobreast indicates a previously failed TRAM flap and a second attempt with an LDM flap or a TDAP flap (Fig. 21.44).

2. Assessing complications of the neobreast:

Fat necrosis is one of the most common complications, especially with a pedicled TRAM flap. It is often caused by problems in the vascularization of the flap. Clinically it is suspected because the patient notes a new, hard, and palpable lesion, close to the scar. It is easily confused with recurrence. Radiologically, it is said to be a great imitator of cancer and complicates differential diagnosis. On mammogram, calcifications (from benign to punctate or pleomorphic calcifications) (Fig. 21.46), dense masses with irregular margins or even distortion images can be seen. On ultrasound, a wide spectrum of findings can be seen, from typically benign oil cysts (which are often mistaken for simple cysts) or hyperechoic lesions because of the presence of fat to hypoechoic, solid, and poorly defined lesions (Fig. 21.47). On breast MRI, a wide spectrum of findings can also be seen: typical image of an oil cyst (well-defined, oval, or round lesion hypointense on T2), a fat-containing solid lesion (hyperintense on both T1 and T1 sequences, suppressed on fat suppressed images that may or may not present peripheral or eccentric enhancement after IVC) (Figs. 21.46 and 21.49), or an irregular lesion with suspicious enhancement after IVC (Fig. 21.47). Conventional tests are enough to diagnose typically benign findings, whereas a breast MRI and/or biopsy are needed to diagnose BI-RADS® 4 and 5 lesions.

Venous congestion (Fig. 21.48) occurs especially in cases where vascular anastomosis is required. Mammographically, a diffuse increase density is seen (whereas usually a low or hypodense density is presented because of fat). On ultrasound, cutaneous and trabecular thickening and diffuse increased echogenicity of fat are seen. On breast MRI, edema and a diffuse increased enhancement related to inflammatory changes are seen.

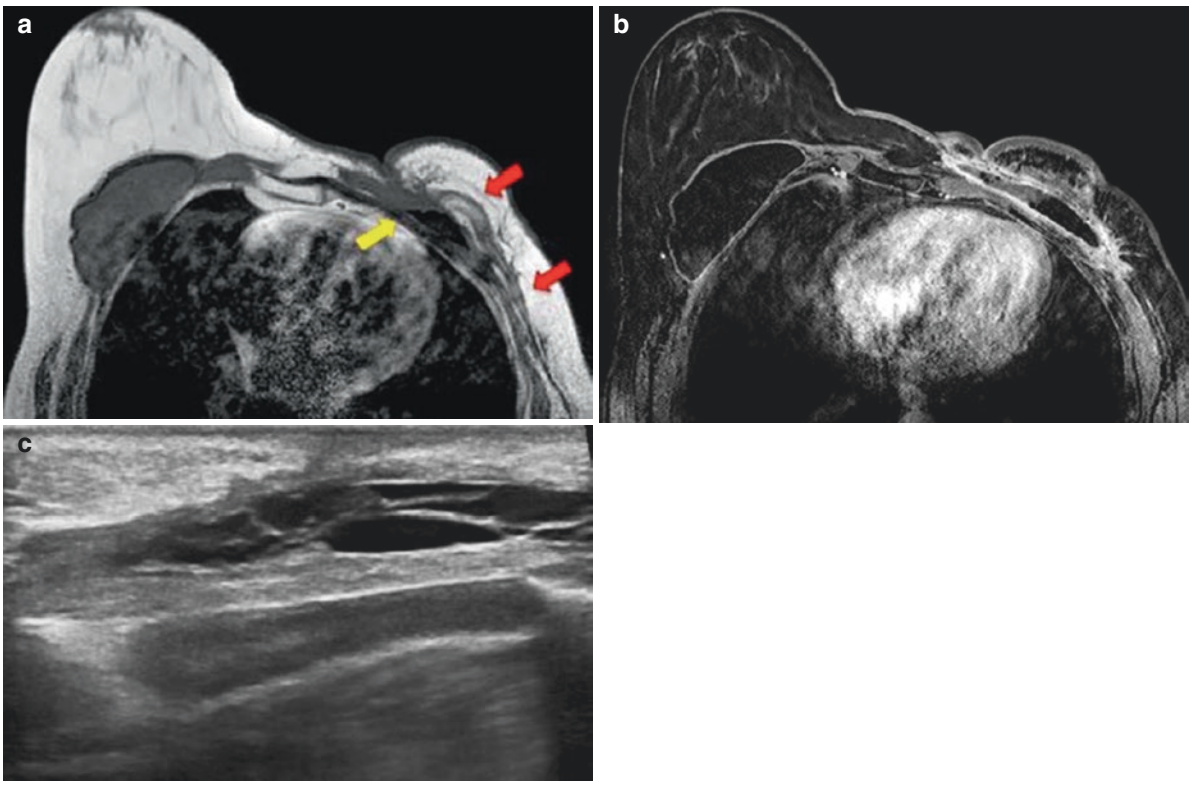

Fig. 21.45 Patient with left mastectomy and failed autologous reconstruction with LDM flap and implant. Due to recurrent peri-prosthetic infection, the implant was eventually removed but the transferred LD stayed. (**a**) Breast MRI with T1 sequences shows the LDM flap (*red arrow*) coming from the back and located anteriorly to the pectoral muscle and also anteriorly to a complex and fluid collection (*yellow arrow*) relating to residual abscess. (**b**) The dynamic sequence shows a thick peripheral enhancement around the collection suggesting infection. (c) Ultrasound shows a tabicated fluid collection; an FNA was performed to obtain an antibiogram

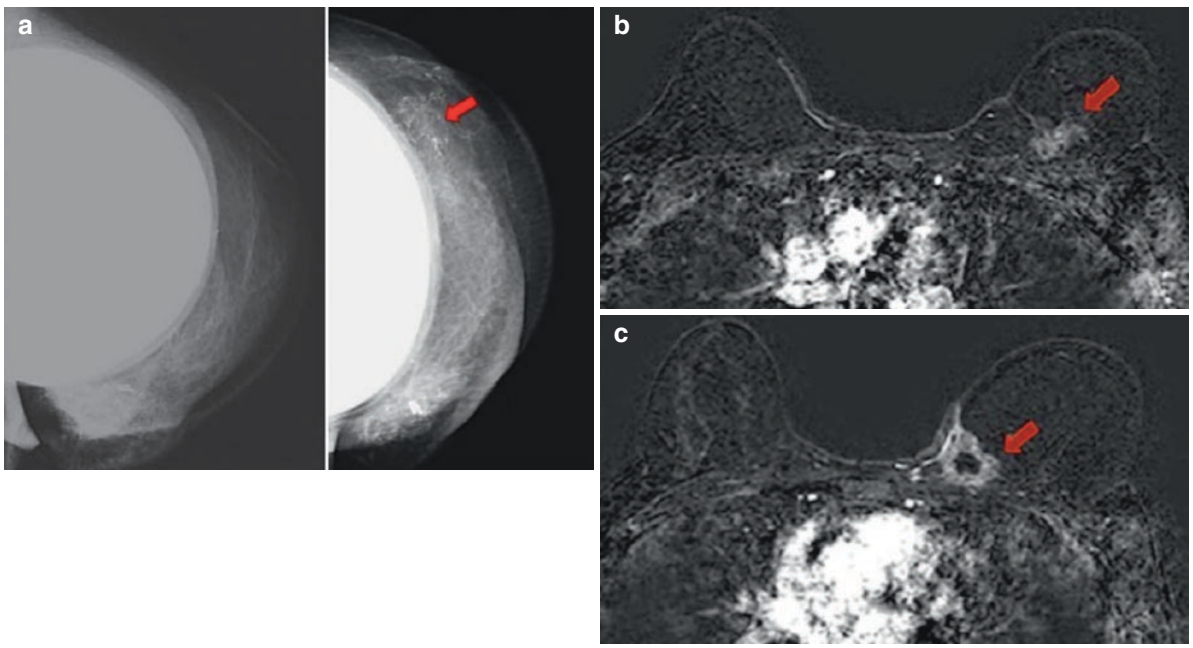

Fig. 21.46 Patient with left mastectomy and autologous reconstruction with LDM flap and implant. The patient had capsular contracture and also noted a new palpable lump in the outer quadrants of the left breast underlying scar. (**a**) Craniocaudal and Eklund projections of the left breast: When the implant was pushed back, a group of new pleomorphic calcifications (*red arrow*) is seen in the outer quadrants that correlated with the palpable area. Those calcifications would be suspicious but a breast MRI was performed. (**b**) A dynamic sequence in a superior slice shows the presence of heterogeneous and ill-defined enhancement in that area. (**c**) In a lower slice, the lesion shows a fat center, indicating fat necrosis. Biopsy was not recommended. Figure 21.46a appeared in the European Aesthetic Plastic Surgery Journal (number 14) and Figures 21.46b and 21.46c appeared in the European Aesthetic Plastic Surgery Journal (number 13). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

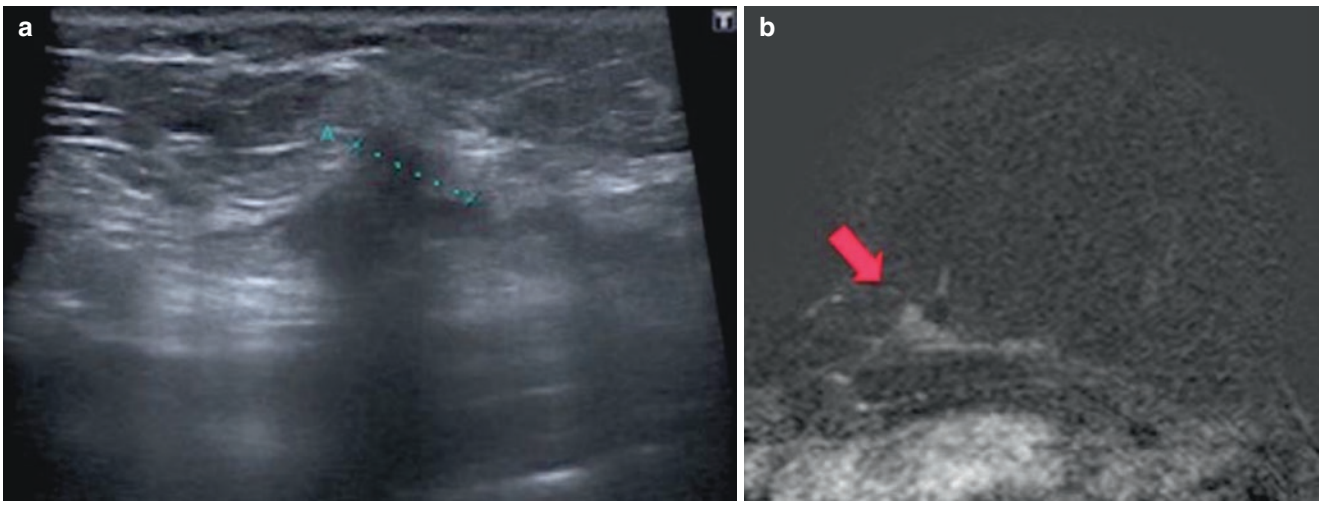

Fig. 21.47 Patient with left mastectomy and autologous reconstruction with DIEP flap. The patient had a superficial, palpable lesion in the UIQ of the left breast. (**a**) Ultrasonography shows a suspicious irregular hypoechoic and poorly defined lesion, with posterior acoustic shadowing. (**b**) Subtracted image after IVC administration: An irregular and ill-defined lesion in that area is seen without a fat center. A core biopsy was performed with fat necrosis result. In this case, the biopsy was necessary to demonstrate the fat necrosis

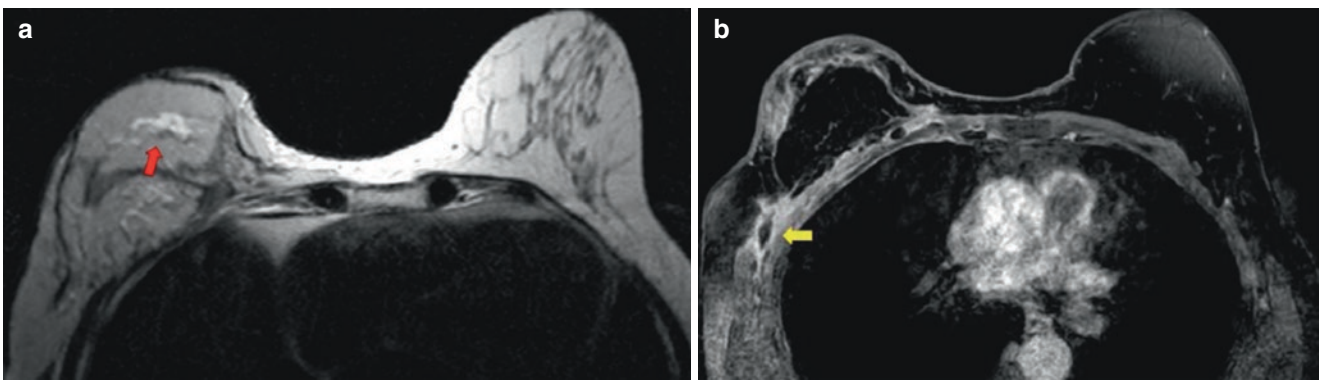

Fig. 21.48 Patient with right mastectomy and autologous reconstruction with DIEP flap who had complications with congestive changes. (**a**) Breast MRI T2 sequence shows edema, cutaneous and trabecular thickening, and fluid collection (*red arrow*). (**b**) Dynamic sequence after IVC administration shows irregular enhancement, predominantly in the periphery of the flap, in the periphery of an organized fluid collection beside the flap (*yellow arrow*), and in the vascular areas. The appearance in some slices looked like an implant. This image originally appeared in the European Aesthetic Plastic Surgery Journal (number 14). Reproduced with permission from the Asociación Española de Cirugía Estética Plástica

Fluid collections (Fig. 21.49) are usually related to postoperative seroma with simple cyst appearance. Sometimes a complicated or complex cyst can be seen, and then the possibility of bleeding, secondary infection, or abscess (Fig. 21.45) should be considered.

Imaging can also assess tissue necrosis and wound closure failure.

21.4.1.3 Follow-Up Protocol

The possibility of recurrence after breast-conserving surgery and mastectomy is low. In autologous reconstruction, the recurrences are located predominantly in two areas:

- *Superficial zone*: in the contact line between the flap and the subcutaneous fat of the native breast. It is usually detected by physical examination although sometimes it can be an incidental finding in a screening test (Fig. 21.50). On imaging, special attention should be paid to the variations and increases of thickness of that line that are not justified by infection or inflammation.
- *Deep zone*: in the posterior margin of the bed mastectomy, typically along the pectoralis major muscle, deep to the flap. Given its deep location, it is not usually detected by physical examination.

Since the incidence of recurrence is so low, there is debate about whether follow-up should be performed in these patients. However, possible screening with annual mammography and ultrasound has been suggested, relegating breast MRI to evaluating possible complications or indeterminate findings on conventional tests.

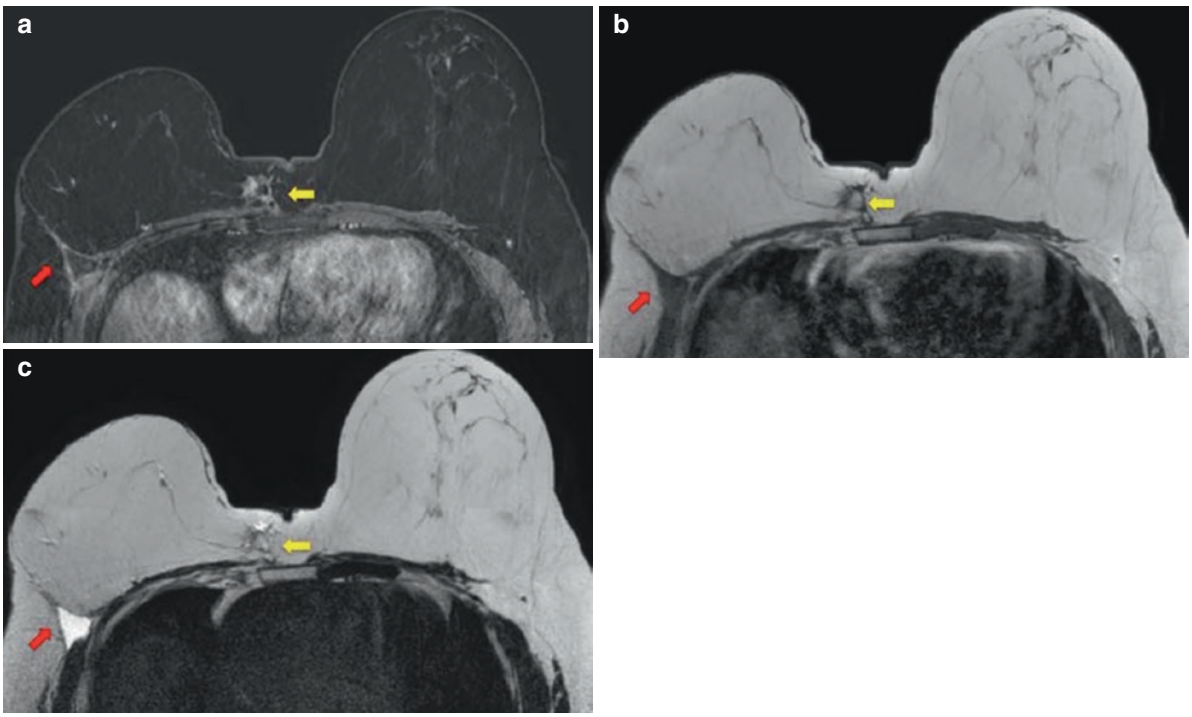

Fig. 21.49 Patient with right mastectomy who had a new palpable lesion in the inner quadrants. (**a**) Breast MRI dynamic shows a fluid collection in the outer quadrants (*red arrow*) with thin and low enhancement and an irregular lesion in the inner quadrants (*yellow arrow*) relating to the palpable lesion. (**b**) and (**c**) T1 and T2 sequences confirm the presence of a simple fluid collection relating to seroma in the outer quadrants and in the inner quadrants the palpable lesion has fat inside indicating fat necrosis. For that reason, biopsy was not necessary

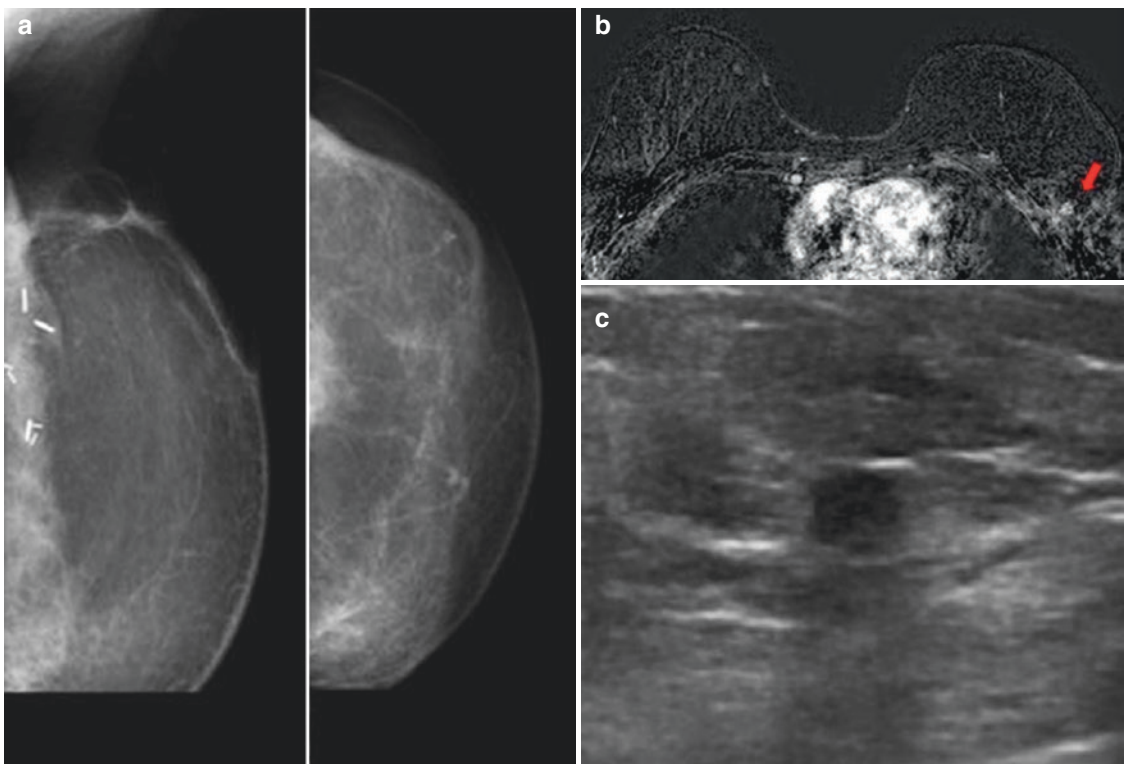

Fig. 21.50 Patient with left mastectomy and DIEP reconstruction with a millimetric recurrence visualized only on a follow-up MRI. (**a**) Left mammography shows a fatty breast without suspicious findings. (**b**) Breast MRI subtracted image shows a small, irregular and ill-defined lesion located in the contact area of the flap with the native breast in the outer quadrants, in the periphery of the flap (*red arrow*). (**c**) Second look ultrasound was performed; a millimetric lesion was found and biopsied with the result of invasive ductal carcinoma, confirming recurrence

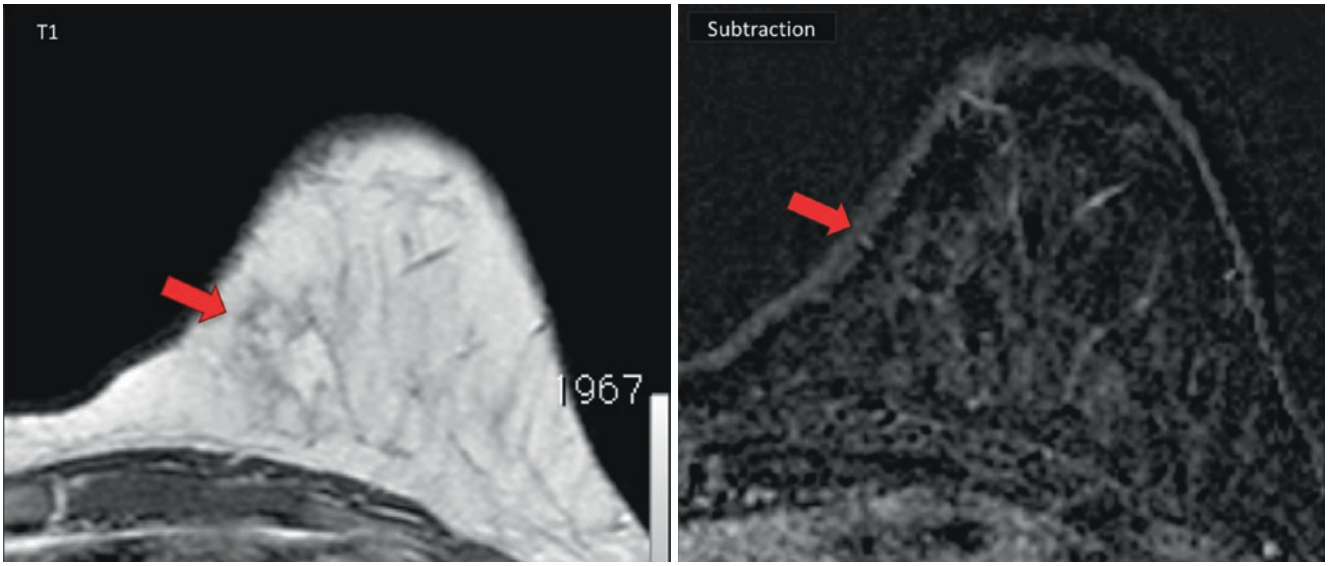

Fig. 21.51 Patient with a personal history of lipofilling for aesthetic reasons. After some time, she presented with a palpable lump at that location. However, conventional imaging tests (mammography and ultrasound) were completely normal. For that reason, an MRI was performed. Only a slight fat trabeculation in that area was seen, without any lesion and with no enhancement (*red arrow*), because the injected fat and the normal fat of the breast fused together. In cases like this where the patient's personal history is unknown, the radiological finding would be a BI-RADS® 1

21.4.2 Lipofilling, Lipomodeling, or Free Fat Grafting

21.4.2.1 Radiological Tests and Findings

1. BI-RADS® 1 Identical to normal breast fat (Fig. 21.51): It is the ideal situation. It is common for the radiologist not to identify a breast with lipofilling if he does not know the patient's clinical history. On mammogram, free fat will mix with the normal fat not giving any especial finding; only the breast will appear as a less dense breast due to free fat, consequently allowing better detection of possible cancer because of increased contrast with a radiodense mass or calcifications. On ultrasound and breast MRI, it would also be indistinguishable from the rest of the mammary fat.
2. BI-RADS® 2 Benign findings (Fig. 21.52): Oil cyst is the most common manifestation when the lipofilling shows radiographic abnormalities. Benign calcifications (usually coarse or rim calcifications) can also be seen. The breast MRI usually shows solid lesions with a fat center, without enhancement or with rim and thin enhancement related to fat necrosis. For that reason, it is important to review T1, T2, and fat suppressed sequences.
3. BI-RADS® 3 Probably benign findings (Fig. 21.53): Round or oval, well-defined solid lesions with type I enhancement curve or a new complicated cyst.
4. BI-RADS® 4 Suspicious findings (Fig. 21.54) especially due to fat necrosis. On mammogram, a distortion image or suspicious calcifications can be seen. On ultrasound, irregular solid lesions with posterior shadowing can be noticed and on MRI lesions with type II or III enhancement curves can be found.

21.4.2.2 Follow-Up Protocol

There is no established protocol because its use has increased only rather recently. Although it seems proven that this technique is not associated with an increase of breast cancer, there are still no conclusive and statistically significant studies regarding its association with complications and with radiological findings. For that reason, if it is possible, it is recommended to have a mammogram and/or ultrasound prior to the lipofilling. Some authors have even recommended performing a baseline mammogram 6 months after lipofilling to be able to assess posterior changes. However, many changes could happen after 6 months, for example, fat necrosis, and other findings change over time despite being benign. Additional tests and interventional procedures present a greater burden on the patient and increase anxiety and concern. For that reason, we try to distinguish two situations:

1. Symptomatic patient with a new palpable lesion: The mammogram and ultrasound should be performed. The breast MRI and/or biopsy may be performed if previous tests are inconclusive or if the patient has a personal history of breast cancer or high risk or family history.
2. Asymptomatic patient: annual mammogram ± ultrasound. Other option is to perform a mammogram and ultrasound 6 months after injection as baseline tests and later performing other tests if there are changes.

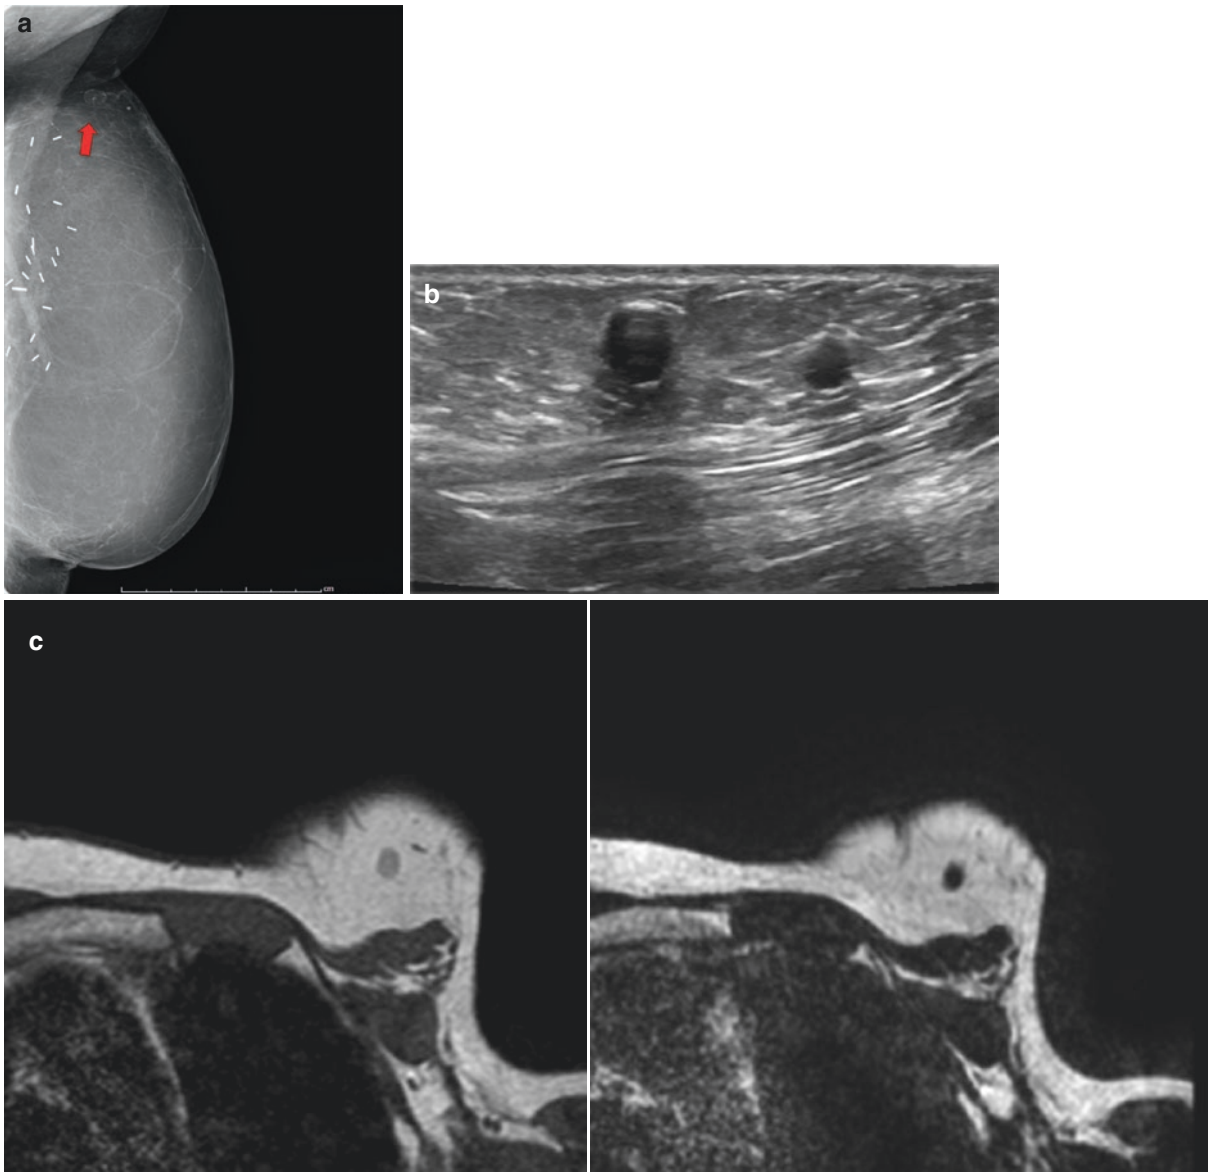

Fig. 21.52 Patient with left mastectomy and autologous reconstruction with a DIEP flap and lipofilling injection a second time in upper quadrants to fill a small defect. The patient presented with a new palpable lump at some time after injection. Mammogram, ultrasound, and MRI were performed, and a BI-RADS® 2 classification was made. (**a**) Oblique view of left mammogram only shows rim calcification related to the palpable lesion. (**b**) Ultrasound shows several lesions with simple cystic appearance. Although appearing as simple cysts they were really oil cysts as MR confirmed, being hypointense on T2, iso-/hyperintense on T1 and with no enhancement after IVC administration (**c**)

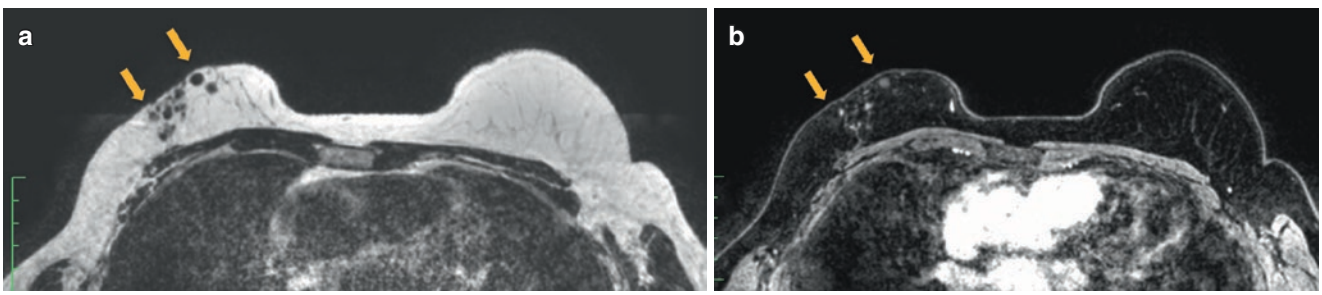

Fig. 21.53 Patient with right breast-conserving surgery and lipofilling in UOQ. The patient presented with some new palpable lumps in that area after lipofilling (*yellow arrows*). MRI shows (**a**) several round lesions, most of them well defined, hypoechoic on T2 and (**b**) with a soft enhancement with type I curve on subtracted image. With those characteristics, it was classified as BI-RADS® 3, and a follow-up was recommended

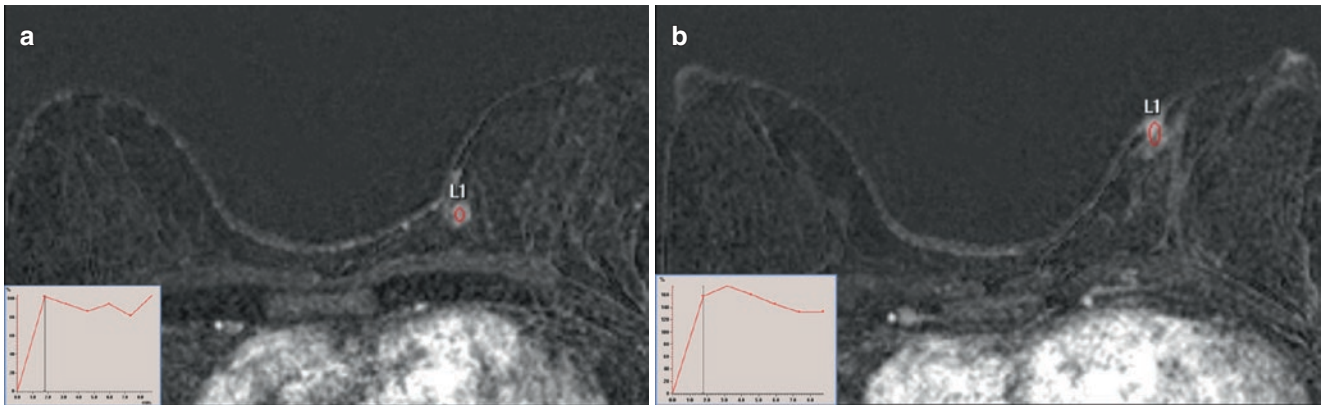

Fig. 21.54 Patient with a history of breast-conserving surgery in the UIQ of left breast with a lipofilling injection in that area. The mammogram did not show any significant finding, only metallic clips. Ultrasound showed several lesions with solid or complicated cystic appearance, but some of them had ill-defined margins. For that reason, MRI was performed. (**a**) One of the lesions shows well-defined margins but a type III curve. (**b**) Another lesion shows spiculated and irregular margins and a type III curve. Therefore, the lesions were classified as BI-RADS® 4, and cytology was performed with the result of fat necrosis

21.4.3 NAC Reconstruction

21.4.3.1 Radiological Tests and Findings

Findings on imaging are not common, but sometimes, when the reconstruction is very fresh, the following can be observed:

1. On mammogram: a radiodense periareolar line can be seen.
2. On MRI: areola skin thickening that can be asymmetrical to the contralateral NAC. Like in mastopexy, periareolar changes can be appreciated especially in gradient echo and fat suppression sequences. Sometimes the new NAC can enhance especially if the reconstruction is recent, which must not be confused with a malignancy. Other times a magnetic artifact produced by the tattoo ink can be observed.

Acknowledgments The authors would like to thank Dr. Martina Marin Gutzke from the San Rafael Hospital, Madrid, Spain, for providing surgical images, as well as Joanne Chin from Memorial Sloan Kettering Center for providing editorial support.

Integrated Breast Biopsy for Best Radiological Diagnosis of Breast Cancer

22

Enrico Cassano and Chiara Trentin

22.1 Introduction

Breast biopsy (BB) is a useful tool for breast cancer diagnosis. It allows characterization of any breast lesion that is undefined at imaging.

In the presence of a known carcinoma, BB can be used to assess its biological features. Over the past years, knowledge of the biological features of breast cancer (e.g., estrogen and progesterone receptor expression and the presence of HER2) has become essential to establish treatment strategies.

22.1.1 Indications for Breast Biopsy

The lesions that need to be characterized are those considered suspicious for malignancy. The level of suspicion for malignancy is classified using the American College of Radiology Breast Imaging Reporting and Data System (ACR BI-RADS) which is valid for mammography, ultrasound, and MRI examinations [1].

BI-RADS classification is described in detail in Table 22.1.

Biopsy is indicated for lesions that are classified as BI-RADS 4 (2–95% chance of malignancy) and BI-RADS 5 (greater than 95% chance of malignancy).

Short-interval follow-up is recommended for BI-RADS 3 lesions (risk of malignancy ≤2%) unless there are valid clinical indications for biopsy or when follow-up with imaging is difficult or unreasonable to perform.

Table 22.1 ACR BI-RADS assessment categories

BI-RADS® assessment categories			
Category 0	*Mammography*: Incomplete—need additional imaging evaluation and/or prior mammograms for comparison		
	Ultrasound and MRI: Incomplete—need additional imaging evaluation		
Category 1	Negative		
Category 2	Benign		
Category 3	Probably benign		
Category 4	Suspicious	Mammography and ultrasound	Category 4A: Low suspicion for malignancy
			Category 4B: Moderate suspicion for malignancy
			Category 4C: High suspicion for malignancy
Category 5	Highly suggestive of malignancy		
Category 6	Known biopsy-proven malignancy		

22.2 Type of Biopsies

Biopsies can be guided by imaging (ultrasound, mammography, or MRI). Imaging guidance is essential for non-palpable breast lesions or for lesions that are deep within the breast tissue or mobile to guide the needle in the biopsy target.

There are three types of imaging guided biopsies:

- Fine needle aspiration (FNA)
- Automated large-core biopsy (CB)
- Vacuum-assisted biopsy (VAB)

The latter two are most commonly used on the breast because of their ability to sample greater amounts of tissue. FNA is still widely used in Europe and Asia.

There are several factors that help a doctor decide which type of biopsy to perform although there is still a certain degree of variability regarding the selection of biopsy and needle type.

22.2.1 Fine Needle Aspiration (FNA)

Fine needle aspiration (FNA) is a popular and valuable tool in preoperative assessment of breast masses. It is the least invasive method of biopsy; it is relatively inexpensive and can be performed with little complications but allows for only cytological analysis.

This will allow to differentiate benign from malignant lesions without further characterization.

FNA is usually performed using fine (27–20-gauge) needles, to remove a sample of cells under ultrasound, or rarely X-ray guidance, without the need of local anesthetic injection.

Ultrasound-guided biopsy is performed with the patient in supine position or slightly tilted to the side.

The sampling can be done using the needle alone (for capillarity) or the needle put together with a syringe (manual suction) or with a distant suction system (manual suction or suction pump).

Usually, the radiologist inserts the needle into the lesion more than once (usually 2–4 times) in a plain coaxial to the transducer in order to visualize the needle's trajectory during the procedure.

Once the lesion is targeted, the radiologist twists and thrusts the needle back and forth within the lesion while keeping negative pressure on the syringe to collect material which is then sent to pathology to be analyzed.

FNA is generally used when the breast nodule is likely to be a fluid-filled cyst, for symptomatic cystic lesions and for suspicious lymph node analysis.

FNA can serve as a valid alternative to excisional biopsy when it is the only available tool to diagnose a malignant lesion due to limited hospital resources.

FNA is also the preferred biopsy type when other biopsy methods are not feasible due to technical reasons such as small breast size and lesions that are too close to the skin or too deep within the breast tissue or due to patient's contraindications such as patients with coagulopathies and patients that cannot discontinue anticoagulant therapy. In the absence of clinical/radiological suspicious findings, any non-bloody fluid aspirate from a cystic lesion (e.g., milk white, gray, yellow, blue, green) can be discarded. If sampled material is bloody, further cytological analysis is mandatory.

FNA has some limitations related to operator and cytopathologist experience.

There are instances where the differentiation of benign and malignant is not possible with FNA. This is most commonly due to paucity of specimen sampling or in cases where there is a morphological overlap between benign and malignant lesions (e.g., atypical hyperplasia and low-grade carcinoma in situ or papillary lesions).

It is difficult to differentiate in situ lesions from infiltrating cancers with FNA; inadequate results are more common that with other biopsy methods (up to 54%) and evaluation of microcalcifications is problematic [2].

Cytological diagnosis is more accurate in lesions with a high cellular component (such as invasive ductal carcinoma or metastatic lymph nodes). In the presence of areas with little cellular component (such as hyalinized fibroadenomas, fibrotic lesions, or infiltrating lobular cancers) or in cases with evidence of morphological overlap between benign and malignant lesions (e.g., atypical hyperplasia and low-grade carcinoma in situ or papillary lesions), some interpretation problems can occur. In order to overcome such problems, biopsy samples are classified according to the National Health Service Breast Screening Program (NHSBSP) into five categories: inadequate (C1), benign (C2), atypia probably benign (C3), suspicious of malignancy (C4), or malignant (C5) [3]. C3 and C4 categories of breast lesions require a second-line biopsy evaluation.

More recently it has become possible to further characterize cancers diagnosed by FNA using cell block immunohistochemistry (IHC) and other molecular studies. Fine needle aspiration samples and cell blocks can be collected simultaneously using a polyvinyl alcohol foam core device that attaches to a fine needle. When FNA sampling is finished, the specimen is ejected from the needle onto a slide by air pressure from an attached syringe; the device is then removed, placed in a formalin specimen pot, and sent for histopathology examination (Fig. 22.1) [4].

22.2.2 Automated Large-Core Biopsy (CB)

Automated large-core biopsy (CB) uses a spring-loaded semiautomatic guillotine needle device (Fig. 22.2). CB is performed under ultrasound guidance (rarely stereotactic). The needles used are 18–14-gauge needles. Each needle insertion gives a tissue sample; two to four needle passes are performed after injection of local anesthesia and skin incision.

During the procedure the patient lies in the supine position. The needle is introduced into the target along the direction of the long axis of the US probe selecting the most efficient, safe, and short trajectory (e.g., parallel to the chest wall to avoid possible pneumothorax). The needle is advanced until the tip is a few millimeters proximal to the edge of the lesion. The core biopsy gun is then fired for sampling. The needle is withdrawn and the specimen is transferred into a fixative (Fig. 22.3).

CB has been well accepted as a valid alternative to surgical biopsy, for its lower cost, increased patient comfort,

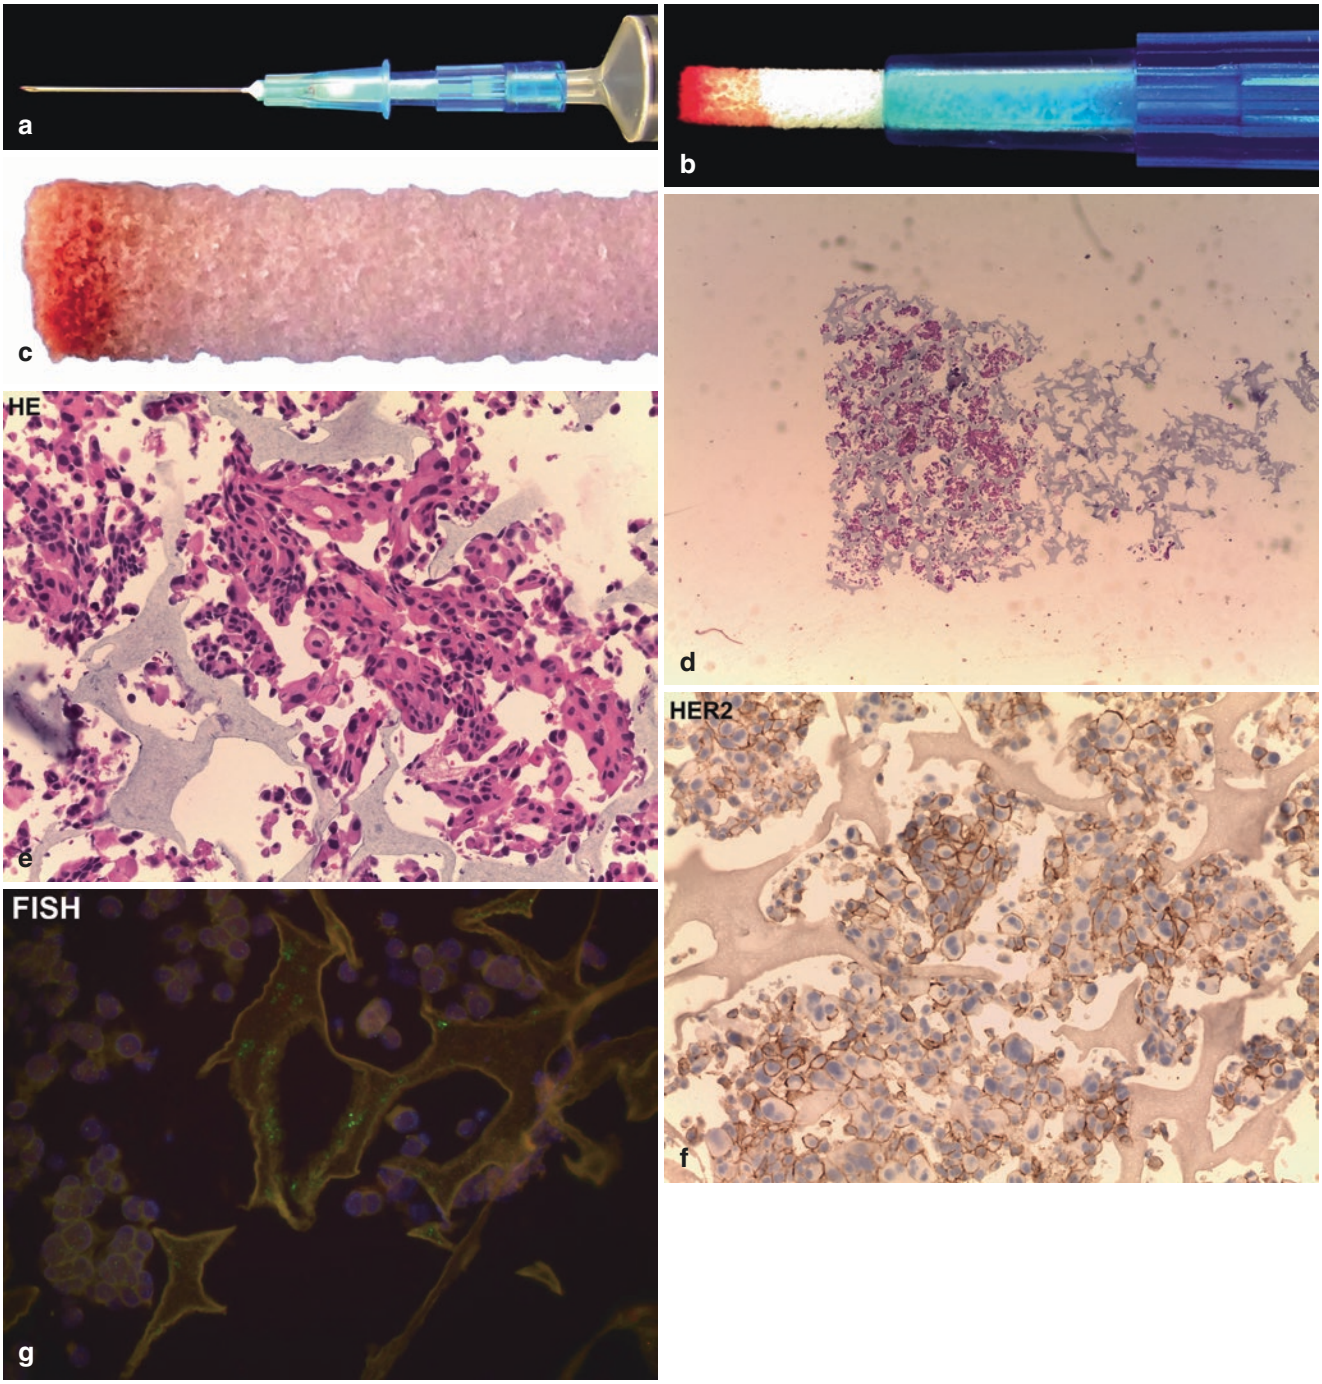

Fig. 22.1 (**a**)–(**c**) *CytoFoam device*: consists of a plastic adaptor that has a core of sterile polyvinyl alcohol (PVA) foam protruding from its lumen at the end that fits onto the hub of the needle. (**d**)–(**g**) After formalin fixation the PVA core is removed from the adapter, paraffin processed, and sectioned in the usual way, allowing histological assessment: hematoxylin-eosin, HER2, and FISH test (for courtesy of Dr G. Renne, IEO, Milan)

and short duration of the procedure. However, literature data reports some limitations related to the need of multiple needle insertions to obtain multiple specimens, technical difficulties related to small-sized lesions, difficulty of sampling microcalcifications, and risk of incomplete characterization for lesions with complex histology (such as lesions containing calcificatios, or atypical ductal hyperplasia and ductal carcinoma in situ (DCIS), or DCIS and invasive cancer) [5]. Also CB has a significant reported false-negative rate of 3–11% and underestimation rates of 16–56% [6, 7].

According to European guidelines [8] pathological analysis of CB specimens is divided into five categories: normal tissue (B1), benign lesion (B2), lesion of uncertain malignant potential (B3), lesion suspicious of malignancy (B4), and malignant lesion (B5).

B3 lesions include atypical epithelial proliferations (atypical ductal hyperplasia (ADH)), lobular neoplasias (LNs: atypical lobular hyperplasia (ALH), and lobular carcinoma in situ (LCIS)), papillary lesions, radial scar/complex sclerosing lesions, and phyllodes tumors.

22.2.3 Vacuum-Assisted Biopsy (VAB)

Vacuum-assisted biopsy (VAB) can be performed under X-ray, ultrasound, or MR guidance, depending on the target characteristics. Biopsy is performed under local anesthesia using larger needles (from 14 to 7 gauge), sampling a larger volume of tissue. The needle has an opening window and a rotating cutter. Tissue is vacuumed into the window as the rotating cutter advances forward to collect the sample. The cutter is withdrawn, and the vacuum system helps to transport the specimen to a tissue collection chamber (as shown in Fig. 22.4) Multiple specimens can be obtained with a single-needle insertion (range 6–18). The needle is positioned preferably under the target or, alternatively, near or inside; the vacuum mechanism produces a cavity around the biopsy site, so particular attention has to be taken for the skin, pectoral muscle, or vascular structures (Figs. 22.5 and 22.6).

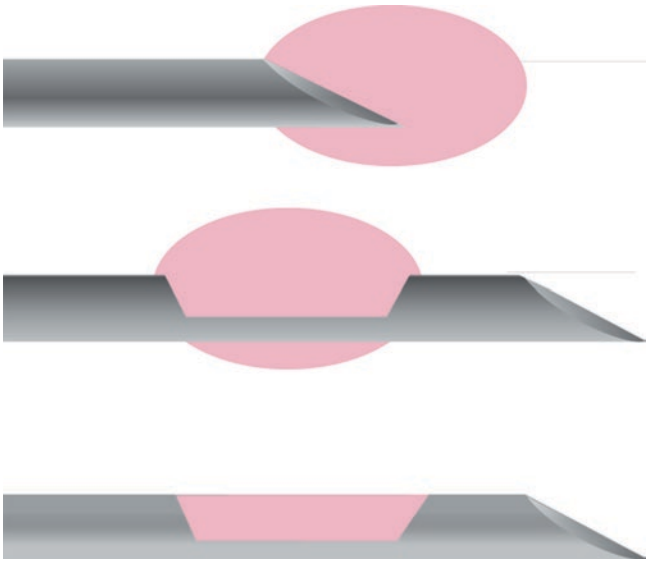

Fig. 22.2 CB needle: the needle is advanced until the tip is a few millimeters proximal to the edge of the lesion. The core biopsy gun is then fired for sampling

Vacuum-assisted devices provide larger-core samples than CB and enable more contiguous sampling potentially allowing more complete sampling of lesions, thereby lowering the chance of sampling error.

The larger-core specimen and contiguous sampling improve retrieval of calcifications and lower underestimation of cancer. In our experience, in a series of 406 cases, classified as BI-RADS 4, US-guided VAB procedure showed an accuracy of 100%, a sensibility of 97%, and a false-negative rate of 0.6% [9].

Complete removal of the imaging target is more likely after vacuum-assisted biopsy than after CB because of the larger volume of tissue removed. For these reasons VAB is preferable for calcifications, in cases where it is necessary to sample large amounts of tissue for lesions with complex histology, in case of discordance between imaging and cytological or histological examination (by CB), or if the cytology is inconclusive. Complete removal of the lesion does not ensure complete excision of the pathologic abnormality, especially for calcifications; thus, even in the case of complete removal of a malignant lesion, surgery is warranted.

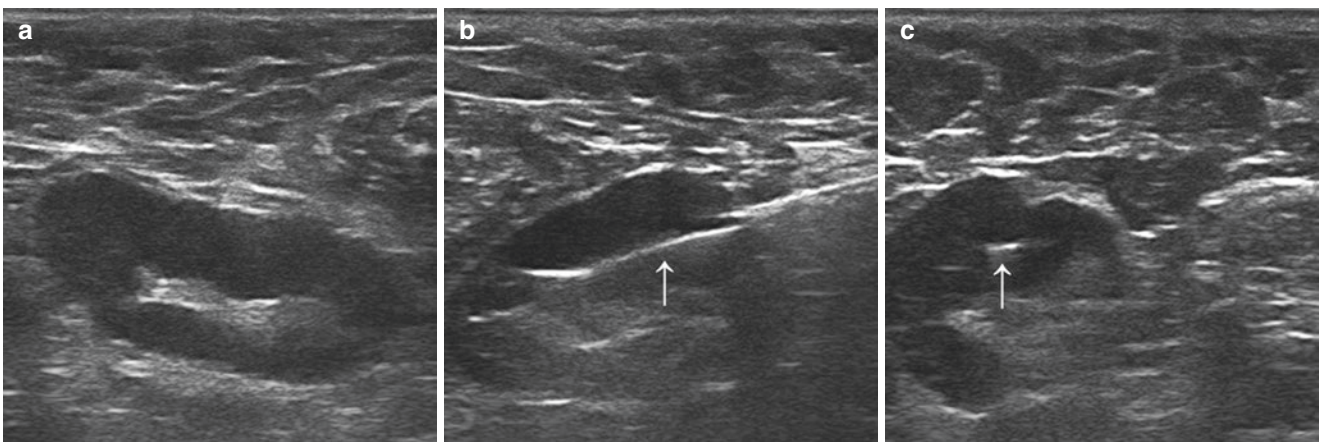

Fig. 22.3 (**a**) Core biopsy using a 14-G automated needle of a lymph node. (**b**) The needle is introduced into the lymph node along the direction of the long axis of the probe (longitudinal view). (**c**) The correct position of the needle is controlled rotating the probe of 90° (transversal view)

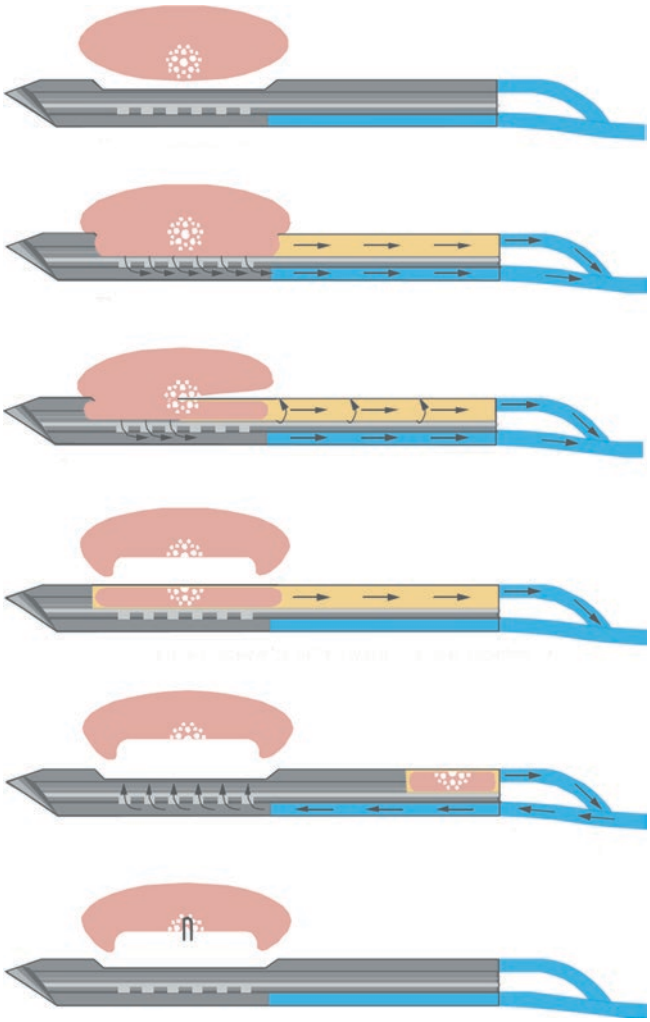

Fig. 22.4 Vacuum-assisted biopsy technique: the needle is placed under the target lesion and the tissue is vacuumed into the opening. The rotating cutter is advanced forward capturing a specimen that is transported to a collection chamber

Before considering any biopsy benefits, limitations and risks of the procedure as well as alternative procedures should be addressed to the patient, and a written informed consent has to be obtained. In the presence of coagulation disorders, anticoagulation drugs have to be stopped according to primary care physician or hematologist instruction. Some institutes recommend to discontinue therapy 1 week before the procedure, even herbal supplements such as ginkgo biloba, vitamin E, and fish oils.

Biopsy guided by the imaging is generally contraindicated if the patient is allergic to local anesthetics, if the undefined lesion is not visible or safely accessible, and if the patient is not cooperative. X-ray-guided biopsy should be avoided in pregnant women.

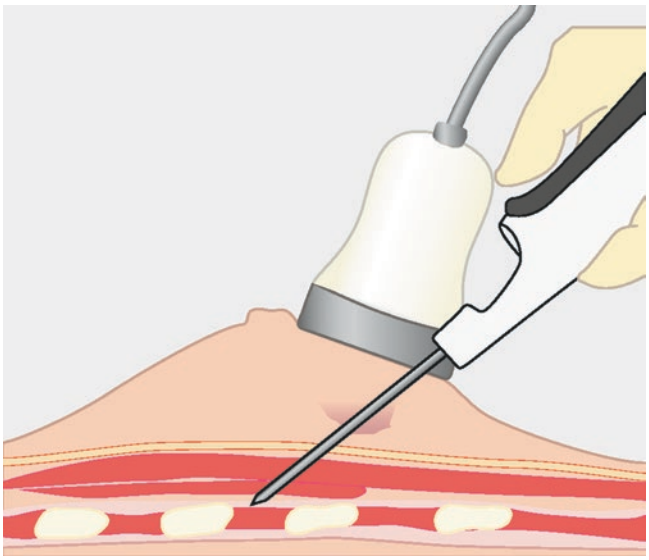

Fig. 22.5 Wrong VAB needle position: the needle is not parallel to the chest wall; there is risk of iatrogenic pneumothorax

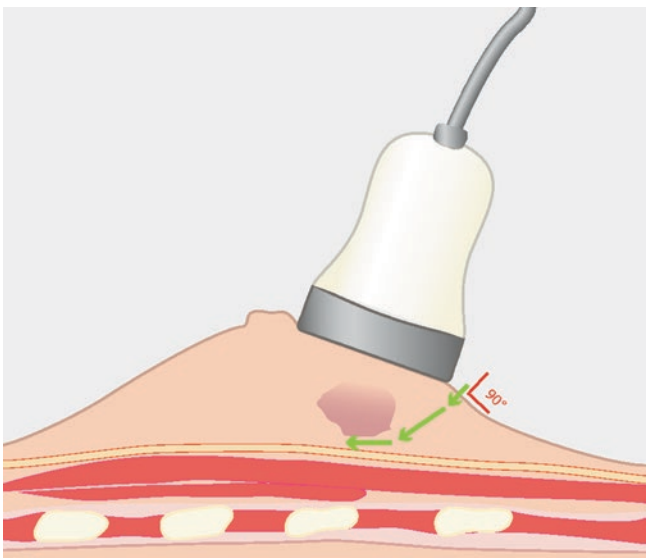

Fig. 22.6 Correct VAB needle position: the needle is placed parallel to the chest wall

22.3 Image Guidance Choice

Image guidance and type of needle choice are based primarily on target characteristics (imaging features, size and position), operator experience, and available devices (hospital resources). If a lesion is visible by more imaging tools, the radiologist has to choose the least invasive and easier access.

Ultrasound guidance, when feasible, is definitely the technique of first choice as it is easier to perform, more comfortable for the patient, and less time-consuming than the X-ray or MR-guided techniques.

If a target is evident in mammography and ultrasound, before initiating the biopsy, we must be assured that the ultrasound image matches the mammographic finding.

Ultrasound guidance can also be used (though not necessarily) in case of a palpable lesion to visualize the needle as it is advanced to the biopsy target. Ultrasound guidance can be used successfully also for smaller lesions or lesions that are located deep within the breast tissue or near to the nipple, regardless of the size of the breast or in the presence of prosthetic implants (Fig. 22.7).

During ultrasound-guided procedures, the patient is supine, and the radiologist selects the safest and most accurate way to proceed.

Stereotactic (X-ray) guidance is preferred for lesions identified by mammography but not adequately visualized by ultrasound. These lesions include microcalcifications, areas of parenchymal distortion/stellate lesions, or small soft tissue masses that are not visible on ultrasound.

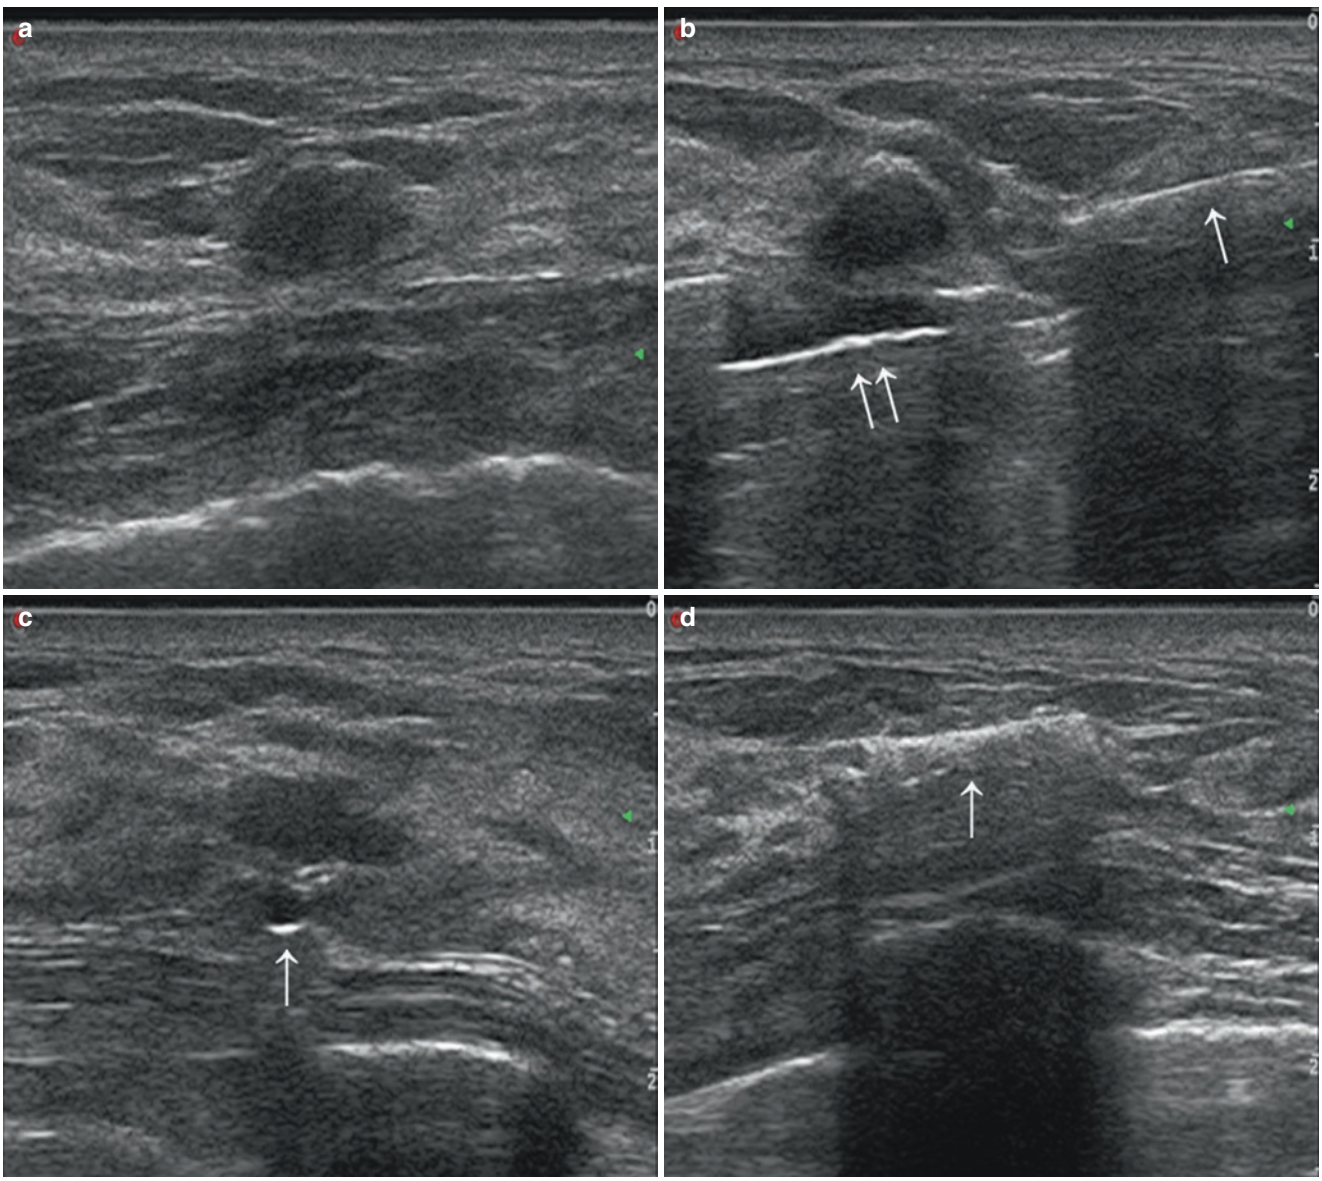

Fig. 22.7 (**a**) Ultrasound-guided VAB with 11-G needle of an ipoechoic lesion (dubious on FNA) in the right breast. Histology: fibroadenoma. (**b**) Longitudinal view: the needle is introduced under the lesion (*single arrow*), and the sampling window is open, facing the target in the center (*double arrows*). (**c**) Transverse view: the needle is well visible under the lesion (*arrow*). (**d**) The lesion is completely removed and a clip is placed (*arrow*)

The patient is usually positioned prone on a dedicated examination table (sometimes upright or in decubitus position, depending on the machine) with the breast hanging freely through an opening. A mammography unit is attached to the table and allows operator to identify the lesion to biopsy. The technician takes three scout radiographs (at 0° and two lateral views at –15° and +15°). The radiologist chooses two out of the three scouts to select the target and estimate exactly the depth of the lesion. After local anesthetic injection, the technician retakes the previously selected scout images to verify that the position of the target has not changed. The radiologist fires the needle into the breast and verifies post-fire scout images and sample specimens.

When sampling areas of microcalcifications, a radiography of the core samples is performed to ensure that tissue collected contains microcalcifications. If they are not present or are too few, the radiologist may decide to sample extra tissue (Fig. 22.8).

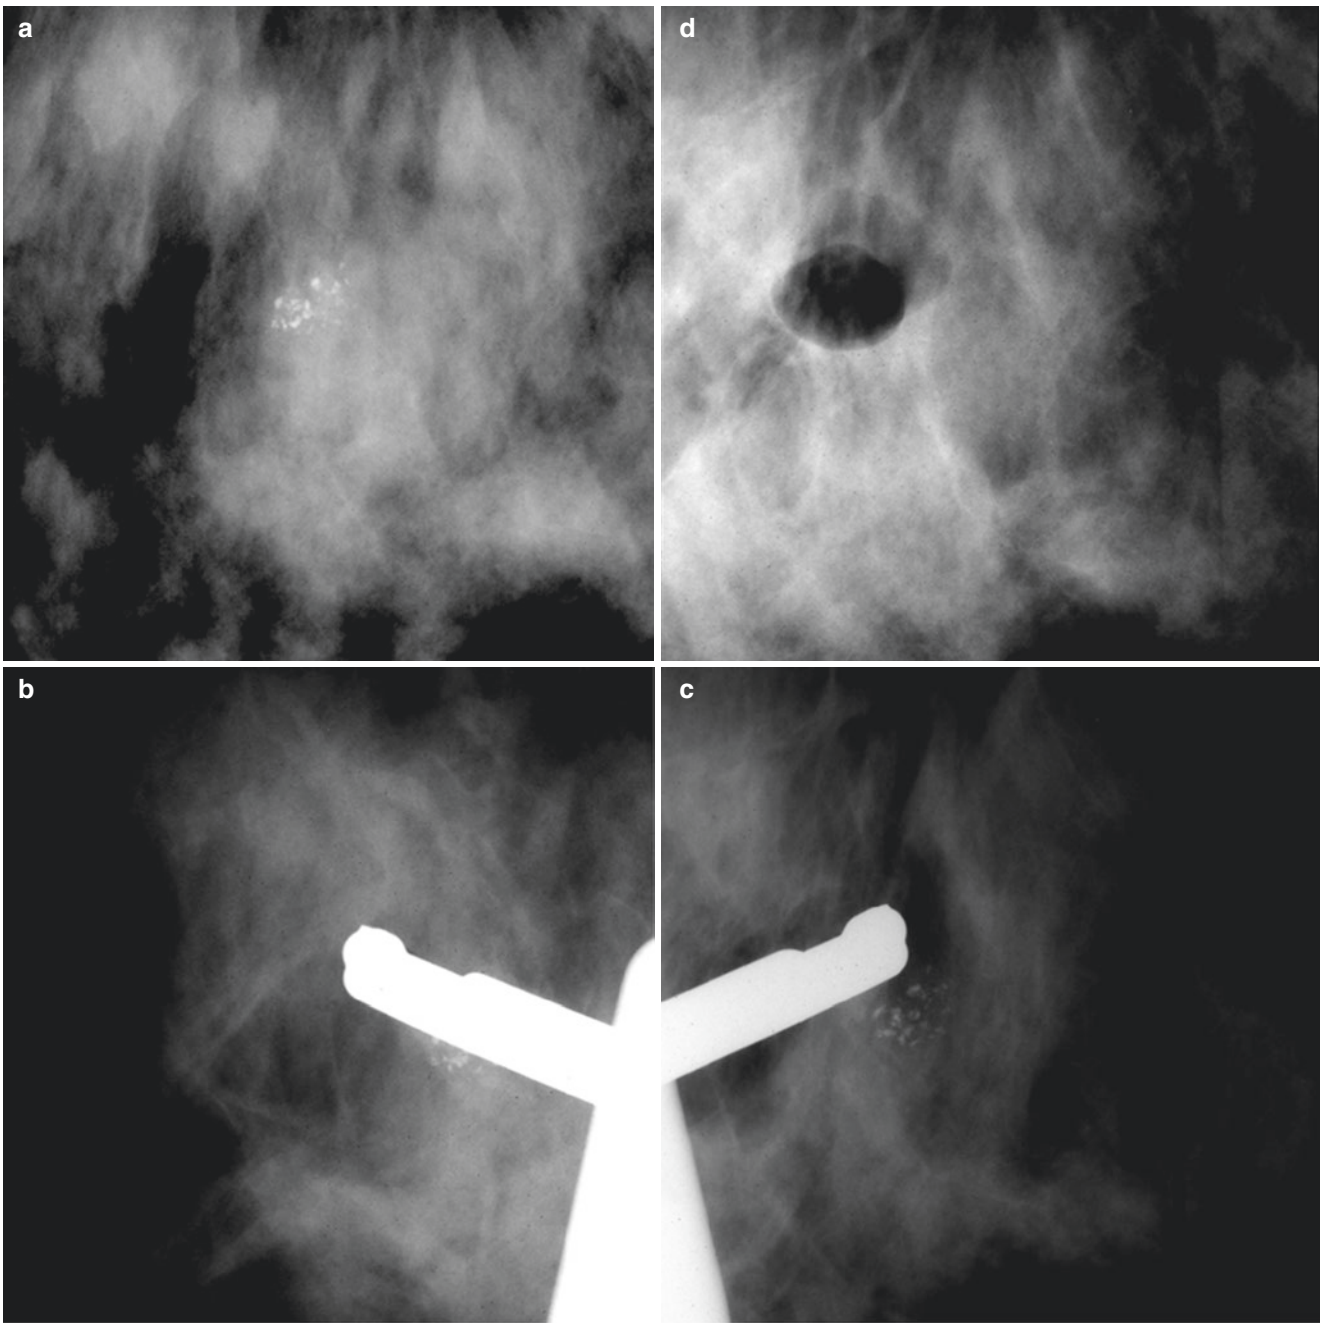

Fig. 22.8 (**a**) Stereotactic-guided VAB with 11G needle of clustered irregular microcalcifications. Histology: ductal carcinoma in situ. (**b**), (**c**) Post-fire views at –15° and +15° off perpendicular demonstrate correct needle position. (**d**) The target is completely removed and a radiolucent cavity is visible at the end of the procedure

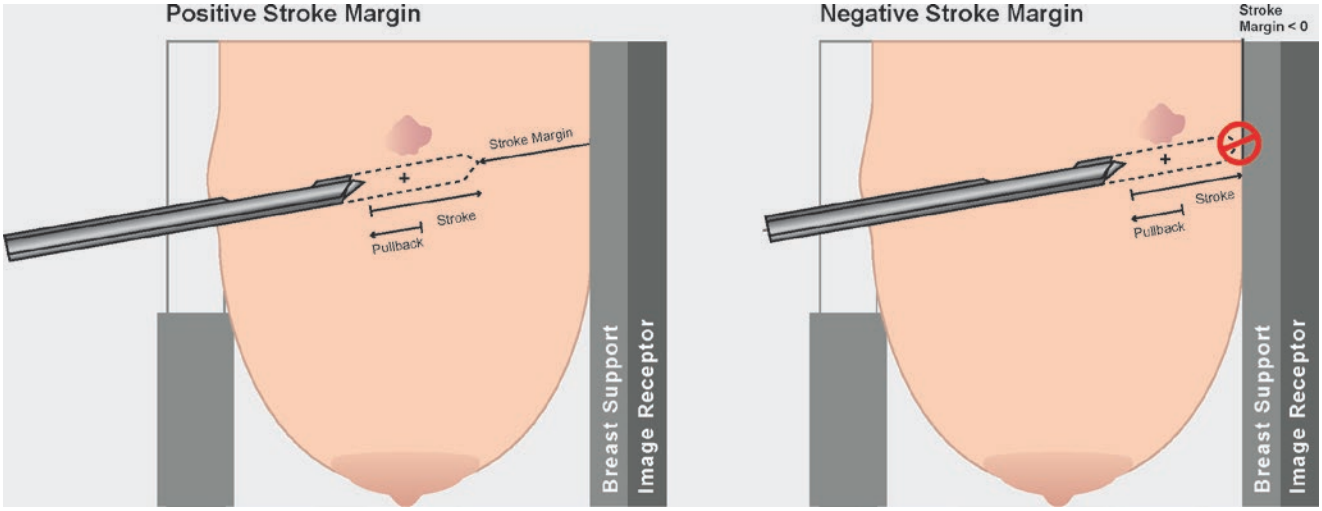

Fig. 22.9 Stroke margin is the distance between the post-fire needle position and the image receptor. Negative stroke margin indicates that the needle will exit the breast and strike the image receptor

Limitations of stereotactic biopsy are related to difficulty in reaching the target for small breast size which yields a negative stroke margin (distance between the post-fire needle position and the image receptor as shown in Fig. 22.9) or for inaccessible position (e.g., close to the nipple or chest wall or skin). In these cases surgical excision is necessary.

MRI guidance is indicated when the target is visible only by magnetic resonance. If the MR finding is visible on US or MX also on hindsight, then it is preferable to proceed with US-guided or MX-guided biopsy. It is important to understand the differences in breast positioning between the three imaging methods and the effect that this will have on lesion location.

MR-guided biopsies are performed with VAB device on only 1.5 or 3.0 T magnet, using a dedicated breast coil. MR-guided procedures are not yet widely diffused given they are more difficult to perform, longer in duration (30–60 min), and more expensive than the other techniques described.

Nevertheless, the large increase in MR use associated to the low specificity of this method has determined a significant growth of these biopsy procedures.

During the procedure the patient is in prone position with the breast compressed between the grid and an often-solid plate. Breast compression is modest since tight compression may cause masking of the enhancement.

T1 pre- and post-contrast images are acquired to select the target. MR does not allow real-time monitoring of needle advancement and biopsy. Instead, the MR table is drawn out from the magnet to place the needle after local anesthesia and then reintroduced into the magnet for each check, in a step-wise approach. Once adequate needle placement is confirmed, samples are taken outside of the magnet to avoid image distortion from the needle (Fig. 22.10).

The clip is always placed after the procedure. Limitations are related to unreachable target due to breast size or lesion position. Sometimes, on the day of biopsy, the target disappears especially in the case of non-mass-like lesions. This is due to different breast compression or to hormonal changes. It is mandatory to repeat the MR after short interval to confirm that the scan is negative.

If MR biopsy cannot be performed, MR can be used to center the lesion to guide surgical biopsy.

22.4 Clip/Marker Placement

At the end of any VAB procedure (sometimes even in CB), it is possible to place a magnetic marker to help localize biopsy site in case surgery is needed.

A variety of clips are available; they are generally composed of different metals, with a number of shapes all of which are visible on radiograph. Clips may be surrounded by cylindrical plugs of material (such as porcine gelatin, artificial polymers, and bovine collagen) that inhibit migration and facilitate subsequent ultrasound visibility for 2–6 weeks following placement.

In the case of lesion that has been completely removed bioptically, the marker is mandatory. In the presence of residual disease, it could be dismissed.

After a MR biopsy, the clip is always necessary because of the impossibility to understand real time whether or not the target has been completely removed (due to bleeding or air bubbles that can blur the biopsy site).

The correct marker placement is controlled by the radiologist real time on the monitor during US-guided procedures or on two orthogonal mammograms for stereotactic or MR-guided biopsies (Figs. 22.7 and 22.10).

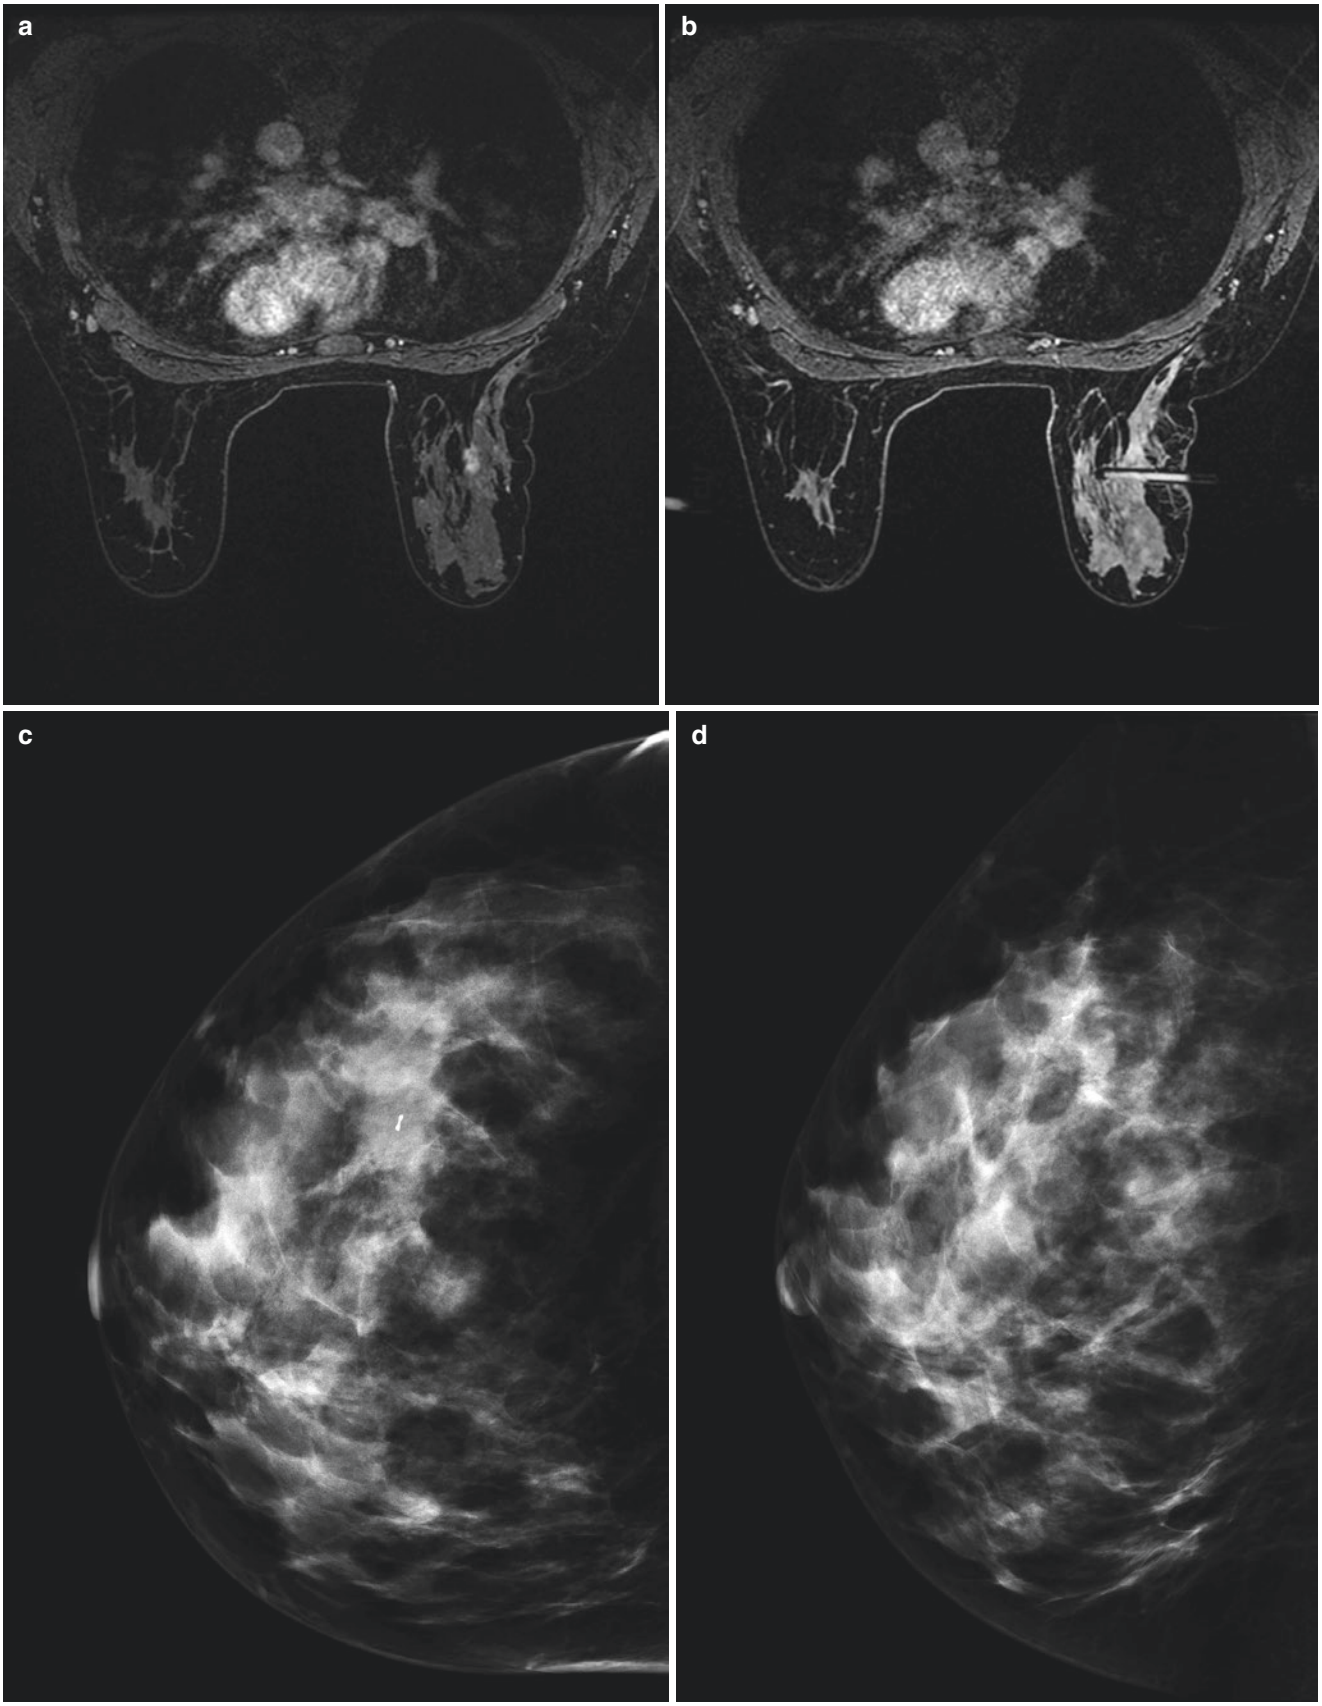

Fig. 22.10 MR-guided VAB with 8G needle of an irregularly shaped enhancing mass in the left breast. Histology: ductal intraepithelial neoplasia (DIN 3). (**a**) Axial contrast-enhanced subtraction image shows target lesion. (**b**) Contrast-enhanced subtraction image shows the biopsy needle in correct position. (**c**) and (**d**) two orthogonal post-biopsy mammograms show that the clip is in place

Post-needle biopsy errors in marker placement include:

- Non-deployment (rare and recognized the day of biopsy)
- Inaccurate initial deployment (common and recognized the day of biopsy)
- Delayed migration from the initial deployment site (rare and recognized days to months after biopsy)

If the marker has migrated from the biopsy site for more than 7 mm, another marker should be placed. In any case it is useful to describe the migration distance from the biopsy site in the medical report.

Alternatively, especially in Europe, carbon particles are sometimes used. These are injected along the needle trajectory to track a dark line in the breast, useful to guide surgery days to weeks after the biopsy.

22.5 Complications

The most frequent complication during and after a percutaneous biopsy is bleeding with consequent hematoma, rarely significant, which is treated with manual compression (up to 30 min), bandaging, and ice. Surgery is rarely necessary.

Less frequent complications include vasovagal reactions.

Very rare complications include infection, pneumothorax, pseudoaneurysm formation, implant rupture, and milk fistula (in pregnant or lactating women). Pneumothorax can occur when the target is very close to the pectoral muscle or rib cage, in noncompliant patients (moving or coughing), or if the needle angle is very steep.

Theoretically percutaneous biopsies can determine displacement of benign or malignant epithelium into tissue along the needle track. This is less frequent for vacuum-assisted biopsy than it is for fine needle aspiration or automated core biopsy (which requires multiple needle passes). There is no evidence that displaced cells are of biologic significance, but displaced epithelial cells can lead to difficulties in histologic interpretation by the pathologist (e.g., displaced DCIS can mimic infiltrating carcinoma). The pathologist should be aware of the findings of epithelial displacement to avoid misdiagnosing DCIS as infiltrating ductal carcinoma or multifocality in case of unifocal disease.

The available literature data does not document an increase in morbidity associated with iatrogenic seeding of the needle tract, although the certainty of the theoretical risk of local recurrence or metastatic spread cannot be definitely excluded. The continuous postsurgical follow-up accorded to patients, however, allows to control this risk [10–12].

At present, the patient benefit of preoperative biopsy diagnosis greatly outweighs the potential risks related with this procedure.

22.6 Management of Results

Every biopsy result has been submitted to concordance analysis.

Imaging-histologic concordance occurs when histologic results correlate with the imaging characteristics.

Imaging-histologic discordance occurs when histologic findings do not provide a sufficient explanation for the imaging features; this is most likely due to false-negative or (less frequently) false-positive results (in case of FNA). Imaging-histologic discordance may happen when BI-RADS category 4 or 5 lesions have benign histologic results or in case of targeting or sampling error.

Targeting error occurs when a sample from a lesion with associated microcalcifications has no calcifications identified by the pathologist or when a discrete mass lesion produces only normal breast tissue.

Sampling error occurs in lesions composed of inhomogeneous tissue when biopsy samples tissue that is not representative of the more altered portion of the lesion (e.g., sampling of only ADH in case of a DCIS associated with ADH).

Literature data reported that in the presence of imaging-histologic discordance after MR biopsies, malignancy rate ranges between 13 and 44% [13–16].

Repetition of biopsy, eventually using a larger needle or surgical biopsy, is recommended in case of imaging-histologic discordance.

Open biopsy procedures are not required in patients with histologically benign findings on percutaneous biopsy if imaging is concordant with the diagnosis. Instead, 6 or 12 or 24 until 36 months of follow-up is accepted (6 months of follow-up in case of MR-guided VAB).

If at follow-up a lesion increases in size or changes morphology or other features, it is necessary to repeat the biopsy or to surgically remove the lesion.

Surgical excision is imperative in case of malignancy, even in the presence of a DCIS after complete removal of the imaging target on biopsy. In our study conducted on 4.047 stereotactic VAB with 1594 cases of complete removal of the target lesion, the DCIS underestimation rate was low (5.5%) but not sufficient to consider VAB as a therapeutic procedure [17]. The underestimations risk in case of DCIS has been well documented and is related to lesion size (increased for lesions >20 mm), presence of residual tissue after biopsy, lesion type (mass lesion vs. microcalcification), biopsy device (CB vs. VAB), number of specimens obtained (≤10 vs. >10), and patient age [18, 19].

22.7 High-Risk Lesion Diagnosed at Breast Biopsy

The reported possibility to obtain a B3 lesion, defined also as high-risk lesion, after a percutaneous breast biopsy ranges between 3 and 10% [20–25]. Some authors consider these

lesions as "non-obligate precursors of malignancy." In other words, if these lesions are not removed, they have potential to become cancerous over time. Other authors consider them as "indicators of risk," which means that they increase the possibility of developing a breast cancer in the same or in the contralateral breast.

For these reasons management of B3 lesions is controversial. There is a large amount of literature data recommending surgical excision over follow-up [26, 27] because of the significant possibility of their upgrade to malignancy (B4–B5) when a larger amount of tissue is sampled [28–30] even in case of complete removal of the imaging target during biopsy [31].

In accordance with international debate, each case should be discussed in multidisciplinary meetings to assess biological risk, representative sampling, lesion size and extent, percentage of lesion removal, and other individual risk factors. The possibility of surveillance should be considered before selecting any management of a lesion.

22.7.1 Atypical Ductal Hyperplasia (ADH)

Atypical ductal hyperplasia is a complex lesion that histologically has some but not all microscopic features of (low-grade) DCIS. Usually, ADH is associated with or nearby suspicious microcalcifications (>80%) that are frequently the target of stereotactic breast biopsy. ADH can also present as a mass lesion without calcifications. Atypias may be also associated with radial scar or contained within fibroadenomas, papillomas, or non-tumorous benign lesions.

The downstaging risk is 20–56% with CB and 11–35% with VAB [5, 32–38]. In our experience using stereotactic VAB (11- and 8-G needles), the risk of downstaging ADH was not negligible (6.6%), even in case of complete target removal [17].

After MR imaging-guided biopsy, the reported risk of downstaging ADH is very significant, up to 50% [13, 39–42].

Due to its histological characteristics and significant number of underestimates to date, usually surgical consultation to discuss excisional biopsy is recommended [43].

22.7.2 Lobular Neoplasia (LN)

Lobular neoplasias include atypical lobular hyperplasia and lobular carcinoma in situ with classic morphology that, like ADH, may have a considerable spectrum of histological appearances without distinctive imaging findings. LNs on mammography typically present as microcalcifications; on ultrasound they present as mass lesions or aspecific architectural changes. LN can be found within fibroadenomas or within other benign lesions. Sometimes they are found incidentally on biopsy performed for other reasons or on surgical specimens.

Currently there is an open debate on the need to excise a breast target that yields LN as the highest-risk lesion at biopsy because of the significant underestimation rate reported after VAB (range 15–33%, 17% in our series) [44–47], making surgical consultation still recommended, especially for LCIS [48].

Nevertheless, in selected cases (patients not considered at high risk or without a past or present diagnosis of breast carcinoma), clinical management of LCIS and ALH can be an effective alternative to surgical excision when radiological and histological characteristics are well defined and suggest a low potential for an upgrade at the time of excision [49, 50].

22.7.3 Papillary Lesions (PL)

Papillary lesions are a heterogeneous group that includes benign intraductal solitary papillomas, atypical papillomas, and multiple papillomas. For benign papilloma the upstaging risk is reported to range from 0 to 7% [51, 52]. Generally, in case of complete VAB removal, conservative treatment should be strongly considered except in those patients with papilloma associated with mass lesions or with imaging/histologic discordance. Data reported that in atypical papillomas, there is a risk of malignancy of up to 67%, making surgical excision necessary [53]. Multiple breast papillomas are characterized by numerous papillomas causing mass-like lesions associated with complex sclerosing lesions and atypical hyperplasia, generally located in the periphery of the breast. Because of their associated risk of malignancy, lesions larger than 1.5 cm should be surgically removed [54, 55].

22.7.4 Radial Scar and Complex Sclerosing Lesion

Radial scars are tumorlike lesions with architecturally distorted glandular tissue that may be difficult to differentiate from low-grade carcinoma in histological section [56]. Complex sclerosing lesions are radial scars greater than 1 cm in size. At mammography they appear as architectural distortions while at ultrasound, if visible, like an ipoechoic irregular mass with posterior shadowing [57]. The upstage risk ranges from 0 to 22% [54].

Surgery is recommended if cellular atypia is present. In cases without atypia and complete removal with VAB, short-term follow-up is appropriate [58].

22.7.5 Phyllodes Tumors

Phyllodes tumors show as masses ranging from 1 to 10 cm, with circumscribed margins that may appear indistinct at

mammography. They can be benign, borderline, or malignant (23–50%) [5]. Surgical excision is always warranted even for benign tumors which can still be locally aggressive.

22.8 Alternative Biopsy Methods

The goal of percutaneous breast biopsy is diagnosis, not treatment; however, in specific cases, this concept is changing.

In the USA an innovative biopsy method that captures breast tissue for histological analysis using RF (radiofrequency) energy, defined as BLES system (breast lesion excision system (BLES)), has been introduced since 2001. The BLES consists of a biopsy "wand" that is placed (after local anesthesia and skin incision) at the edge of the target under ultrasound or stereotactic guidance. Five metallic prongs (depending on wand size), with their tips connected by an extensible cutting radio-frequency ring wire, pass from the wand and envelop an area of tissue ranging from 10 to 20 mm in diameter (depending on wand size) in only 8 s (Fig. 22.11) [59]. The prongs pass RF waves into surrounding tissue in order to excise and allow hemostasis, but not to the extent of damaging the sample. The stereotactic guidance seems to be more accurate because during the procedure the breast is maintained in a static position. Compared with VAB, this procedure can export a single entire sample keeping the architecture intact and margins clear. This facilitates the work of the pathologist and reduces the risk of underestimation (especially for histologically complex lesions) [60]. Furthermore, it may allow the removal of small borderline or benign lesions, thus eliminating the traditional wide local surgery [60–62]. The procedure is well tolerated with few complications. It is contraindicated in patients with a cardiac pacemaker or other radio-frequency devices and in patients who are pregnant. Caution is recommended in patients taking anticoagulation drugs and in patients with clotting disorders. During the biopsy the RF waves emanating from the metallic prongs produce heat that could burn the skin; for these reasons it cannot be used in lesions too close to the skin or to the chest wall, in small breasts, or in the axilla [59, 63].

Other recent ultrasound technical developments include three-dimensional (3D) US-guided biopsy and biopsy conducted with tissue harmonic imaging (THI) and compound imaging (CI).

The 3D-guided biopsy allows a better understanding of the position of the breast lesion and the surrounding tissue, without needing to change the transducer plan, especially in small lesions. The precise point of post-fire is visualized in a multiplanar display, facilitating the procedure. So far the

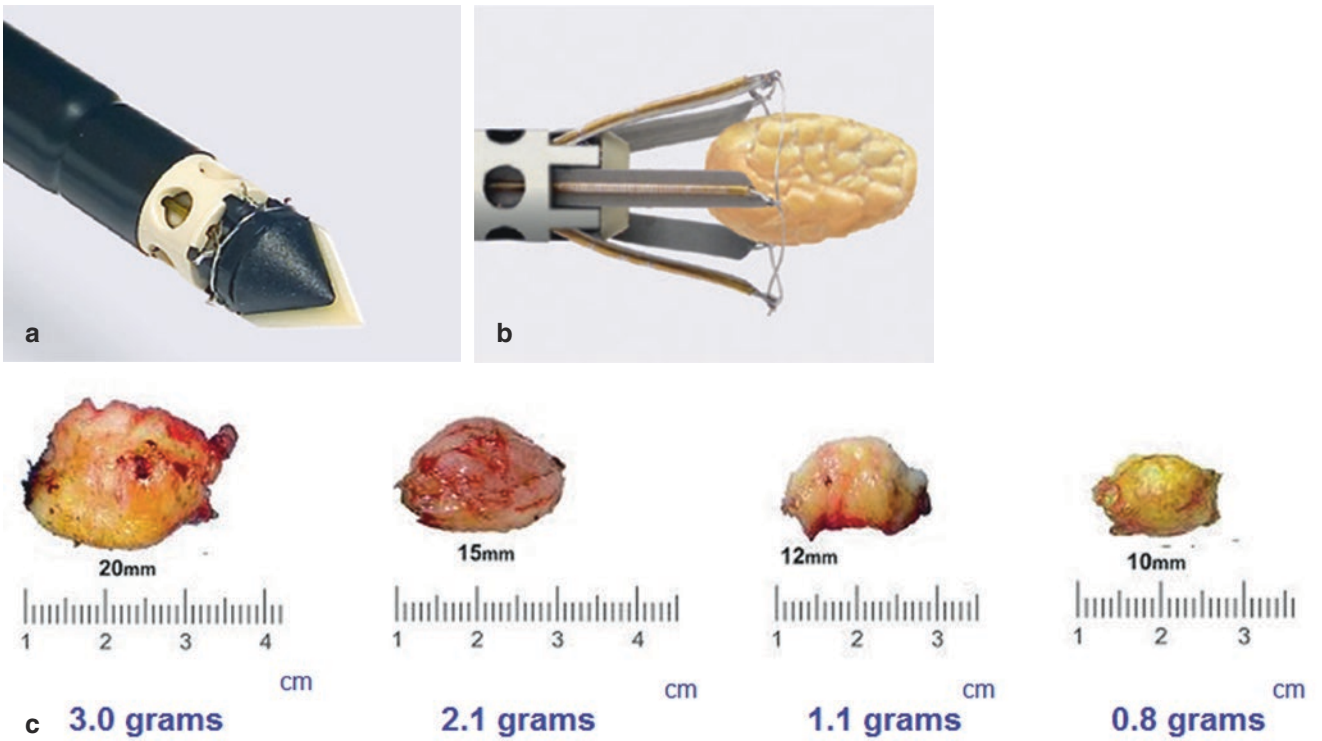

Fig. 22.11 (**a**), (**b**) BLES capture basket: five small RF-enabled wires exit from the wand to circumscribe the lesion. As they proceed, they draw out five supporting elements which support and cradle the sample for withdrawal. (**c**) Specimen samples are available in four sizes: 10-, 12-, 15-, and 20-mm diameters

reported rate of false negatives and underestimation is similar to that of the 2D system [64, 65]. It is a safe procedure and appears to be more useful for nonexpert in freehand positioning operators or in centers where the number of requested breast biopsies is small [66]. More studies are needed to define the real value of this method.

Tissue harmonic imaging (THI) and compound imaging (CI) were applied to ultrasound machine to enhance the detectability of the biopsy target, especially when the surrounding tissue appears as hypoechoic as the target lesion. THI creates images generated by US-tissue interactions solely from higher frequencies. This enhances tissue contrast between the lesion and the surrounding tissue [67]. THI can be useful in the visualization of a lesion surrounded by fatty background, but is of limited value for needle visualization during biopsy [68].

Compared with the B mode imaging, the single image obtained with the CI has more defined margins and internal architecture because it is created from multiple frames and from different frequencies (frequency CI) or from different angles (spatial CI) [68, 69]. Therefore CI improves the visibility of the lesion and the needle in breasts with a glandular background and suppresses lesion shadowing.

Despite these apparent advantages, conventional B mode is still considered the best compromise in breast biopsy.

In recent years, technological innovations have included also the tomosynthesis with digital mammography. Tomosynthesis acquires, with a low dose of radiation and in a short period of time, multiple images to predefined levels throughout the breast volume. It helps identify benign or suspicious masses in dense breasts, usually not visualized with conventional digital mammography, and gives information on their exact depth and location. Generally, in the presence of a suspicious lesion highlighted by tomosynthesis, without corresponding ultrasound image, the patient is subjected to an MR exam and to a possible subsequent MR-guided biopsy. However, targets visualized only on 3D mammography can be biopsied using tomosynthesis-guided VAB. Further studies are needed to demonstrate the clinical significance of this innovation [70–72].

Acknowledgments We would like to acknowledge the contribution of Roberto Lo Gullo (MD) in the writing of the English form of this chapter.

Part V

Oncological Surgery

Conservative Surgery

23

Umberto Veronesi

23.1 Premises

Surgical oncology showed a great evolution over the past century. The increased incidence of malignancies leads to an increased interest in discovering new diagnostic and therapeutic techniques. Since the end of the nineteenth century, the objective of the surgeons was to offer the "maximal tolerable treatment," as the effort was concentrated on delivering as extensive surgery as could be tolerated, in order to improve disease control. This approach resulted in devastating interventions with a negative effect on the quality of life. At the end of the sixties, when it was made clear that the prognosis was mainly linked to the presence or absence of distant metastases and not to the extent of local treatment, the opposite trend was developed with the objective to identify the "minimal effective treatment," aiming at preservation of the affected organ, that would improve the patients quality of life.

The advances in the field of systemic treatments led to an improved control of the disseminated disease. Adjuvant chemotherapy and endocrine therapy became therefore component of the treatment. More recently the progress in the knowledge on cell genetic is leading to targeted treatments increasing the therapeutic efficiency and sparing the patient the side effects of chemotherapy.

Radiotherapy is often essential for obtaining a good local control. The progression of informatics technology changed the radiation treatment from two-dimensional radiotherapy to three-D conformal radiotherapy and recently to intensity-modulated radiation therapy.

Since the publication of the paper on a study conducted from January 1988 to December 1989 [1], neoadjuvant treatments are being used for several oncologic patients for downstaging. Chemotherapy, as well as hormone therapy for hormone-dependent tumors, in the preoperative setting is shown often to decrease the extent of the solid tumors, rendering them operable, often with the conservation of the organ.

23.2 Value of Randomized Trials

Randomized trials have contributed significantly to the changes in surgical oncology in breast cancer that were fundamental for all the revolutionary changes performed. An attempt to improve the prognosis through a more extended treatment was the aim of the trial on internal mammary node dissection. A large international randomized trial was published in 1976 comparing radical mastectomy with or without internal mammary dissection [2]. From 1963 to 1968, 1,453 patients in five centers were randomized. The 5-year survival was similar in the two groups. The Cancer Institute of Milan participated in this study and published the 10-year follow-up of 716 patients in 1981 [3], without differences in overall survival and disease-free survival in the two groups. There was no difference in recurrence rates on the operating field, the axilla and the supraclavicular fossa. The 10-year update of the multicenter study that was published 2 years later confirmed no difference in survival and in relapse-free survival [4]. This first large trial attempted to explore the impact of more aggressive surgery failed the goal and inspired myself to look at opposite solutions. The passage from "maximally tolerated" to "minimally effective" treatment has not been easy, and the idea of conserving a large portion of an affected organ was challenged by many surgeons and medical oncologists. It was only the large randomized trials performed in breast cancer patients that made possible the acceptance of breast conservation and led to a complete modification of the principles of breast surgery.

23.3 Breast-Conserving Surgery

Over the years, Halsted mastectomy has been replaced by lumpectomy or quadrantectomy, with external high-energy radiotherapy as an integrated component of treatment (Figs. 23.1 and 23.2).

A milestone was the publication in 1981 of the results of a randomized trial that compared Halsted mastectomy with breast-conserving surgery plus complete axillary dissection plus full-dose radiotherapy to the breast [5]. The trial, which recruited 701 patients with tumor ≤2 cm, showed no difference in survival between the two groups. The findings of the Milan trial were confirmed by long-term follow-up published in 1981 [6] (Figs. 23.3 and 23.4).

In the USA, Fisher and colleagues, 5 years later, adopted a slightly more conservative approach. Their trial, published in 1985 [7], compared a more limited tumor resection (initially defined partial mastectomy and later lumpectomy) with a total mastectomy that included removal of the fascia overlying the muscles but not the muscles themselves. As in the Milan trials, patients with stage I–II breast cancer were eligible, but maximum tumor diameter was 4 cm. Patients were treated with lumpectomy only if resection margins were negative. Axillary dissection was generally more limited than in the Milan trial.

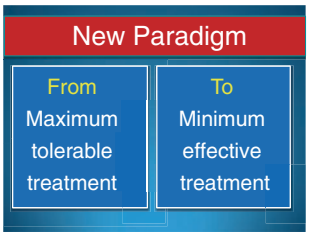

Fig. 23.1 Cancer surgery revolution from 1970

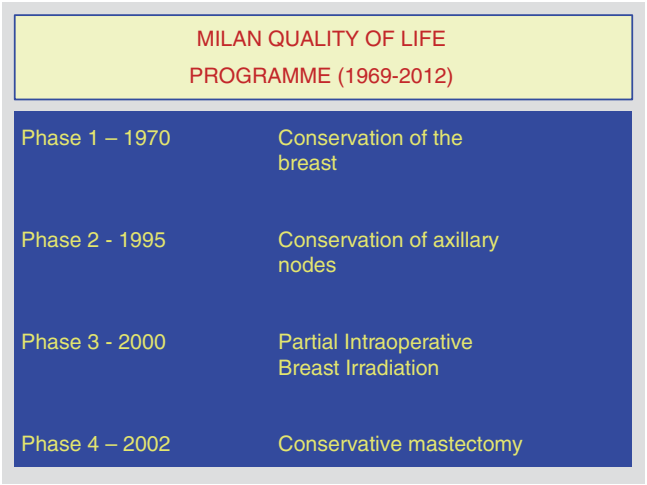

Fig. 23.2 Milan program for quality of life for breast cancer patients

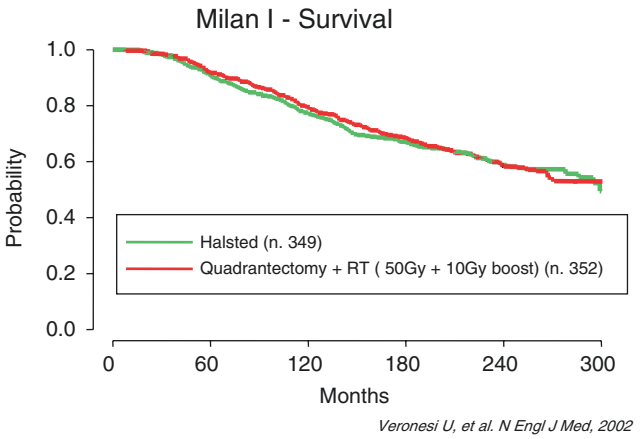

Fig. 23.3 Long-term survival of patients treated with Halsted mastectomy (349 patients) and quadrantectomy plus radiotherapy (352 patients)

Fisher found that distant disease-free survival and overall survival were no worse in the lumpectomy arm than mastectomy arm. The results were confirmed after a long-term follow-up [8].

In 1979, the National Cancer Institute conducted a prospective randomized study comparing modified radical mastectomy vs. lumpectomy—with resection margins, either positive or negative, with axillary dissection and adjuvant radiotherapy [9]. After 20 years of follow-up of 237 patients, OS and DFS were comparable; however according to the authors, "breast failures continued to occur throughout the follow up" [10].

A study with a similar design was launched in 1980 by EORTC. The trial randomized 868 patients with T1 and T2 tumors until 1986 to either modified mastectomy or lumpectomy—with positive or negative resection margins—with axillary dissection and adjuvant radiotherapy [11]. At 10 years, the results were similar to those of the NCI trial. Overall survival and distant metastasis-free survival were similar; however local recurrences were higher in the lumpectomy group.

Between 1983 and 1989, the Danish Breast Cancer Cooperative Group after randomizing 905 patients to either modified radical mastectomy or lumpectomy with axillary dissection and radiotherapy concluded that OS and DFS did not differ significantly [12].

These large randomized trials conducted in the 70s and early 80s showed the way to "less surgery" and practically changed the principles of breast cancer surgery. Furthermore, they confirmed the hypothesis that the prognosis of breast cancer patients is linked to the presence or absence of distant metastasis and changes in local treatment do not affect the overall survival. Breast conservation became a standard treatment, and the updates published at the beginning of the twenty-first century confirmed that mutilating interventions such as Halsted radical mastec-

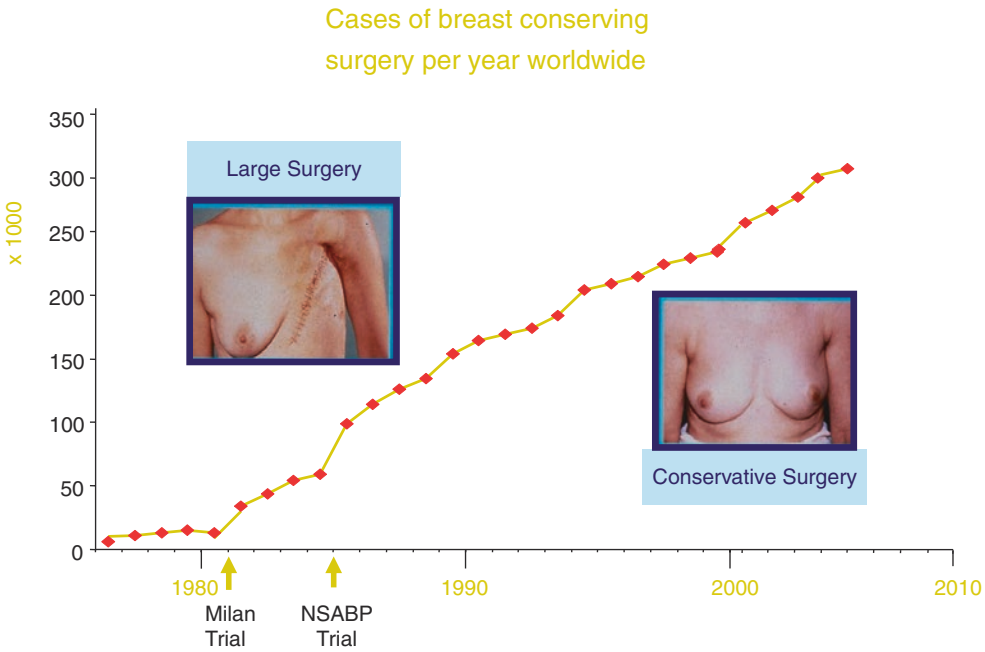

Fig. 23.4 Rough estimate of the increase of conservation of the breast worldwide

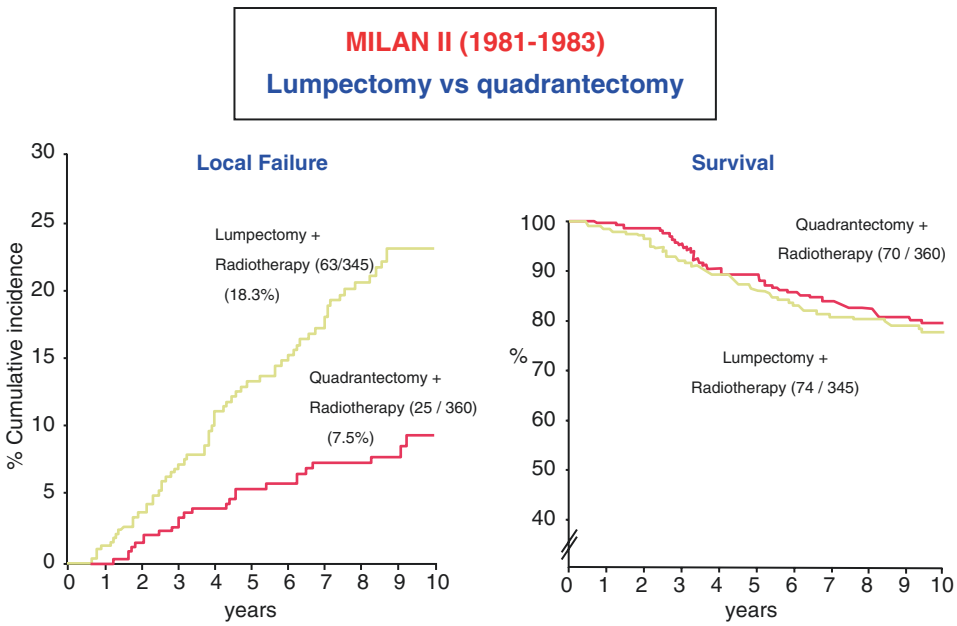

Fig. 23.5 Ten-year results of the randomized trial (705 cases) comparing lumpectomy vs. quadrantectomy (*left* Local Failure, *right* Survival)

tomy belong to the past. However, some uncertainty remained about the extent of the breast conservation. This issue was further investigated with a randomized study (Milan II) that was conducted between 1985 and 1987, and its results were published in 1990 [13]. Seven hundred and five patients with tumors up to 2.5 cm were randomized to receive either quadrantectomy or lumpectomy. All patients underwent axillary dissection and radiotherapy. In quadrantectomy, 2–3 cm of normal tissue surrounding the tumor was excised, as well as the tumor overlying the skin and the underlying fascia. In lumpectomy, only a rim of 1 cm around the tumor was excised. After a follow-up of 10 years, OS and distant metastasis rate were not different, while in breast tumor recurrence was significantly higher in the lumpectomy group [14] (Fig. 23.5).

23.4 Postsurgical Radiotherapy

Following the establishment of breast conservation as treatment of choice for early breast cancer, the role of radiotherapy on locoregional control remained to be clarified. The effects of adjuvant radiotherapy were evaluated by two randomized trials. The first was conducted at the Milan Cancer

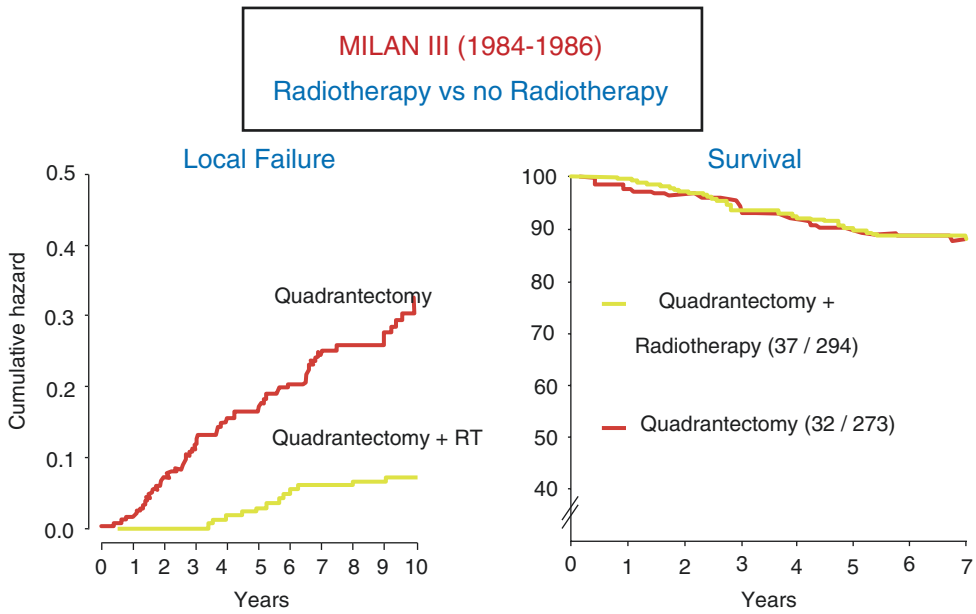

Fig. 23.6 Ten-year results of the randomized trail (567 patients) comparing postoperative radiotherapy vs. no radiotherapy (*left* Local Failure, *right* Survival)

Institute (Milan III) between 1987 and 1989 and recruited 567 patients with tumors up to 2.5 cm [15, 16]. They were randomized to quadrantectomy with axillary dissection with or without adjuvant radiotherapy. The radiotherapy group had a significantly lower local recurrence rate; however the 5-year overall survival was comparable. Similarly, the Uppsala-Orbero Breast Cancer Study Group reported the same conclusions in a study of 381 patients with pT1 tumors [17]. Radiotherapy is considered an important component of breast conservation, at least in women who are younger than 60 years old. For patients over 60 years old, a multicenter randomized trial was conducted, in order to assess the necessity of radiotherapy. Between 2001 and 2005, 749 patients with early breast cancer were assigned to either surgery only or to surgery and breast radiotherapy, and after 5 years of follow-up, a difference in breast recurrence (2.5% vs. 0.7%) was found, but no difference in overall survival and in distant disease-free survival [18] (Fig. 23.6).

23.5 Intraoperative Radiotherapy

Up to 85% local recurrences after conservative treatment develop in the scar area. This finding suggests that in many patients, only the tumor bed needs to be irradiated [18]. Furthermore, if this partial-breast irradiation could be given in single session and was noninferior to conventionally fractionated whole-breast irradiation, it would substantially ease the difficulties of women who have to contend with long waiting lists for radiotherapy or who live distant from a radiotherapy center. Such treatment would also be simpler and less expensive than conventional whole-breast irradiation. For these reasons, the European Institute of Oncology developed an intraoperative radiotherapy ELIOT (electron intraoperative therapy) technique that can deliver full-dose irradiation (21 Gy) over a few minutes during the surgery. The method employs a mobile linear accelerator that delivers an electron beam via an arm to which is attached a sterile cylindrical applicator. After cancer removal, the surgeon detaches the residual breast from the underlying fascia and inserts an aluminum-lead disk between the fascia and the gland to protect deep structures. The breast is temporarily reconstructed and the skin retracted out of the way. The energy of the electron beam (variable from 3 to 12 MeV) is selected based on gland thickness as measured by a needle [19–21].

In the year 2000, a randomized study was started at the European Institute of Oncology (Milan, Italy). Women aged 48–75 years with early breast cancer, a maximum tumor diameter of up to 2.5 cm, were assigned in a 1:1 ratio to receive either whole-breast external radiotherapy or intraoperative radiotherapy with electrons (ELIOT). Study coordinators, clinicians, and patients were aware of the assignment. Patients in the intraoperative radiotherapy group received one dose of 21 Gy to the tumor bed during surgery. Those in the external radiotherapy group received 50 Gy in 25 fractions of 2 Gy, followed by a boost of 10 Gy in five fractions. This was an equivalence trial; the prespecified equivalence margin was local recurrence of 7.5% in the intraoperative radiotherapy group.

One thousand three hundred five patients were randomized (654 to external radiotherapy and 651 to intraoperative radiotherapy) between November 20, 2000, and December 27, 2007. After a medium follow-up of 5–8 years (IQ 4.1–7.7), 35 patients in the intraoperative radiotherapy group and four patients in the external radiotherapy group had an IBTR ($p < 0.0001$). The 5-year event rate for IBRT was 4.4% (95% CI 2.7–6.1) in the intraoperative radiotherapy group and

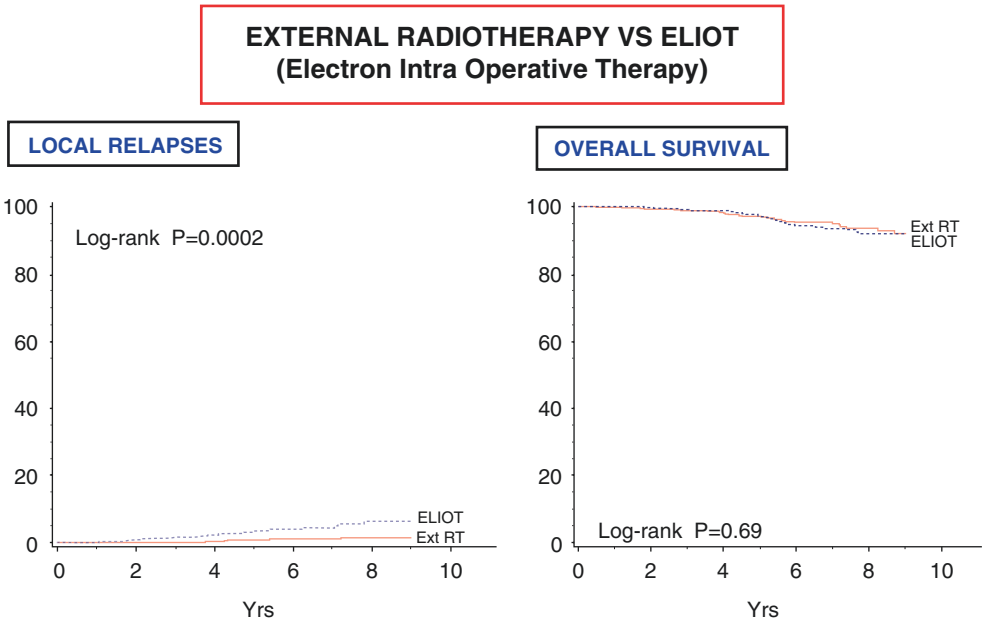

Fig. 23.7 Ten-year results of the randomized trial comparing external radiotherapy vs. intraoperative radiotherapy with electrons (1305 cases)

0.4% (0.0–1.0) in the external radiotherapy group (hazard ratio 9.3 [95% CI 3.3–26.3]). During the same period, 34 women allocated to intraoperative radiotherapy and 31 to external radiotherapy died ($p = 0.59$). Five-year overall survival was 96.8 (95% CI 95.3–98.3) in the intraoperative radiotherapy group and 96.9% (95.5–98.3) in the external radiotherapy group. In patients with data available ($n = 464$ for intraoperative radiotherapy; $n = 412$ for external radiotherapy), we noted significantly fewer skin side effects in women in the intraoperative radiotherapy group than those in the external radiotherapy group ($p = 0.0002$) [22].

In conclusion, although the rate of IBTR in the intraoperative radiotherapy group was within the prespecified equivalence margin, the rate was significantly greater that with external radiotherapy, and overall survival did not differ between groups. Improved selection of patients could reduce the rate of IBTR with intraoperative radiotherapy with electrons (Fig. 23.7).

23.6 Conservation of Axillary Nodes

The concept of "less surgery" was extended to the treatment of the axilla. The role of radiotherapy on the axilla was evaluated in a study conducted in Milan between 1995 and 1998 [23]. Four hundred and thirty five patients with small tumors, ≤1.2 cm, were randomized to either axillary radiotherapy or nothing. After 63 months of follow-up, the axillary metastases presented were lower than expected in both groups, suggesting that axillary dissection can be avoided in this subgroup of patients and that radiotherapy has a protective effect.

The introduction of the sentinel lymph node biopsy puts under investigation the role of axillary dissection. It was already anticipated that the positivity of the axilla was an element of prognosis and not a reason to perform more extensive surgery. Sentinel lymph node biopsy is a method of "predicting" the axillary status sparing the patient from axillary dissection and its often devastating complications, like arm lymphedema. As soon as the technique of sentinel lymph node biopsy was standardized, a series of randomized control studies started worldwide. The first was the Milan Trial that in 1998 and 1999 randomized 506 patients with tumors up to 2 cm to two arms, one receiving immediate axillary dissection and the other receiving the dissection only if the sentinel node was involved [24]. After 79 months of follow-up, OS and DFS were equal. Only one case of axillary recurrence was observed among the patients in the group who did not receive axillary dissection. The long-term analysis showed that patients had less mortality rates after sentinel lymph node biopsy policy than after immediate dissection (18 vs. 25 deaths).

An identical study was conducted between 1999 and 2004 that randomized 5,611 women with invasive breast cancer up to 4 cm from 80 centers in the USA and in Canada to either axillary dissection or to sentinel lymph node biopsy alone with axillary dissection only if the SLN was positive [25, 26]. After 95.6 months of follow-up, OS and DFS were similar in the two groups. A sub-study reported that up to 12 months postoperatively, patients with axillary dissection had significantly higher arm morbidity and significantly more restricted social activity and impaired QoL.

A multicenter UK trial, ALMANAC trial, studied the QoL in patients with SLN vs. axillary dissection between 1999 and 2003 [27]. One thousand and thirty one patients participated, and at 12 months, it was evident that lymphedema was higher in the axillary dissection group; operative time, drainage use, and hospitalization were much longer in

axillary dissection group, while in SLN group, patients had better arm functioning score. The results of the Danish Breast Cancer Cooperative Group confirmed the ones of ALMANAC. Arm lymphedema and dysfunction were significantly higher in the axillary dissection group at 12 months for ALMANAC and at 18 months for DBCCG [28].

It appeared clear that in case of absence of metastatic nodes, axillary dissection is not only unnecessary but also harmful. But what if the axillary lymph nodes are positive? Is axillary dissection still necessary or can it be avoided? The answer to this question is nowadays under investigation. The NSABP Z0011 trial has randomized 891 patients with T1 and T2 tumors and positive SLN from 115 centers from 1999 to 2004 to receive axillary dissection or no further treatment [29]. At 6.3 years of follow-up, the 5-year OS and the DFS were not different in the two groups, suggesting that prophylactic axillary dissection may not be necessary. The EORTC AMAROS trial has randomized patients with positive SLN to either axillary dissection or axillary radiotherapy from 2001 to 2010 [30]. At the European Institute of Oncology, a multicenter randomized, non-inferiority, phase 3 trial was conducted on 465 patients who had clinically nonpalpable axillary lymph node(s) and a primary tumor of 5 cm or less and who, after sentinel-node biopsy, had one or more micrometastatic (≤2 mm) sentinel lymph nodes with no extracapsular extension. Patients were randomly assigned (in a 1:1 ratio) to either undergo axillary dissection or not to undergo axillary dissection. Between April 1, 2001, and February 28, 2010, 465 patients were randomly assigned to axillary dissection and 469 to no axillary dissection. After a median follow-up of 5–0 (IQR 3.6–7.3) years, we recorded 69 disease-free survival events in the axillary dissection group and 55 events in the no axillary dissection group. Breast cancer-related events were recorded in 48 patients in the axillary dissection group and 47 in the no axillary dissection group [31] (Fig. 23.8). Another multicentric randomized trial

Fig. 23.8 (continued)

studying the role of axillary treatment is the SOUND trial starting at the IEO, in Milan. Patients with pT1 tumors and negative axillary US scan are randomized to either SLN biopsy and axillary dissection if positive or to no sentinel biopsy at all. The results of this trial might completely change the approach to the axillary treatment, abandoning the sentinel node biopsy in patients with an uninvolved axilla at clinical and ultrasonographical examination.

23.7 Radioguided Occult Lesion Localization

Widespread use of mammography and ultrasound resulted in an increase in the number of nonpalpable breast lesions [32–34]. Various techniques are used to localize nonpalpable lesions and guide their removal, including wire-guided localization, carbon localization.

Radioguided occult lesion localization was developed in 1996 at the European Institute of Oncology [35]. Radioactive tracer is injected into the center of the lesion under ultrasound or mammographic control. During surgery, a gamma ray probe is used to locate the lesion and guide its removal. For malignant lesions, ROLL is used together with SNB, a technique called SNOLL [36]. In SNOLL, the patient receives two radiotracer injections: one directly into the lesion and another peritumorally. The first contains ^{99}Tc bound to colloid macroaggregates and serves to locate the lesion. In the second, the ^{99}Tc is bound to colloid microaggregates that move in the lymph ducts to reach the SN.

In recent decades, a steady improvement in imaging diagnostics has been observed together with a rising adherence to regular clinical breast examinations. As a result, the detection of small clinically occult (not palpable) lesions had progressively increased. At present in our institution, some 20% of the cases are treated when nonpalpable.

An analysis focused on 1,258 women who presented at the European Institute of Oncology [37] with a primary clinically occult carcinoma between 2000 and 2006, who underwent radioguided occult lesion localization (ROLL), axillary dissection when appropriate, whole-breast radiotherapy, or partial-breast intraoperative irradiation and received tailored adjuvant systemic treatment.

Median age was 56 years. Imaging revealed a breast nodule accompanied by microcalcifications in 9%. Microcalcifications alone were present in 17.1% of the cases, whereas distortion or thickening represented the remaining 24.6%. Most tumors were characterized by low proliferative rates (68.9%), positive estrogen receptors (92.3%), and non-overexpressed Her 2/neu (91.3%). After a median follow-up of 60 months, we observed 19 local events (1.5%), 12 regional events (1%), and 20 distant metastases (1.6%). Five-year overall survival was 98.6%.

The very high level of curability of patients whose breast carcinoma is not palpable and is discovered only with mammography, ultrasound, and MRI underlines the fundamental role of the imaging progress for the control of this disease.

23.8 Conservative Mastectomy

Conservative mastectomy might initially seem a contradiction in terms; however, if we regard conservation as the maintenance of body image, the expression is appropriate. Conservative mastectomy entails removal of breast parenchyma and saving the outer covering of the mammary gland

(subcutaneous fat, skin, and nipple), leaving the patient with a normal breast appearance. Substitution of the mammary gland for an implant is the only change made. The use of the term "conservative mastectomy" is, in our opinion, more appropriate than the alternative ones, such as "nipple and areola sparing mastectomy," which miss the notion that body image is the final objective.

Mastectomy with preservation of the skin and nipple-areola complex was first described by Rice and Strickler in 1951 for benign disease [38]. In 1962, Freeman [39] used the term subcutaneous mastectomy, and in the past 15 years, the procedure was called either nipple-sparing or total skin-sparing mastectomy. The techniques are similar to those of skin-sparing mastectomy with regard to the dissection of the skin flaps; however, additional preservation of the nipple needs a technically demanding retro-areolar dissection aiming at balancing complete removal of ducts with protection of nipple vascularization.

Location of the incision can be periareolar, with or without lateral extension, on the submammary fold, radial, or an omega pexy incision [40–42]. Periareolar incisions have the highest risk of nipple necrosis, whereas lateral radial incisions facilitate glandular dissection and access to the axilla for sentinel lymph-node biopsy. Some surgeons advocate video-assisted or endoscopic techniques with a midaxillary line incision [43, 44]. Sentinel lymph-node biopsy should always be undertaken during conservative mastectomy, with the breast incision used as access to the axilla (Fig. 23.9).

Skin flaps are created during conservative mastectomy that follow the cleavage plane within the subcutaneous fat, ensuring excision of all glandular tissue while a thin subcutaneous layer is preserved to support the vascular network [45]. The technique of flap dissection is important to provide adequate vascularization yet guarantee complete excision of ducts. During dissection from the pectoralis muscle, the fascia should be preserved. For large-breasted women, this dissection is risky and demanding, and sometimes skin reduction might be mandatory to achieve a normal-looking breast shape with acceptable ptosis [46–48]. In this case, nipple-areola complex preservation can be difficult, because final positioning of the nipple and areola after reconstruction might not be symmetrical to the contralateral.

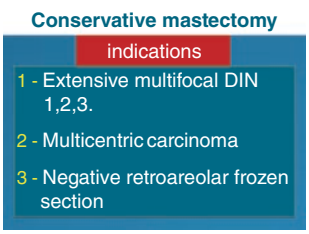

Fig. 23.9 Indications for conservative (or nipple sparing) mastectomy

The most challenging part of conservatory mastectomy is the subareolar excision because of the risk of nipple ischemia. Jensen [49] and Palmieri [50] both attempted to precondition the nipple-areola complex by dissecting it under local anesthesia from the underlying breast tissue several days before the mastectomy procedure, to stimulate blood flow from the peripheral skin. This approach has the advantage of retroareolar biopsy before mastectomy. Routinely, at the time of conservative mastectomy, the duct bundle and all retroareolar tissue are removed, and the specimen is analyzed by frozen section. This method is reliable, but some clinicians advocate the use of imprint cytology instead [51].

Intraoperative radiotherapy of the nipple-areola complex has been implemented in some centers when the frozen section of retroareolar tissue is negative, as a risk-reducing technique for local recurrence [21, 52]. However, radiotherapy is not used in all studies, yet favorable results are reported [53, 54].

The areola and a margin of 1 cm around it are included in the 90% isodose, and the dose administered must be equivalent to a fractionated dose ranging from 40 to 45 Gy [52]. In rare cases of impaired nipple vascularization diagnosed intraoperatively, external radiotherapy to the nipple-areola complex can be delivered in one session on the first postoperative day. Is radiotherapy really needed, and would a specific subgroup of patients benefit from it? A randomized trial is planned at our institute.

Heterologous implants are used extensively in breast reconstruction, and the option of fixed-volume silicone or expander implants is available. Expander implants are preferred in cases of compromised blood supply because they offer the advantage of minimal retroareolar pressure in the immediate postoperative days, when the areola is still at risk. The implant is positioned under a muscular pocket created by the pectoralis major and the serratus muscle [55]. Expanders are also preferred over fixed-volume implants, to avoid excess skin tension and flap ischemia [56, 57]. Autologous myocutaneous flap reconstruction is preferred for large-breasted women with a large skin envelope after glandular excision (Fig. 23.10).

Between March 2002 and December 2011, 2,487 patients underwent conservative mastectomy at the European Institute of Oncology. Exclusion criteria were nipple retraction, bloody discharge from the nipple, inflammatory changes of the breast, Paget's disease, and previous radiation therapy. Furthermore, tumor size needed to be less than 4 cm in diameter, and distance from the nipple-areola complex to the tumor had to be at least 2 cm. Clinical lymphadenopathy was not criterion for exclusion. A series of 934 women underwent surgery between March 2002 and December 2007 with a median follow-up of 50 months. Five-year overall survival was 96.4%, and women with invasive cancer had 5-year survival of 95.5%, and a 5-year cumulative incidence

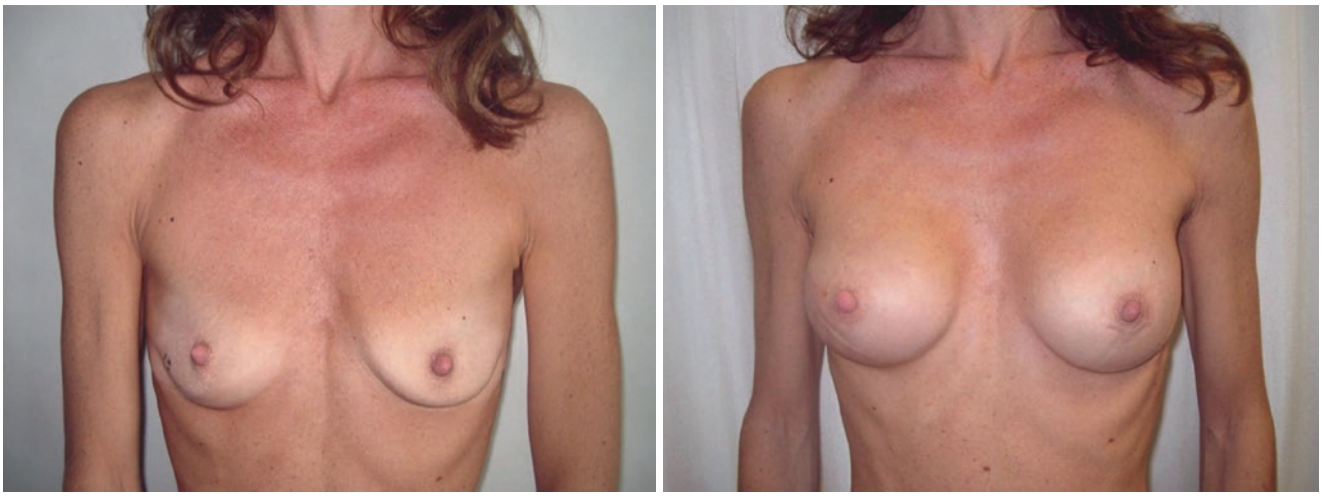

Fig. 23.10 Forty-one year-old patient before and after nipple sparing mastectomy (right breast)

of breast-related events was 14.7%. Patients with ductal intraepithelial neoplasia has 5-year overall survival of 100%. The high survival rates of our series suggest that conservative mastectomy combines safety with good cosmesis [58].

The Conservative Mastectomy

24

Alberto Luini

24.1 Introduction

Mastectomy is the complete removal of breast gland during a surgical act: this kind of surgery seems not reliable when included in a list of conservative treatments. In fact, mastectomy is not conservative at all, but the recent evolution of breast cancer surgery has made this radical approach more conservative with the new techniques that spare a portion of the skin and mainly the nipple and areola complex (NAC).

The NAC removal in the mastectomy technique has always been needed to reduce the risk of local relapse of disease in this area, due to the fact that duct terminations are into the nipple and behind the NAC the portion of breast gland can be equally affected by all the other anatomic areas. Unfortunately, this removal has a deeply negative impact on the cosmetic outcome of mastectomy and on patients' quality of life. The absence of NAC on a reconstructed breast represents a worsening of the cosmetic result even if the reconstruction with plastic surgery has had a perfect outcome.

Patients who must undergo mastectomy (around 30% of breast cancer patients) are always worried about the mutilation they are going to receive, and this mutilation becomes particularly evident in the absence of the NAC: the breast shape can be restored and sometimes ameliorated, but the lack of the nipple and areola is difficult to repair. Of course, the plastic surgery repairs also this kind of damage with subsequent interventions, but the feeling of mutilation exists and can remain for several months.

At the European Institute of Oncology in Milan, we developed a modified mastectomy technique, and we named it *nipple-sparing mastectomy*, putting together the concept of skin sparing applied to the nipple and areola anatomic area and the occasional adoption of radiotherapy with electrons (possibly delivered during surgery with intraoperative radiotherapy with electrons ELIOT) to reduce the risk of local relapse of breast cancer. Fundamental requisite for the correct procedure is the negativity of retro-areolar breast tissue examined by histopathology during surgery.

24.2 The Nipple-Sparing Mastectomy

The nipple-sparing mastectomy is a mastectomy that removes the entire breast gland and preserves the NAC after adequate intraoperative histopathology on the retro-areolar breast tissue to exclude the presence of microscopic disease (Fig. 24.1).

This kind of surgery can be indicated to patients affected by extensive intraepithelial lesions and/or invasive breast carcinoma not located in the central quadrant of the breast and with no high risk of local relapse in the nipple area.

When we started studying nipple-sparing mastectomy, we decided to adopt two main procedures to reduce the risk of local relapse in the nipple area (after adequate selection of patients, of course):

- Intraoperative complete histopathology to the retro-areolar tissue
- ELIOT at a dose of 12 Gy to the NAC

The intraoperative histopathology on the retro-areolar tissue removed during surgery is mandatory: to preserve the NAC, we must be sure that the pathologist did not find tumor cells in the portion of the breast gland located exactly behind the nipple. Regarding ELIOT, at the beginning of our experience, we wanted to reinforce the protection to the preserved NAC by giving a dose of electrons during surgery, but subsequent analysis confirmed that a deep pathological examination of the tissue behind the NAC can guarantee extremely good results even with the avoidance of radiotherapy [1–3].

The technique of this surgery is comparable to a subcutaneous mastectomy, and great care should be taken not to compromise the blood and lymphatic flow behind the nipple: the necrosis of the nipple is, in fact, one of the main undesired

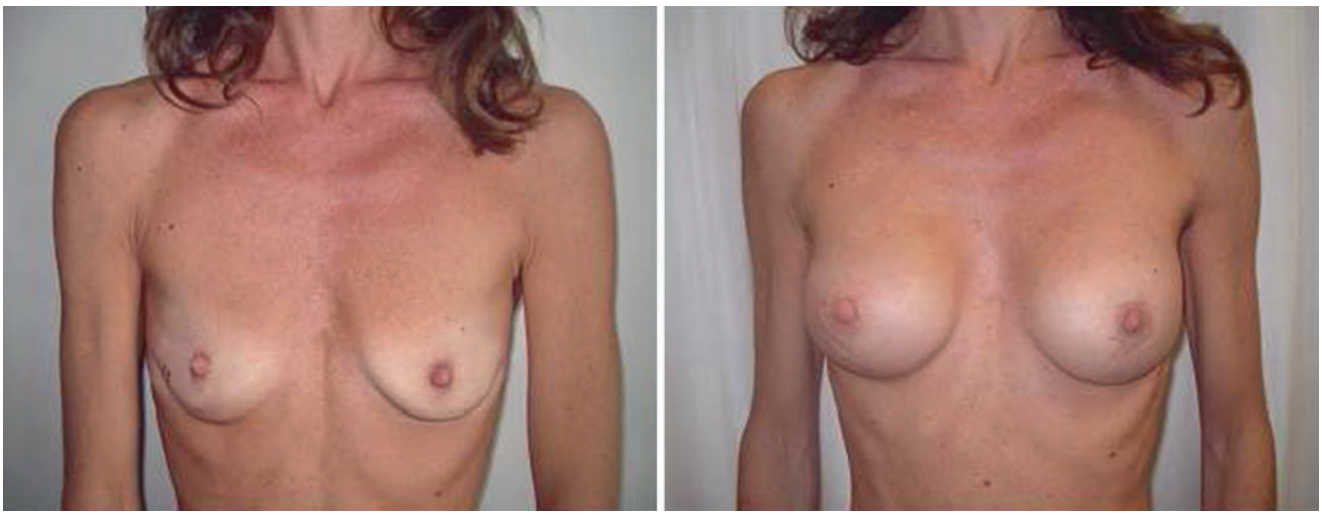

Fig. 24.2 Patient with right breast cancer before (image on the *left*) and after (image on the *right*) nipple-sparing mastectomy to the right breast and prosthesis implant in the left breast

effects of this operation together with the partial or complete loss of skin sensitivity at the nipple. Good surgical experience is crucial to obtain a representative specimen of the breast tissue behind the NAC, to be sent to the pathologist for the intraoperative examination, and the need of preserving blood nourishment to prevent an eventual necrosis [4, 5].

To decide the type of incision and the skin removal over the tumor, it is important to know the distance of the tumor from the skin or, even better, the distance among the tumor and the superficial overlying fascia (we can obtain this element with the imaging): the skin removal is suggested when this distance is less than 5 mm. Another indication to remove the skin could be a previous excisional biopsy of the tumor.

An accurate patient anamnesis is crucial to determine the presence of specific risk for skin necrosis at the NAC, such as skin pathology or defects, smoke habit, diabetes, and cardiovascular diseases.

The close cooperation between breast surgeon and plastic surgeon is mandatory (Fig. 24.2).

At the European Institute of Oncology, we are also studying a robotic approach: the nipple-sparing mastectomy is under evaluation with the aid of the Da Vinci technology. High proportion of patients with newly diagnosed early-stage breast cancer in Europe and the USA undergo mastectomy, and more conservative approach should be studied to improve quality of life of patients who need unavoidable mastectomies. Despite the lack of a natural cavity needed for endoscopic viewing, applications of robotic surgery have recently emerged for superficial organs such as in the fields of thyroidectomy, oropharyngeal surgery, and plastic and reconstructive surgery. However, it has never been applied in breast cancer except for a feasibility and safety study conducted by Toesca et al. [6] that firstly published the robotic technique considering the first three cases. In these initial cases of robotic nipple-sparing mastectomies and immediate robotic reconstruction with implant, we found two main advantages such as the robotic optical vision and the minimal invasiveness. The two main limitations noticed in this

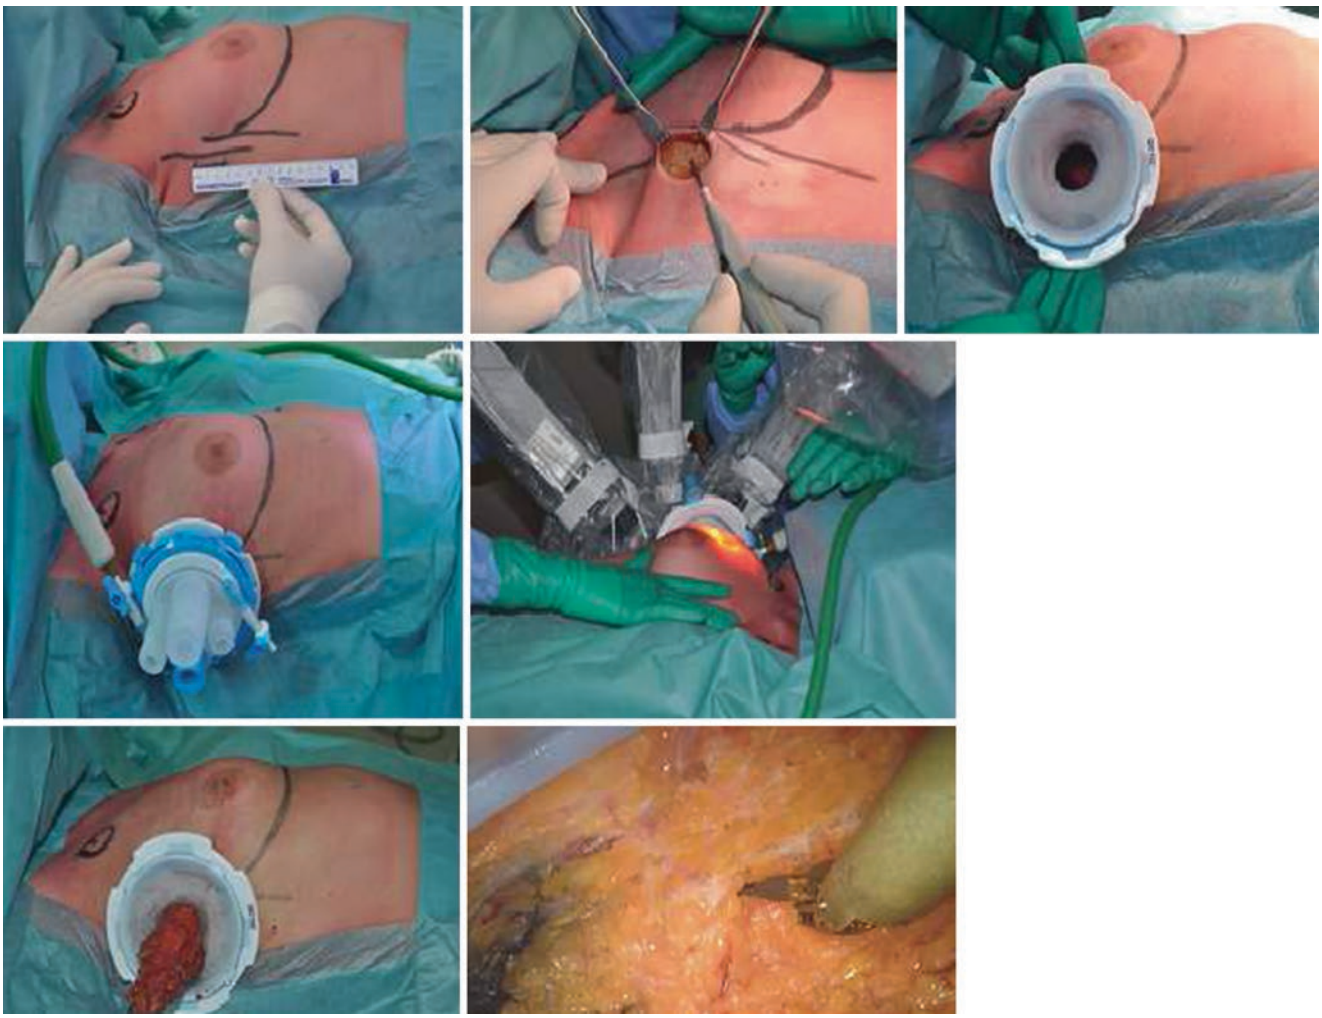

Fig. 24.3 Robotic technique

initial experience were the duration of operating time and the additional costs related to the operation. The limitations of the applicability of robotic surgery to the breast, such as operating time and costs, might be offset by the advantages we observed such as better vision and minimally invasive approach with an anatomically more respectful mastectomy. The same research has continued on breast cancer evaluating not only the feasibility and safety and oncological outcome but also patient satisfaction and quality of life of patients who undergo to this robotic approach (study ahead of print) (Fig. 24.3).

Our experience and a good amount of external trials have already confirmed that a well-conducted nipple-sparing mastectomy is effective in treating selected cases of breast carcinoma with no significant difference in the risk of local relapse of disease, NAC local relapse, and overall and disease-free survival among the new technique and the radical mastectomy that removes the NAC [7–12]. Regarding the rate of side effects, the NAC necrosis and the loss of skin sensitivity in that area are the most frequent events, but they should be compared with the total absence of NAC of the standard approach, so the impact on patients' quality of life of the nipple-sparing mastectomy seems absolutely better whenever the technique is feasible.

The reconstruction technique is chosen depending on breast volume and shape.

24.3 Indication and Present Guidelines

Retrospective trials on skin-sparing mastectomy showed a great variability on the occult involvement of the NAC by tumor cells, but the most relevant reports demonstrate a percentage of this involvement not superior to 20%: these data become lower (to 2.6%) when the lesion is at least at a 2 cm—distance from the NAC.

Patients candidate to nipple-sparing mastectomy have the following characteristics:

- Invasive or noninvasive neoplasm not involving the NAC at the evidence of the clinical and instrumental examinations
- Breast with small or medium dimension with minimal or intermediate ptosis

Absolute contraindications are:

- Clinical and instrumental evidence of pathological involvement of the NAC
- The presence of pathological nipple discharge
- Paget disease
- Inflammatory breast cancer

Relative contraindications are:

- Previous radiotherapy to the breast or prevision of radiotherapy
- Previous periareolar surgery
- Smoke habit, diabetes, cardiovascular disease.

We do not consider contraindications:

- Patient's age
- Close proximity of the tumor to the skin (not NAC), but the skin must be removed during surgery
- Previous neoadjuvant therapy
- Tumor dimension[1]
- Multifocality and multicentricity
- Tumor histology
- Lymph node status

In some selected cases, radiotherapy could have an alternative role to the NAC removal when the final histology demonstrates free margins with a distance disease NAC less than desired. The electron treatment can be postponed during 48–72 h after surgery.

[1]These elements increase the risk of NAC involvement, but they lose their significance if the distance from NAC is maintained.

Surgical Treatment of Local Recurrence in Breast Cancer Patients

25

Jose Vila, Francisco Ripoll, and Oreste D. Gentilini

25.1 Introduction

25.1.1 Definition of Local Recurrence

Local recurrence is defined as the reappearance of an invasive tumor in the ipsilateral preserved breast after Breast-conserving surgery (BCS), or a breast cancer recurrence in the skin, subcutaneous tissue, muscle, or underlying bone after mastectomy. When a local recurrence occurs after a conservative approach, it is called ipsilateral breast tumor recurrence (IBTR) and chest wall recurrence (CWR) when it occurs after mastectomy [1]. Local recurrence tends to occur later after a conservative procedure than after mastectomy, especially in those patients treated by endocrine or chemotherapy [2–4]. Chest wall recurrences are generally diagnosed during physical examination. In contrast, IBTRs are more frequently detected during posttreatment mammographic surveillance [5].

A local failure is considered a marker of aggressiveness as it has been demonstrated to be associated with a three to five times greater risk of distant metastasis and represents the main cause of breast cancer-related death [6]. In the US National Surgical Adjuvant Breast and Bowel Project B-06 (NSABP B-06) study, Fisher et al. demonstrated that patients with IBTR have 3.41 greater risk of developing distant metastasis than patients who do not develop such recurrences [7]. Several factors have been associated with the reappearance of breast cancer such as initial surgery and use of adjuvant therapies (chemotherapy, hormonal therapy, and radiation therapy), residual tumor burden, clinical and pathologic characteristics, and biologic markers of the primary breast tumor [8, 9]. Recently, Shangani et al. updated and validated a web-based predictive model, called IBTR! Version 2.0, to estimate individualized risk of IBTR after breast-conserving therapy. This online tool incorporates seven variables that are routinely assessed and has been associated with increased risk of local failure after conservative surgery, such as age, margin status, lymphovascular invasion (LVI), size tumor, grade, and use of chemo- and/or hormone therapy [10]. This nomogram can be easily implemented in many centers worldwide and may help guide decisions about adjuvant therapies in patients according to their risk of IBTR.

A recent analysis of 86.598 patients from 53 randomized clinical trials showed that isolated local-regional recurrences are now an uncommon event. Advances in the management of early stage breast cancer have significantly reduced the rate of local-regional recurrence from approximately 30% in past studies to 5–15% in recent trials [11]. Even though a rare event, local recurrences are associated with an increased risk of distant metastasis, especially early recurrences occurred within the first 2 years after primary treatment. So, a careful restaging evaluation including a complete blood test, radionuclide bone scan, breast magnetic resonance imaging (MRI), a total body positron emission tomography (PET), and/or chest, abdomen, and pelvis computed tomography (CT) scan may be appropriate in all patients with local recurrence after BCS or mastectomy to rule out the presence of distant disease.

25.1.2 Classification of IBTR

IBTR after BCS comprises a heterogeneous group of tumors with distinct biological behavior and different rates of survival. Although a recognized standard classification for local recurrence after BCS does not exist to date, IBTR has traditionally been categorized as true local recurrence (TR) and new primary tumor (NPT). These two entities were first described by Veronesi et al. in 1995 and were classified basically by its location relative to the primary tumor. TR was defined as the regrowth of invasive disease

at the tumor bed or the boost volume of the treated breast and NPT as a new lesion located at a different site from the primary tumor [12].

Others methods of classifying IBTRs have been proposed by different groups that have attempted to evaluate indicators of prognosis in patients with IBTR. In this sense, Huang et al. classified local recurrences after BCS as either NP or TR based on location and histology [13]. More recently, Sakai et al. have proposed a novel classification of IBTR into four different subtypes based on strict pathologic rules [14]. Initially IBTRs should be classified according to their origin as new primary or true recurrence, similar to others, but subsequently classified again according to the relationship between the IBTR and the primary lumpectomy scar, surgical margin of the primary tumor, and the presence of carcinoma in situ into the IBTR.

The importance of establishing an accurate classification of IBTR is due to the prognostic significance related to both entities [15]. A new primary tumor has been associated with a more favorable prognosis than true local recurrences. Smith et al., in a retrospective study on 130 patients with IBTR, 60 of which were classified as a true recurrence and 70 as a new primary according to the site of failure, histologic subtype, and results from the flow cytometry, assessed the prognostic value of this classification. After a median follow-up of 10.4 years, patients with NPT had significantly better 10-year overall survival, distant-free survival, and cause-specific survival than patients diagnosed with TR [16].

25.1.3 Risk Factors of Local Recurrence

As local recurrence after BCS or mastectomy has been associated with a poor prognosis, it is important to identify patients who are at higher risk of recurrence and might benefit from additional adjuvant therapies and close follow-up [17]. In this sense, several risk factors of local recurrence have been identified either in patients treated with primary conservative surgery or mastectomy [18, 19].

– *Patients treated with primary BCS*. Reasonably, the most important predictor of increased risk for IBTR in patients treated with BCS is the failure to achieve optimal local control. Optimal local control includes a margin-negative surgery (no evidence of invasive cells at the inked border on microscopic evaluation) and use of radiation therapy with or without regional nodal irradiation. Other risk factors for recurrence after BCS include (1) tumors with aggressive biology such as triple-negative tumors, high proliferation rate of Ki-67, multicentric disease, tumors with high nuclear grade, etc., (2) young age at diagnosis of primary tumor, and (3) lymphatic invasion and extensive intraductal component at the first tumor.
– *Patients treated initially with mastectomy*. The clinical risk factors associated with increased risk of local failure after mastectomy include (1) young age at diagnosis, (2) tumor greater than 5 cm, and (3) multicentric disease. Histopathologic risk factors for CWR include (1) patients with four or more positive lymph nodes, (2) positive margins, (3) high-grade triple-negative tumors, and (4) presence of lymphovascular invasion.

25.2 Surgical Treatment of Chest Wall Recurrence

The incidence of CWR after mastectomy ranges from 8 to 40% and depends on several factors such as primary tumor characteristics and the use of adjuvant therapies after mastectomy, mainly the use of postmastectomy radiation therapy (PMRT). Several studies have demonstrated that the use of PMRT resulted in better local control of primary tumors by reducing the rate of CWR by up to 70%, especially in patients with node-positive disease in whom the absolute reduction in the recurrence risk is bigger [20]. Similar CWR rates and survival outcome have been found between patients treated with conventional mastectomy versus skin-sparing mastectomy as well as comparing different types of reconstruction [21, 22]. CWR is diagnosed with concomitant distant disease in up to 30% of patients. Absolute contraindications for curative intent resection include extensive local disease with multiple skin nodules and concomitant distant metastasis. Those patients are candidates to receive systemic therapy prior to evaluate the role of salvage surgery [23]. Although CWR may manifest itself as a macroscopically extensive disease or fungating masses, often it is presented as an asymptomatic nodule in the skin or a slight erythematous rash. Hence, diagnosis requires an experienced physician with high index of suspicion, particularly in high-risk patients. Any suspicious lesion mandates a careful evaluation including biopsy and pathologic confirmation.

The surgical management of these patients is complex and requires a preoperative planning between breast surgeons and plastic surgeons to help decide on the best reconstructive option. An estimation of the extent of the disease and the need for skin grafts or rotational flaps are discussed at these meetings. In all cases, achieving clear margins is essential to provide excellent long-term local control.

For no-reconstructed breast patients with isolated CWR confined to the bed tumor or proximal to the scar, a surgical tumor resection followed by primary closure is generally feasible and oncologically safe. However, for extensive recurrence, chest wall reconstruction using coverage with

skin grafts or autologous flaps is usually needed. In some cases, chest wall resection might require resection of the ribs, sternum, and costal cartilages, and the reconstruction technique depends on the site and extent of the chest wall defect [24]. However, it has to be highlighted that the utility of such wide resection is controversial.

For patients with previous reconstructed breast, the surgical management depends on the type of reconstruction. If patients with CWR had implant-based reconstruction, removal of the implant is sometimes required, but this is not absolutely indicated and, if technically possible, implant might be left in place. In patients with flap reconstruction (transverse rectus abdominus musculocutaneous, TRAM, or latissimus flap), wide surgical resection preserving the flap may be safe in selected cases of isolated CWR [25].

Postmastectomy radiation therapy (PMRT) has been proven to be a determinant for local control of the disease in patients treated with surgical resection after CWR [26–28]. Recent guidelines recommend a complete course of irradiation to the chest wall and supraclavicular and infraclavicular regions for patients initially treated with mastectomy and no prior radiation therapy. A standard dose of 50 Gy with 1.8/2 Gy fractions followed by an additional boost of 10 Gy should be applied [29]. In selected patients with previous irradiations, a second course of radiation as part of an individual multimodal treatment concept is feasible as is associated with acceptable acute and late morbidity and encouraging local control. Wahl et al. reviewed the toxicity and clinical outcomes of a second course of radiation in a multi-institutional study on 81 patients with CWR who underwent repeat radiation therapy of the breast. After a median follow-up of 12 months (range 1–144 months), only four patients developed grade 3 or 4 toxicity and no treatment-related deaths occurred [30]. A similar report was published by Hannoun-Levi et al. [31] evaluating the effect of chest wall re-irradiation using brachytherapy. The study included 32 patients with local recurrence after BCT treated with mastectomy followed by low- or high-dose rate interstitial brachytherapy. At a median follow-up of 22 months, the second local recurrence rate was low (3%), but the distant metastasis rate was 28%. Grade 3 late skin toxicity was observed only in two patients with no grade 4 toxicity.

25.3 Surgical Treatment of Ipsilateral Breast Tumor Recurrence

Though there have been significant advances in the management of breast cancer patients, the optimal treatment for patients with local recurrence after a conservative surgery is still controversial, and there are no data from randomized trials to guide treatment decisions. According to recent studies, 15% of patients with IBTR after BCT are considered inoperable due to the extensive local disease or concomitant distant metastases. The remaining 85% of patients who are diagnosed with operable tumor recurrence are candidate to surgery. International guidelines still recommend mastectomy as the standard approach for IBTR after BCS [32, 33]. However, several retrospective studies comparing mastectomy and repeating BCS have reported similar survival outcomes between both procedures, suggesting that a second conservative approach may be recommended in selected patients (Table 25.1).

Desire of the patient for conservative approach
Acceptable cosmetic results

From Vila J, Garcia-Etienne CA, Gentilini O. Conservative surgery for ipsilateral breast tumor recurrence. J Surg Oncol 2014; 110:62–67 [43]

Patient selection criteria are crucial and represent a guide to selecting the best candidates for consideration of second conservative surgery. Vila et al. in a recent review proposed six clinical conditions that should be taken into account to help select the subset of patients who might benefit of less radical surgery with acceptable long-term survival outcome and local-regional control [43]. The selection criteria are listed in Table 25.2. Careful restaging workup of patients with local recurrence after BCS is mandatory to exclude distant disease and to identify patients who can be managed with curative intent.

25.3.1 Mastectomy

Although breast cancer treatment is becoming more conservative, mastectomy still remains the standard treatment for ipsilateral breast tumor recurrence after breast-conserving surgery [44]. Mastectomy for IBTR provides excellent local control that ranges from 69 to 98% [45]. The benefit of chest wall or regional nodal irradiation in patients treated with post-recurrence mastectomy has not been addressed but generally is not recommended in previously irradiated patients. However, regional nodal irradiation should be considered in high-risk patients who initially did not receive irradiation of the regional nodes. Ideally, mastectomy should be followed by immediate breast reconstruction using either a breast implant or autologous tissue.

25.3.2 Second Breast-Conserving Surgery ± Radiation Therapy

Retrospective studies addressing the role of a second conservative procedure have shown similar survival outcome when compared with mastectomy. Clinical outcome of patients treated with a second lumpectomy with or without re-irradiation is listed in Table 25.3. The largest series evaluating second BCS alone for in-breast local relapse was reported by Gentilini et al. This retrospective study evaluated 161 patients who underwent a second conservative alone approach after BCS and whole breast irradiation [55]. With a median follow-up of 81 months after IBTR, the 5-year overall survival was 84% (95% confidence interval [CI] 78–89) and a 5-year cumulative incidence of a further local reappearance of the tumor of 29%. This rate was lower than previous series and may be related to the small tumor size in the second BCS cohort (60% of the tumors were <1 cm). However, for patients with the diagnosis of a small relapse (<2 cm) occurring late after primary treatment (>48 months), the cumulative incidence of a further in-breast event was 15%. This finding suggests that motivated patients with the early diagnosis of a second primary tumor might be considered for a repeat BCS as an alternative to mastectomy. The local control after repeat BCS in the published series is similar to the outcome achieved by conservative surgery alone without radiotherapy. Therefore, due to improved radiotherapy treatments, a second course of radiation treatment should be carefully considered in those patients undergoing a second conservative procedure for the treatment of IBTR [56].

The largest experience evaluating the combination of a second conservative procedure followed by radiation therapy in patients with previously irradiated breast exists for multicatheter brachytherapy. As shown in Table 25.3, the addition of a second course of irradiation resulted in better local control. For patients treated with second lumpectomy alone, the

second LR rate ranged from 19% to as high as 39%, while in patients treated with a second course of irradiation, the second LR rate ranged from 3 to 21%. However, OS was less influenced by the effect of the re-irradiation as similar 5-year OS rates were observed.

Several limitations have been associated with these retrospective studies such as patient selection for second conserving surgery and the fact that no prospective studies or randomized trials have been performed comparing both procedures. So, the most important question still remains unanswered: Are all patients with operable tumor recurrence forced to undergo mastectomy instead of a second conservative procedure? The answer is no.

25.4 Surgical Axillary Management in Local Recurrence of Patients with Prior BCS

Although sentinel lymph node biopsy (SLNB) has replaced axillary lymph node dissection (ALND) in primary early stage breast tumors for women with clinically negative axilla [57], the axillary surgical management of women diagnosed with IBTR is highly controversial. Widely consulted guidelines still suggest that prior axillary surgery due to oncological reasons is a contraindication to the use of SLNB as the draining lymphatic channels are thought to be disrupted caused by the fibrosis directly related to the surgery resulting in unacceptable false-negative rates [44]. However, data from several retrospective series showed that SLNB is a technically feasible and an oncologically safe procedure to restage the axilla in patients with IBTR (Table 25.4). The success rate of second SLNB ranges from 53.7 to 92.5%. The numbers of the lymph nodes removed during the first surgery is one of the most important factors for successful identification when a second SLNB is performed [58]. In case of previous axillary lymph node dissection, no further treatment of the axilla should be necessary although several studies have reported that SLNB is feasible even in these patients. However, previous ALND is associated with the lowest detection rate of sentinel nodes.

Table 25.4 Experience with the use of second sentinel lymph node biopsy in locally recurrent breast cancer

Matsumoto et al. [65]	22	81.8% (18/22)	4.5% (1)

Abbreviations: *ref* reference, *sSLNB* second sentinel lymph node biopsy

The prognostic value of axillary restaging and the role for treatment decision making process has not been fully elucidated yet. A recent study by Ugras et al. from Memorial Sloan Kettering Cancer Center evaluated the value of axillary restaging in 83 patients with local recurrence (79 IBTR and 4 CWR) and clinically negative nodes at diagnosis. Axillary surgery was performed in 47 patients and 36 patients did not undergo axillary staging. Both groups of patients were similar according to primary tumor characteristics and adjuvant therapies received; however, time to local recurrence in the non-axillary surgery group was significantly shorter (median 3.5 vs. 6.5 years; $p < 0.05$). After a median follow-up of 4.2 years, both groups of treatment had similar rates of axillary failure, non-axillary recurrence, distant metastasis, and death. The authors concluded that preoperative SLNB, although technically feasible, may not be necessary in some cases and should be confirmed in larger cohort of patients [66].

Conclusions

The surgical management of local recurrences after BCS or mastectomy requires integration of health professionals providing multidisciplinary care that comprises breast and plastic surgeons, oncologists, and radiotherapists. Factors such as time to recurrence, site of relapse, initial nodal status, and clinical characteristics of the primary tumor have been shown to predict for differences in overall survival, disease-free survival, and local-regional control. A summary of the surgical options for breast tumor recurrence is represented in Fig. 25.1.

The management of isolated CWR depends on accurate assessment of many variables, such as age, comorbidities and desire of the patients, initial treatment, and size and location of the recurrence. For patients with previously non-irradiated mastectomy, wide resection with clear margins followed by radiation therapy should be indicated. In patients who previously received PMRT, a second course of irradiation may be considered when patients have a high risk of second recurrence. In case of IBTR, motivated patients with the early diagnosis of a second primary tumor might be considered for a repeat BCS as an alternative to mastectomy. Careful preoperative workup including breast MRI should be performed for the best patient selection. A second course of radiation treatment should be carefully considered in those patients undergoing a second conservative procedure for the treatment of IBTR. Although a second sentinel lymph node biopsy has demonstrated to be technically feasible and oncologically safe, little is known about the value of axillary restaging in these patients. Further prospective studies involving patients with local recurrences after BCS and mastectomy are needed to provide solid data that help guide physicians' treatment decisions.

Management of the Axilla

26

Viviana Galimberti

26.1 Introduction

For much of the twentieth century, Halsted mastectomy was the standard treatment for operable breast cancer [1]. The operation included dissection of the axillary lymph nodes, which was reasonable since the nodes were metastatic in most patients [2]. From the early 1980s, breast-conserving surgery, flanked by irradiation of the residual breast, became an acceptable alternative to mastectomy, and by 1990, breast-conserving surgery was the preferred treatment for early breast cancer [3]. Early breast-conserving protocols included axillary lymph node dissection (AD) since most patients still presented with axillary node involvement. However there was much debate as to the utility of this procedure in patients with a clinically uninvolved axilla. As early as 1977, 5-year results of the NSABP B04 trial had shown that mastectomy patients with no clinically evident axillary disease who did not undergo AD were at no greater risk of distant disease or death than those who did receive AD [4]. Furthermore many surgeons were anxious to avoid AD if possible because of its sequelae: permanent lymphedema was relatively common [5], and pain, arm weakness, loss of arm movement, and limitation of hand movements were not infrequent [6].

On the other hand, axillary node status was recognized as a prognostic indicator in breast cancer [7], and this was important since, at that time (1980s), the only other widely used prognostic factor was the size of the primary.

In the final decade of the twentieth century, sentinel node biopsy (SNB) was introduced as a means of determining axillary status in patients with clinically node-negative disease. This proved to be a major turning point in axillary management and remains the axillary staging procedure of choice today for most women with a clinically negative axilla [8]. For a time, the introduction of SNB muted the debate on the utility of AD in patients with a clinically negative axilla, as it proved to be an accurate but minimally invasive staging procedure, yet permitted avoidance of AD in the growing proportion of patients with a pathologically negative sentinel node (SN).

However the debate on the utility of AD soon reignited as understanding of breast cancer biology increased and systemic treatments improved: in selected patients with limited axillary involvement determined by SNB, AD seems to confer no advantage, while total avoidance of axillary surgery may be justified in selected patients with an uninvolved axilla as determined by palpation, ultrasound or other presurgical investigations. In what follows current indications for axillary management will be presented in detail, followed by an outline of expected future developments.

26.2 Management of the Clinically Uninvolved Axilla

SNB is the standard approach [8] to a clinically uninvolved axilla in all patients except those with T4 disease (including inflammatory breast cancer) and those with a clinically involved axilla prior to neoadjuvant treatment. SNB was validated by a series of trials [9–14], and it is now clear that SNs can be detected in over 97% of patients, that their status predicts axillary status with about 90% accuracy, and that the axilla is site of first failure in less than 1% of cases [15].

26.2.1 SNB Technique

Several methods have been developed to identify SNs. The commonest involve peritumoral or periareolar injection of either blue dye or colloid labeled with the short-lived gamma emitter ^{99m}Tc. If blue dye is used, the surgeon searches visually for blue lymph ducts leading to blue nodes after making an incision in the axilla [16]. If the radiotracer method is used, the surgeon uses a gamma-detecting probe to guide the axillary incision and also find and remove the SNs.

V. Galimberti

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_26

Scintigraphy may be used to identify axillary hotspots prior to surgery [17]. Some advocate use of both blue dye and radiotracer to ensure that at least one SN is always found [18]. Experience at the European Institute of Oncology is that an SN is identified in over 99% of cases using radiotracer alone [19]. Only if an axillary hotspot is not seen on scintigraphy after two radiotracer injections is the blue dye method used [20]. Recently the dye indocyanine green which fluoresces in the infrared has been used as an alternative to radiotracer [21]. It has a closely similar SN identification rate to radiotracer (≈99%) and is recommended for centers not equipped to handle unsealed radioactive materials. After indocyanine injection, fluorescence is elicited and detected by a "photodynamic eye" camera: the lymphatic drainage thus made evident is visualized in real time on a monitor. The fluorescence is followed from the injection site to the axilla, and an incision is made where the fluorescence disappears into the axilla. The fluorescent nodes are localized and excised [21].

Another recently developed SN detection technique, called SentiMag, involves injection of magnetic particles (Sienna+) and their detection with magnetic sensor. The system comprises a mains-powered base unit, a handheld probe connected to the base unit by flexible cable, and an air-operated footswitch for balancing [22]. The particles move in the lymph ducts to accumulate in the SN. The probe emits an alternating magnetic field which is absorbed by the Sienna+ particles. In turn these particles emit a magnetic field detected by the probe. Results using this method appear comparable to the radiotracer method [22].

26.2.2 Surgical Removal and Pathological Examination of SNs

If the radiotracer method is used, the gamma-detecting probe is used in the operating room to verify the presence of one or more axillary hotspots. SNB begins after the primary tumor has been removed with a 2–3-cm incision made over the hotspot (loudest audio signal on the counter connected to the probe). The isolated SNs are removed and tagged separately for frozen section examination. The axilla is then checked any for residual activity, which if present is removed. While waiting for the result of the frozen section examination, the surgeon closes the breast. If the SNs are disease-free or contain only micrometastases, the axilla is closed and not further axillary treatment given. If one or more SNs harbor metastases, complete (three-Berg-level) AD is performed (see below).

Examination of three to six SN sections is insufficient to ensure a low false-negative rate and consequently high probability that SN status reflects axillary status, so a more extensive examination of all SNs is necessary. The method used at the European Institute of Oncology is to bisect each node along its major axis and cut 15 pairs of 4-μm thick sections 50–100-μm intervals in each half node (60 sections per node). If any residual tissue is left, additional pairs of sections are cut at 100-μm intervals to completely sample the node. One section of each pair is stained with hematoxylin and eosin and examined. Only is there is any doubt as to the presence of metastasis is the second section of a pair stained by a rapid immunohistochemical method to reveal cytokeratins. SN status is then communicated to the surgeon, and depending on the result AD is performed or not performed.

26.2.3 One-Step Nucleic Acid Amplification

One-step nucleic acid amplification (OSNA) is a relatively new technique for the intraoperative analysis of SNs in breast cancer. The removed SNs are homogenized, and the number of copies of cytokeratin-19 (CK19) mRNA is determined by a rapid quantitative method shown to accurately reflect SN status as determined by pathological analysis of SN sections [23]. The number of mRNA copies correlates with extent of SN involvement (absent, micrometastatic, or macrometastatic) and permits no further axillary treatment when the copy number is low. The method has the advantage that it is reproducible and standardized and does not depend on the expertise of the pathologist, so it is particularly suited to institutes that cannot spare a pathologist for intraoperative SN examinations.

26.2.4 SNB After Breast Surgery

Previous breast-conserving surgery does not contraindicate SNB when a woman presents with disease recurrence in the breast and a clinically negative axilla. It was initially thought that surgery would disrupt the lymphatic drainage so that a new SN would be less likely to be found and would probably not receive lymph from the tumor. The European Institute of Oncology carried out 543 SNBs with radiotracer in women who had received prior breast surgery (excisional biopsy or quadrantectomy). The radiotracer was injected between the breast scar and the axilla, and the presence of an axillary initially verified with lymphoscintigraphy. An SN was identified intraoperatively in 99% of cases and was negative in 70% of them. Among the 161 patients with a positive SN, it was the only positive node in 61.5% of cases. After a median of 2 years, four cases developed axillary failure, two of which had received complete AD [24].

Even a previous mastectomy does not seem an absolute contraindication for SNB. Four patients treated at the European Institute of Oncology with total mastectomy and breast reconstruction with prosthesis developed an isolated

subcutaneous recurrence, with a clinically negative axilla. Subdermal injection of radiotracer has permitted to identify SNs [25]. Preoperative lymphoscintigraphy showed one axillary SN in three patients and two SNs in the fourth patient: SNs were positive in two patients who received AD, negative in the other two who received no further axillary treatment. Follow-up is too brief to suggest conclusions. Nevertheless it is difficult to decide where to inject radiotracer in mastectomied patients since scar tissue and fibrosis surrounding the scar are likely to impede lymphatic drainage and hence SN identification.

26.2.5 SNB After SNB and Radiotherapy

When disease reappears in the operated breast (recurrence or second cancer) after breast-conserving surgery and SNB, a new SNB is indicated if the axilla is clinically clear. Although the lymphatic system is disrupted by breast and axillary surgery, lymphatic drainage subsequently re-forms to allow identification of a new SN [26]. Even after radiotherapy the lymphatic drainage system re-forms, allowing SN identification in most patients [27]. In recurring patients, as in those treated for the first time, the prognostic information provided by SN examination is important; and the patient should be spared AD if possible. From May 2001 to December 2011, 212 patients treated at the European Institute of Oncology by breast-conserving surgery plus SNB with a pathologically clear SN experienced local reoperable recurrence. Preoperative lymphoscintigraphy demonstrated at least one new SN in 207 patients (97.7%), whereas no drainage was observed in five patients (2.3%). One or more SNs were surgically removed from 196 of the 207 patients. SNs were not isolated from the remaining 11 patients. The success SNB rate was 92.5%. Extra-axillary drainage pathways were visualized in 17 (8%) patients. The annual axillary recurrence rate after a median follow-up period of 48 months was 0.8%, and the cumulative incidence of axillary recurrence at 5 years was 3.9%. These data indicate that second SNB should be considered for patients who underwent conservative surgery and had a negative axilla and subsequently recurred locally [28].

26.2.6 SNB After Neoadjuvant Treatment

The 2014 ASCO guidelines indicate that most women with breast cancer should have SNB and reported "intermediate level evidence" that the benefits of SNB after neoadjuvant treatment outweighed the harms. However the guidelines did not recommend SNB in women with an involved axilla prior to neoadjuvant treatment, even if they became cN0 afterward. The reason given was that the false-negative rate (FNR) may range from 10 to 30%, and this was considered unacceptably high [8]. Several studies in fact found FNRs above 10% [29–32]; others however found FNRs below 10% [33–36]. Furthermore the clinical significance of a high FNR is unclear, since the early randomized trials on SNB found that while the FNR was of the order of 10% (control arms), the axillary failure rate in the SNB-only arms was of the order of 1% [10, 14].

To address this issue, a retrospective study from the European Institute of Oncology investigated outcomes in a consecutive series of patients treated between 2000 and 2010. One group of 147 patient was cN1/2 before neoadjuvant treatment and became cN0 afterward and received SNB with AD if the SN was positive. These were compared with to those in a consecutive series of 247 patients, treated over the same period, who were cN0 before neoadjuvant treatment and remained so afterward. After a median follow-up of 61 months, just one patient in each group developed axillary failure as first event; one other patient in each group developed simultaneous local plus regional failure suggesting that SNB is acceptable in cN1/2 patients who become cN0 after neoadjuvant therapy. Furthermore survival outcomes were closely similar in the two groups [37]. The 2015 St. Gallen Conference Panel [38] considered that SNB was appropriate in patients with a clinically positive axilla at presentation who downstaged after neoadjuvant chemotherapy, but that AD was required if even one SN was positive. Nevertheless FNRs remain high unless three or more SNs are examined.

26.2.7 SNB in Multicentric Disease

In multicentric breast cancer, the different disease foci may drain to different axillary nodes so a negative SN has a greater probability of being a false negative (and not reflecting the true state of the axilla). At the European Institute of Oncology, two techniques are adopted to minimize this possibility: (a) if there are two cancer foci, two subdermal injections of radiotracer are given; (b) if there are several tumor foci, a single sub-areolar injection is given, since there is evidence that the axillary nodes receive lymph from a periareolar network of superficially located lymph ducts [39]. Between June and December 2007, 337 patients with multicentric breast cancer and a clinically negative axilla underwent SNB at the European Institute of Oncology. In 100% of cases, at least one SN (median 1.7, range 1–7) was identified. A total of 138 patients with either negative SNs ($n = 134$) or isolated tumor cells in the SN ($n = 4$) did not undergo AD. There were 27 (19.5%) events in the latter group, but only three (2.2%) developed axillary disease after a median follow-up of 5 years (range 17–134 months) providing evidence that SNB is acceptable in patients with multicentric disease [40].

26.2.8 SNB in Pregnancy

Results of a dosimetry study carried out at the European Institute of Oncology indicate that the use of radiotracer to identify the SN in pregnant women is unlikely to have any adverse effects on the fetus. The study recruited 26 premenopausal, nonobese, nonpregnant breast cancer patients of median age 36.7 years scheduled for SNB with radiotracer. Scintigraphy revealed radiation (gamma rays) coming only from the injection site and the axilla. Skin dosimeters (thermoluminescent detectors) were placed on the epigastric, umbilical, and hypogastric regions to measure radioactivity that might be received by the fetus. In 23 of these patients, the absorbed dose was below that detectable by the detectors; in the remaining three patients, minimal doses (about 1000 times lower than the threshold for deterministic effects) were recorded. These findings suggest that use of the standard amount of radioactivity (12 MBq di ^{99m}Tc) to perform SNB is safe at all stages of pregnancy [41].

26.2.9 SNB in Male Breast Cancer

Only about 1% all breast cancers occur in men. Breast cancer is generally diagnosed later in men than women, and around 60% of male cases have axillary involvement at diagnosis, when SNB is not indicated. However, tumor biology, prognostic factors, and prognoses seem closely similar in the two sexes [42] (even though trials to define optimal treatments in men have not been conducted), and men with a clinically clear axilla should therefore be candidates for SNB. SNB is particularly indicated because the sequelae of AD may be more incapacitating in men as their job or lifestyle may be physically demanding [43]. Between April 1999 and January 2005, 75 men were treated at the European Institute of Oncology for breast cancer. Thirty-two with a clinically negative axilla underwent SNB, and at least one SN was found in all cases (mean 1.5, range 1–3). In six cases the SN was metastatic: micrometastatic in two, only one involved axillary node in the other four. After a median follow-up of 30 months (range 1–63), there were no recurrences or axillary failures [23].

26.2.10 SNB in Ductal Intraepithelial Neoplasia

Since ductal intraepithelial neoplasia (DIN) does not metastasize by definition [44], SNB does not seem appropriate. This is supported by a study from the European Institute of Oncology [45] which found that, in 854 cases of pure DIN (no microinvasive foci identified on definitive pathological examination), SN involvement occurred in only 1.9% of cases, decreasing to 1.4% if SNs with only isolated tumor cells were excluded. This finding and others [46] justify not performing SNB in patients with "pure" DIN.

Nevertheless there is always the possibility that DIN may harbor foci of invasive or microinvasive disease not found by preoperative biopsy. The review by Shapiro-Wright et al. [47] found that the risk of a metastatic SN was relatively high in the presence of high-risk DIN (characterized by high grade, comedo necrosis, or large size) and also when the lesion was palpable. In such cases DIN was frequently (10–38%) upstaged to microinvasive or invasive breast cancer on pathological examination. This study also found that in DIN patients scheduled for mastectomy, the SN was involved in a high proportion of cases. In fact contraindication for breast conservation is a risk factor for the presence of invasive cancer or progression to invasive cancer. Tunon-de-Lara et al. [48] also found that invasive disease was frequently underestimated by vacuum-assisted biopsy of DIN patients scheduled for mastectomy.

These findings indicate that SNB should be performed in DIN patients only when biopsy indicates invasive disease; when mastectomy is indicated; when the lesion is palpable; and when the lesion is large. These recommendations are essentially the same as those of ASCO 2014 [8].

The question remains, however: should axillary dissection be performed in DIN patients with a positive SN?

Since the Z0011 trial showed that AD is not necessary in patients with invasive breast cancer and fewer than two positive SNs treated by conservative surgery and systemic therapy [49], it would seem that AD is overtreatment in DIN patients with or without micro-invasion, provided they are scheduled for conservative breast surgery. In fact, in only 0.39–13.7% of such cases are other axillary nodes involved [49, 50]. It is therefore recommended that immediate AD not be performed if the SN is positive during intraoperative examination, in DIN patients undergoing conservative breast surgery.

26.3 Management of the Metastatic Axilla

AD remains the standard treatment if the axilla is metastatic, irrespective of whether breast-conserving surgery or mastectomy is scheduled. If an SN is positive, the AD procedure initially involves enlargement of the excision to access the SNs. If the patient has clinically palpable axillary lymph nodes, increasingly, they are confirmed as positive prior to surgery by needle biopsy, ultrasound, or both, and the surgeon proceeds to AD after removing the primary tumor. The excision is made in continuity with the breast incision when the cancer is in the upper-outer quadrant and is separate when the tumor is located elsewhere. A small lateral cutaneous flap is then prepared to allow access to the lateral margin of the

latissimus dorsi, its insertion in the humerus, the coracobrachialis muscle, and the lateral portion of the vasculonervous tract. The margin of the latissimus dorsi is isolated along its length so as to identify and prepare the blood vessels and the thoracodorsal nerve. The adipose tissue between the internal fascia of the latissimus dorsi and the surface of the chest wall is detached. At this point the long thoracic nerve (Bell's nerve) adherent to the chest wall may be observed under the muscle fascia and whose pathway runs from the high portion of the latissimus dorsi vasculonervous tract to the lower part of the serratus muscle. The medial cutaneous flap is now prepared to access the lateral margin of the pectoralis major and to identify the surface between this and the underlying pectoralis minor. By introducing a retractor, the pectoralis minor may be accessed. The adipose tissue between the two muscles, which includes the Rotter lymph nodes, is thus carefully explored, and if nodes are palpable they are removed, sparing always the thoracic acromial peduncle and the interpectoralis vessels. The coracoclavicular pectoralis ligament is now located and is displaced medial to the vasculonervous thoracic acromial fascia. The margins of the pectoralis minor muscle are identified, and, medially and laterally to the coracoclavicular pectoralis fascia, the index finger is introduced under the venter musculi. Dissection of the adipose tissue continues by uncovering the plexus brachialis and the axillary vein—the anterior surface of which is isolated. By following the vein medially, the tendon of the subclavius muscle becomes visible, thus reaching the apex of the axilla (third level) where the highest axillary lymph nodes and lymphatic vessels are located. These should be isolated carefully, excising the adipose tissue from the tendon of the subclavius muscle and pulling it downward. The lateral limit of each lymph node level should be marked by metal disks or different colored threads to facilitate pathological examination. Performed in this way, so as to spare all vascular and nervous tracts of the muscles, including the intercostal nerves, AD causes side effects in less than 6% of cases yet provides maximum possible prognostic information [51]. By contrast random biopsy of one axillary node, sampling, or removal of the first level only does not ensure disease removal, does not completely obviate the risk of lymphedema, and ignores the possibility of skip metastases, which are may occur in up to 12% of cases.

26.4 Future Developments

In a sense, the future of axillary management is already here. Trials have shown that AD does not confer any benefit in selected patients with a metastatic SN. Perhaps the most important of these was the Z0011 trial [49] which recruited 891 patients with T1-T2 disease, non-palpable axillary nodes, and macrometastases in no more than two SNs, who underwent breast-conserving surgery and whole breast irradiation. They were randomized to either AD (at least ten nodes removed) or no further treatment to the axilla. Most patients also received systemic adjuvant therapy. Overall 5-year survival was 91.8% (95% CI, 89.1–94.5%) in the AD group and 92.5% (95% CI, 90.0–95.1%) in the SNB only group. Axillary failure rates were low in both groups.

The IBCSG 23-01 trial [52] assessed whether omitting AD in patients in whom one or more SNs contained only micrometastases (foci ≤2 mm) had any effect on outcomes. Patients with a non-palpable axilla and tumor up to 5 cm in diameter were eligible; they could also be scheduled for mastectomy. They were randomized to AD versus no further axillary treatment, and after 5 years, there were no significant differences in outcomes between the groups, with axillary failure rates low in both groups.

The AMAROS trial investigated whether axillary irradiation could serve as an alternative to AD in patients with clinically node-negative disease found to have a positive SN. After a median follow-up of 6.1 years, survival outcomes did not differ between the two arms, and regional control rates were high (99.5% and 99.0%) although there were fewer side effects in axillary irradiation arm (lymphedema in 28% of AD arm vs. 14% of axillary irradiation arm patients; $p < 0.0001$) [53, 54].

Further evidence was provided by long-term results of the INT09/98 trial [55], which started the pre-SNB era. The trial randomized patients, age 30–65 years, with T1N0 disease to quadrantectomy with or without AD. A total of 517 patients were evaluated. After a median follow-up of nearly 11 years (127.5 months; interquartile range 113–141 months), neither overall nor disease-free survival differed between the AD and no AD arms. Although overt axillary disease occurred in 22/245 (9.0%) of no AD arm patients (a median of 30 months after surgery), this had no effect on survival outcomes. The authors noted that the biological characteristics of primary were an adequate guide to adjuvant treatment.

Based on the findings of these studies, the 2014 ASCO guidelines [8] and 2015 St. Gallen Conference guidelines [38] recommended that most women scheduled for breast-conserving surgery and whole-breast radiotherapy, and found to have just one to two metastatic SNs, should not undergo AD, although it might be preferable if they were given some form of systemic therapy.

The question obviously arises: if AD can be omitted in many patients with a positive SN, why should we bother to perform SNB? The ongoing SOUND trial was designed to answer this question. Patients with a clinically negative axilla but positive SN are randomized either to AD or to no further surgical treatment of the axilla. To be eligible, patients must be candidates for breast-conserving surgery and have a lesion of ≤2 cm; furthermore axillary negativity must be ascertained by palpation plus axillary ultrasound, with ultrasound-guided fine needle aspiration if a single doubtful lymph node is identified on ultrasound [56].

Management of Intraepithelial Disease

27

Antonio Toesca

27.1 Introduction

Ductal intraepithelial neoplasia (DIN) and lobular intraepithelial neoplasia (LIN) are the new acronyms that many authors now use to replace the traditional definition of ductal or carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) of the breast, respectively. This is because some authors [1] found it difficult to accept the intraductal proliferation of tumor cells being defined as a malignant tumor and others [2, 3] consider that in these cases, the "N" and "M" categories should not be applied and that there is therefore no reason to keep them within the TNM classification, as "intraductal carcinoma" [4].

In this chapter we shall examine DIN1c to DIN3 (DCIS any grade) considering the rest of the intraepithelial neoplasias, such as flat epithelial atypia (DIN1a) and atypical ductal hyperplasia (DIN1b), as risk factors of variable magnitude in the subsequent development of "in situ" breast cancer. Considering that LIN does not require treatment by way of cancer therapy, careful observation is needed to watch for any signs of invasive breast cancer. In addition, strategies such as medication or surgery can be taken into consideration to reduce the risk of breast cancer in the future. Not so long ago, most patients with DIN presented with clinical symptoms, such as breast mass, bloody nipple discharge, or Paget's disease [5].

Today, most lesions are non-palpable and generally detected by imaging alone, due to the widespread use of mammography screening programs [6].

Issues in the management in DIN include: type of surgery performed in terms of indications for breast conservative surgery (with or without radiation therapy), indications for mastectomy with reconstruction, assessment of margins, and staging of the axilla.

27.2 Breast Conservative Surgery With or Without Radiation Therapy

Until approximately 20 years ago, the treatment for most patients with DIN was mastectomy. Today, almost 70% of newly diagnosed patients with DIN are treated with breast preservation [7].

Multiple trials have demonstrated the feasibility and oncologic safety of breast conservative surgery (BCS) in DIN [8], and BCS is used in DIN for similar indications to those for invasive carcinoma [9, 10].

Breast conservative surgery is performed particularly for those patients with small solid masses, mammographically detected lesions, or limited microcalcification areas resulting in an extremely high survival rate and low absolute risk of local recurrence. At present, mastectomy is performed in about 30% of DIN patients, BCS without RT in about 30%, and BCS followed by RT in about 40% [11].

By the early 1990s, with the launch of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 trial, which specifically looked at excision versus excision plus radiotherapy (RT), BCS joined mastectomy as a standard option of care in breast cancer surgery management [12].

Clearly, the benefit of RT for decreasing ipsilateral breast tumor recurrence is well established; however, none of the most important prospective studies such as NSABP B-17, the European Organization for the Research and Treatment of Cancer (EORTC) 10853 trial, the Swedish Breast Cancer Group, and the UK Coordinating Committee on Cancer Research (UKCCCR) showed an overall survival benefit, and there was no decrease in metastasis [2, 3, 13–16].

In the current management of DIN patients, physicians are faced with the issue of whether to recommend radiotherapy and/or tamoxifen treatment to their patients in addition to surgery. To aid in this decision, a number of factors are taken into account, including patient age and tumor margins, grade, and size, but the evidence to support these and other potential features as prognostic is variable [17].

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_27

Considering that the goal in the management of DIN is to maximize local control with the least-aggressive treatment, avoiding overtreatments and multiple important risk factors can be involved in the choice of performing radiation therapy for some low-grade low-risk neoplasia such as age, multifocality, margin status, Ki-67, and menopausal status as prognostic factors for local events [18].

The most significant predicting factor for local recurrence is the presence of multifocality. In fact, a recent meta-analysis of three randomized control trials (RCTs) and two observational studies including 3895 patients showed an increased risk of recurrence in patients diagnosed with multifocal DIN of any grade (range from 1.55 to 2.97 in RCTs and from 1.8 to 6.0 in observational studies) [19]. Moreover, a large observational study of 260 patients treated by BCS alone or BCS plus external radiation therapy concluded that multifocality is an independent risk factor for the development of ipsilateral breast tumor recurrence (IBTR) after BCS for any DIN with or without RT [20].

Although many studies have the bias of retrospective material, and often have no comparison to a radiotherapy group, several previous reports have studied the association between age and risk of IBTR after BCS for DIN.

In a study by Lagios [21], low-grade disease, not greater than 25 mm, discovered mammographically and excised with at least 1 mm margins, revealed a 12% IBTR rate at 5 years and 16% at 10 years, with no breast cancer-related deaths and no systemic recurrences for patients treated without RT [22].

Adverse prognostic factors for DIN outcomes include younger age at diagnosis, symptomatic presentation (i.e., palpable), larger tumor size, higher nuclear grade, presence of comedo necrosis, and positive margins on excision. The benefit of radiation based on the presence of these factors has been a topic of controversy. The retrospective work of Silverstein in the development of the Van Nuys Prognostic Index was the first attempt at stratifying risk and prescribing a different surgical and RT regimen for DIN according to age, tumor size, pathological classification, and margin width [23–25].

The Van Nuys Prognostic Index combines several clinicopathological factors to aid decision-making regarding the use of radiotherapy and completion mastectomy after lumpectomy. The original VNPI was introduced in 1995, and it classified DCIS cases according to nuclear grade and the presence of comedo necrosis. Subsequent revisions of the VNPI included tumor size, margin width, and patient age in the scoring system. In its current format, scores of 1–3 each are assigned for patient age, tumor size, margin width, and tumor class (the nuclear grade and presence/absence of comedo necrosis), giving a sum of 4–12, with a score of 4 being associated with the lowest recurrence risk [26]. High mammographic density (at least 75% density) has been associated with a relative risk of 2.8 (95% CI 1.3–6.1) for the development of local recurrence in patients treated with local surgical excision and radiotherapy [27].

A meta-analysis conducted by Wang et al. again reported multifocal DIN to be associated with an increased risk of ipsilateral recurrence compared with unifocal tumors (overall risk estimate 1.95, 95% CI 1.59–2.4063) [28].

In conclusion, the use of RT for patients treated with BCS is still a matter of debate. In a recent Saint Gallen Consensus Conference, the majority of the panel supported radiation after complete excision of ductal carcinoma in situ (DIN) but was prepared to consider its omission for some elderly patients and for those with low-grade low-risk DIN [29].

27.3 Mastectomy and Reconstruction

In the past, when mastectomy was common, reconstruction was uncommon; if it was performed, it was generally done so as a delayed procedure. Today, reconstruction for patients with DIN treated by mastectomy is common; when it is performed, it is generally done immediately, at the time of mastectomy.

The evolution of mastectomy techniques enables patients requiring mastectomy and patients undergoing risk-reducing surgery to benefit from advances in oncoplastic surgery, with improved cosmetic outcomes and reduced psychological impact.

In the past, when a mastectomy was performed, large amounts of skin were discarded. Today, it is considered perfectly safe to perform a skin-sparing mastectomy for DIN and in many instances, nipple-areola sparing mastectomy.

In the past, there was little confusion. All breast cancers were considered essentially the same, and mastectomy was the only treatment. Today, all breast cancers are different, and there is a range of acceptable treatments for every lesion. For those who choose breast conservation, there continues to be a debate as to whether radiation therapy is necessary in every case. These changes were brought about by a number of factors. Most important were increased mammographic utilization and the acceptance of breast-conservation therapy for invasive breast cancer.

The widespread use of mammography changed the way DCIS was detected. It also changed the very nature of the disease detected, by allowing us to enter the neoplastic continuum at an earlier time. Until the 1980s, the treatment for most patients with any form of breast cancer was generally mastectomy. Since that time, numerous prospective randomized trials have shown an equivalent rate of survival with breast conservation therapy for selected patients with invasive breast cancer. On this basis, it made little sense to continue treating a lesser disease (DIN) with mastectomy while treating the more aggressive invasive breast cancer with breast preservation.

Recently, numerous investigators have assessed the value of preoperative MRI in DIN, and today the debate centers on whether or not the addition of MRI to conventional mammograms and ultrasound in the preoperative evaluation of DIN would result in a better prediction of disease extent and thus potentially improve the rate of mastectomies. Doyle et al. [30] clearly stated that they saw a statistically significant improvement with concordance between the predicted and pathologically proven extent of DIN when using a mammography-MRI combination, compared with using mammography alone. They conclude that the addition of MRI to mammography in preoperative evaluation for DIN does improve concordance with the final pathology. This is a promising result in terms of the potential for MRI to aid decision-making in DIN-diagnosed patients, given that one of the key preoperative decisions is whether or not one should proceed with BCS or with mastectomy.

27.4 Assessment of Margins

The definition of positive margins has varied widely, making data synthesis challenging. In one meta-analysis of 4660 patients in 21 studies who underwent partial mastectomy and radiation for DIN, recurrence rates were as high as 10% and showed a correlative increase in rates of recurrence with reduced thresholds for margin positivity [31].

Yet, Houssami et al. found that when the data were adjusted for the administration of adjuvant therapy, there was no significant decrease in local recurrence rates for 1-, 2-, and 5-mm margins [32, 33].

The overview of the four prospective randomized trials of RT for DCIS reported that negative margins are associated with a lower risk of recurrence [15].

Solin et al. [34] reported that in a multivariable analysis of 1003 women with mammographically detected DCIS treated with BCS and RT, and median follow-up of 8.5 years, margin status and age were the only statistically significant factors associated with recurrence. Compared with negative margins, positive margins (tumor on ink) had an HR of 3.35 (P¼ 0.00035), and close margins (defined as <2, <2–3, or <3 mm) had an HR of 1.9 (P¼ 0.03). As well demonstrated by Shaikh et al. [35] in a large series of women with DIN, where numerous factors were controlled for, they found that margin width was strongly associated with risk of recurrence for women undergoing BCS who do not receive RT. In contrast, they found no association among those who do receive RT, demonstrating a differential association of margin width and recurrence, depending on adjuvant treatment. These results support the conclusion that obtaining wider negative margins may be important in reducing the risk of recurrence in women who choose not to undergo RT or some adjuvant systemic therapy and may not be necessary in those who receive RT.

27.5 Staging of the Axilla

Over the past decade, sentinel lymph node biopsy has widely replaced axillary lymph node dissection as the preferred method of nodal staging for breast cancer. In recent years new data confirm that sentinel node biopsy for DIN should be limited primarily to those patients who require mastectomy. While earlier studies suggest a number of possible indications such as high-grade tumor, large lesion, palpability, inability to rule out invasion, etc., the percentage of micro-invasion in the resected specimen and therefore consequent percentage of positivity of the sentinel lymph node are described as less than 1% [36].

With BCS, the risk of second surgery after accidental diagnosis of infiltrating carcinoma is very low. In the event of invasion after BCS, a sentinel node biopsy is always technically feasible. The situation is different when mastectomy is performed considering that a second surgery on the axilla could be technically more problematic.

In 2014, ASCO updated recommendations on the use of sentinel node biopsy for patients with DIN [37] stating that sentinel node biopsy is recommended when mastectomy is performed. Concerning the staging of the axilla for breast conserving surgery, the panel also recommended: (1) sentinel node biopsy only for minimally invasive breast cancer demonstrated on the core needle biopsy, (2) for a lesion highly suspicious of invasive cancer, or (3) in case of an area of DCIS on imaging >5 cm.

Breast-Conserving Surgery After Neoadjuvant Therapy

28

Mahdi Rezai and Stefan Kraemer

28.1 Introduction

Early randomized trials of the addition of neoadjuvant chemotherapy (NACT) to the treatment regimen of patients with breast cancer failed to demonstrate an improvement in overall survival compared with conventional adjuvant therapy; nevertheless, the increased opportunities for breast conservation, owing to downstaging of the primary tumour, and enthusiasm regarding the potential to tailor systemic therapy based on responses observed in the neoadjuvant setting, resulted in the adoption of this approach as a useful clinical tool. That the effectiveness of NACT varies by molecular subtype is becoming increasingly clear, and although the potential of tailoring adjuvant systemic therapy based on treatment response before surgery remains to be realized, the increasing rates of pathological complete response following NACT have had a considerable impact on locoregional treatment considerations. For example, NACT reduces the need for mastectomy and axillary lymph node dissection, thus decreasing the morbidity of surgery, without compromising outcomes. However, selection of the ideal candidates for preoperative chemotherapy remains critical, and personalizing local therapy based on the degree of response is the subject of ongoing clinical trials. The concept of *targeted breast surgery* is a systematic model of surgical techniques for breast conservation after NACT with optimized local outcome and aesthetic results for the patients.

28.1.1 Neoadjuvant Chemotherapy (NACT)

Preoperative or neoadjuvant chemotherapy (NACT) was initially used in the treatment of patients with locally advanced breast cancer (T4a–T4d disease), after historical series of patients with inflammatory breast carcinoma (T4d disease) and other T4 breast tumours who were treated with initial surgery demonstrated high rates of local recurrence and poor survival [1, 2]. The demonstration in the 1970s that adjuvant chemotherapy improved both disease-free survival and overall survival of women with lymph node-positive breast cancer [3, 4] led to a number of studies examining the role of NACT in locally advanced breast cancer. The results of early studies of NACT indicated a prolongation of disease-free survival and overall survival compared with historical controls [5, 6], coupled with the observation that major reductions in tumour volume occurred in 60–80% of patients treated [7], providing the rationale for clinical trials of this approach in earlier-stage operable breast cancer. The primary aim of these studies was to determine if NACT, through prompt treatment of micrometastases, improved survival compared to chemotherapy given postoperatively. However, a meta-analysis of nine randomized studies, comprising a total of 3946 patients, found no significant survival difference between patients who received NACT and those who received adjuvant therapy, with a summary risk ratio of 1.0 (95% CI 0.90–1.12) [8]. Although this lack of survival difference has persisted in more recent studies [9], a number of benefits of NACT have nevertheless emerged, including increased opportunity to perform breast-conserving surgery (BCS) and a reduced need for axillary lymph node dissection (ALND) [10]. Additionally, the achievement of pathological complete response (pCR) to NACT has emerged as a powerful prognostic factor [11]. The acceptance by the FDA of pCR rate as a criterion supporting the approval of new drugs [12], together with the other benefits discussed, suggests that the use of NACT will continue to increase. This paradigm shift raises a number of important questions regarding appropriate approaches to local therapy for breast cancer, as the

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_28

guiding principles for surgery and postoperative radiotherapy in use today were developed based on the findings of trials in which surgery was the initial treatment modality.

28.1.2 NACT and Breast-Conserving Surgery (BCS)

A meta-analysis of 14 prospective randomized trials of neoadjuvant versus adjuvant chemotherapy in a total of 5500 patients with breast cancer demonstrated that NACT was associated with an absolute decrease in the mastectomy rate of 16.6% (95% CI 15.1–18.1%) [9]. In fact, this 16.6% reduction in the mastectomy rate was an underestimation of the potential benefit of NACT, as many of the patients were candidates for BCS at presentation and, with regard to the surgical approach, could not benefit from NACT. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-18 trial [10] and the European Organisation for Research and Treatment of Cancer (EORTC) 10901 trial [13], the rates of BCS after four cycles of anthracycline-based NACT in patients deemed to have required mastectomy if surgery had been the initial treatment were 27% and 23%, respectively. Paradoxically, although rates of pCR to NACT have increased markedly with the use of newer therapeutic agents and targeted therapies, rates of BCS have not risen. For example, in the NSABP B-27 trial [14], the addition of docetaxel to doxorubicin and cyclophosphamide NACT increased the pCR rate from 13.7% to 26.1% ($P < 0.001$), but the rates of BCS were not significantly different between the patients who received docetaxel and those who did not (61.6% vs. 63.7%; $P = 0.33$). More recently, in the Neoadjuvant Lapatinib and/or Trastuzumab Treatment Optimization (NeoALTTO) trial in patients with HER2-overexpressing tumours [15], which compared chemotherapy plus trastuzumab and lapatinib with chemotherapy plus either lapatinib or trastuzumab, rates of pCR differed considerably: 51.3% with dual HER2 blockade, 29.5% with trastuzumab, and 24.7% with lapatinib. However, in patients who were not candidates for BCS at randomization, rates of BCS after NACT were 26.4% in the trastuzumab–lapatinib combination group, 27.7% in the trastuzumab group, and 26.4% in the lapatinib group [15]. Indeed, failure to translate increased pCR rates into a higher rate of BCS has been observed in multiple studies (Tables 28.1 and 28.2). This trend is somewhat inexplicable, but is probably attributable to the difficulty in evaluating the extent of residual disease after NACT and before surgery and confusion regarding whether resection of the entire volume of breast tissue originally occupied by the tumour is necessary. Additionally, some definitions of pCR include patients with residual ductal carcinoma in situ (DCIS), which can preclude BCS. Furthermore, just as patients who are candidates for primary BCS often opt for mastectomy [16], patient preference after NACT might also contribute to the observed rates of mastectomy in this setting.

28.1.3 Patient Selection for NACT to Enable BCS

Both anatomical and biological factors are useful in selecting patients with breast cancer in whom NACT is likely to result in tumour downstaging that enables BCS. For instance, patients with high-grade breast tumours that are oestrogen receptor (ER)-negative and/or HER2-positive have a higher likelihood of pCR to NACT. In one study, patients with ER-positive, HER2-negative luminal tumours, which are generally low grade, had a 6% pCR rate with paclitaxel, 5-fluorouracil, doxorubicin, and cyclophosphamide NACT, compared with 45% for HER2-positive or basal-like tumours (which are mostly negative for ER, progesterone receptor [PR], and HER2 and triple-negative breast cancer [TNBC]) [17]. In patients with ER-positive tumours, a 21-gene assay for estimation of disease recurrence (Oncotype DX©, Genomic Health, USA) is predictive of the probability of pCR to NACT, just as this assay is predictive of a benefit from chemotherapy added to endocrine therapy in the adjuvant setting [18]. The suitability of patients with infiltrating lobular carcinoma (ILC) for preoperative therapy to downstage tumours to enable BCS is uncertain. A meta-analysis of data from 12,645 patients with infiltrating ductal cancers and 1764 with ILC reported a pooled pCR rate for ductal cancers of 16.7% (95% CI 13.5–20.5) compared with 5.9% (95% CI 3.6–9.4%) for ILCs—a pooled odds ratio (OR) of 3.1 ($P < 0.00001$) [19]. In the 13 studies included in this meta-analysis that reported rates of BCS, a higher rate was observed in patients with ductal versus lobular cancers (54.8% vs. 35.4%; pooled OR 2.1; $P < 0.00001$). Of note, a comparison of patients with lobular cancer ($n = 75$) and those with ductal cancer ($n = 671$) in two prospective NACT trials found that, after adjusting for hormone-receptor status, HER2 status, histological grade, and p53 expression, rates of pCR did not differ between ductal and lobular cancers, indicating that these additional clinicopathological features could potentially be used to select the subset of patients with lobular carcinoma most likely to benefit from NACT [20]. Importantly, pCR is not absolutely necessary for BCS: only sufficient tumour shrinkage to enable resection of the tumour to clear margins with an acceptable cosmetic result is required. Nevertheless, patients who achieve a pCR are by definition candidates for BCS, and rates of pCR provide a minimum estimate of the proportion of patients likely to benefit from the NACT approach. On the basis of the current data, the patients in whom NACT is most likely to result in tumour downstaging to enable BCS are those with unicentric,

high-grade, ER-negative, and/or HER2-positive breast cancer [21, 22].

Multiple studies have evaluated the accuracy of MRI compared with physical examination, mammography, and ultrasonography in determining the presence and extent of viable tumour within the breast after NACT [23–27]. In a multi-institutional study of 41 women with palpable breast cancers, Yeh et al. [27] demonstrated that preoperative MRI had the best correlation with surgical specimen pathology when compared with physical examination, mammography, and ultrasonography. Furthermore, in 216 women who participated in the prospective, multi-institutional I-SPY trial [23], MRI was shown to be a better predictor of pathological response to NACT than clinical examination. A meta-analysis of 44 studies including a total of 2050 patients who received NACT found that the median sensitivity of MRI for the detection of residual cancer across studies was 0.92 and the median specificity was 0.60 [24]; however, accuracy differed

depending on the definition of pCR used and was lower in studies that permitted residual DCIS in the definition of pCR [24]. This meta-analysis also provided evidence that mammography had lower accuracy for detection of residual disease than MRI (relative diagnostic OR 0.27; 95% CI 0.07–1.02; $P = 0.02$), but differences in accuracy between MRI and ultrasonography and MRI and physical examination were not statistically significant [24]. All of these methods of evaluation are limited in their ability to detect scattered microscopic foci of viable carcinoma, which might have an impact on the success of BCS [26]. Current evidence indicates that the accuracy of MRI after NACT varies with ER, PR, and HER2 status and is greatest in patients with HER2-positive disease or TNBC, probably owing to the higher rates of pCR in these patients than those with other tumour types [28, 29]. Studies addressing the ability of MRI to identify patients who are appropriate candidates for BCS, as opposed to those aimed at identifying pCR or correlating tumour size

based on MRI assessment with pathological tumour size post NACT, are more limited. Straver et al. [30] examined pre-NACT and post-NACT MRI exams in 208 patients; in 35 patients (17%), MRI underestimated tumour size by more than 2 cm, which would have led to inappropriate attempts at BCS in 27 patients (13%). Conversely, MRI overestimated the extent of disease in nine patients (4%), leading to unnecessary mastectomy. Thus, the overall accuracy of MRI for the selection of surgical therapy was 83% [30]. In a study that investigated the relationship between MRI estimation of tumour size after NACT and positive surgical margins in 182 patients with breast cancer, one-third of patients (33%) in whom tumour size was underestimated by more than 2 cm had positive margins compared with 12% of those with lesser degrees of underestimation or overestimation of tumour size (P = 0.005); however, underestimation of tumour size by greater than 2 cm occurred in only 10% of patients [31]. In aggregate, the literature indicates that MRI is useful for selecting patients who are candidates for BCS after NACT. In patients with malignant calcifications, a post-NACT mammogram is also useful for planning the extent of the resection: although calcifications do not always indicate residual malignancy [32], the presence of residual disease cannot be reliably excluded unless all radiographic abnormalities are removed.

28.1.4 Surgical Issues

In patients undergoing NACT with the potential for breast tumour downstaging to enable BCS, the tumour site should be marked with a clip before initiating NACT. Resection of the entire volume of breast tissue originally occupied by tumour is not necessary [33]; however, no consensus has been reached on what constitutes an adequate surgical margin in this setting. The NSABP B-18 trial [34] used the standard NSABP margin definition of no ink on tumour and, after controlling for age and tumour size, found no statistically significant differences in local recurrence between patients who required NACT for downstaging to BCS candidacy, those who were candidates for BCS before NACT, and those who underwent BCS and received adjuvant therapy. Similarly, the meta-analysis by Mieog et al. [9] reported no significant differences in local recurrence for patients with breast cancer who received NACT versus those who received adjuvant therapy, including the subset of patients requiring NACT to downstage the primary tumour to enable BCS. Thus, BCS after NACT can clearly be safe, although the 'Swiss cheese' pattern of response, characterized by scattered microscopic foci of residual viable tumour, has been shown to predict an increased risk of local recurrence in a large population of patients with breast cancer treated with NACT at the University of Texas MD Anderson Cancer Center (MDACC) [35]. In our opinion, the presence of multiple scattered tumour foci in close proximity to the surgical margin warrants consideration of re-excision when less than the original pretreatment tumour volume has been resected after NACT. In the absence of this pattern of tumour response, a margin of no ink on tumour is probably adequate.

28.1.4.1 Targeted Breast Surgery

Breast-conserving therapy (BCT) consisting of surgical removal of the primary tumour followed by whole breast irradiation is an alternative to mastectomy which results in equivalent long-term survival [36]. Although rates of BCT have increased over time worldwide, there remains remarkably little consensus about what amount of normal breast tissue should be removed as a margin to minimize the risk of local recurrence. The conclusion of the SSO (Society of Surgical Oncology)–ASTRO (American Society for Radiation Oncology) Consensus Panel reinforced the importance of obtaining negative margins defined as no ink on tumour (invasive cancer or DCIS) to optimize local control [37]. The most important and potentially practice-changing conclusion was based on the finding in the meta-analysis of Houssami et al. that margins of 1, 2, or 5 mm were not associated with significantly different risks of local recurrences [38]. This meta-analysis could not be used to demonstrate whether a margin of no ink on tumour is adequate for patients with invasive lobular cancer, an EIC in association with invasive cancer, and tumours of unfavourable biological subtype (i.e., triple-negative breast cancer) and in young patients.

Oncoplastic principles were introduced into breast-conserving surgery 20 years ago to allow oncologically safe breast conservation, by performing a wide excision for larger or poorly located tumours, while limiting the risk of postoperative deformities [39]. Numerous surgical techniques with tissue displacement and tissue replacement have been published with different indications, incision lines, and suggested rotation techniques, missing a systematic and structured approach for oncoplastic breast surgery [40]. During the last years, we have defined five reconstruction principles introducing a new concept of breast-conserving surgery, termed *targeted* (*oncoplastic) breast surgery* [40–43].

We prospectively defined six major reconstruction principles in oncoplastic breast-conserving surgery (BCS) based on the localization, size of the segmental resection defect, size of the breast, and the necessity for skin resection during breast-conserving therapy. These major principles were BCS glandular rotation, BCS dermoglandular rotation, BCS thoracic wall advancement, BCS tumour-adapted reduction mammoplasty, BCS thoracoepigastric flap, and BCS latissimus dorsi flap (Figs. 28.1, 28.2, 28.3, 28.4, 28.5, 28.6, and 28.7). Partial mastectomy defects could be reconstructed

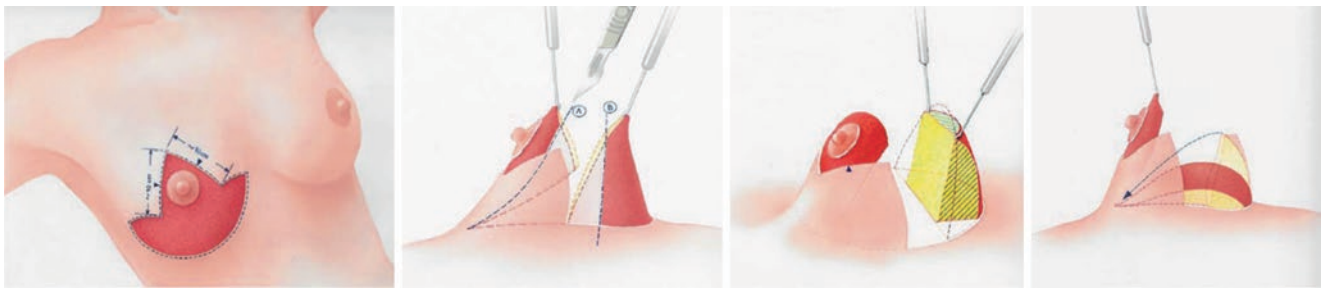

Fig. 28.5 Principles in targeted oncoplastic breast-conserving surgery: BCS tumour-adapted reduction mammoplasty according to Rezai. *BCS* breast-conserving surgery

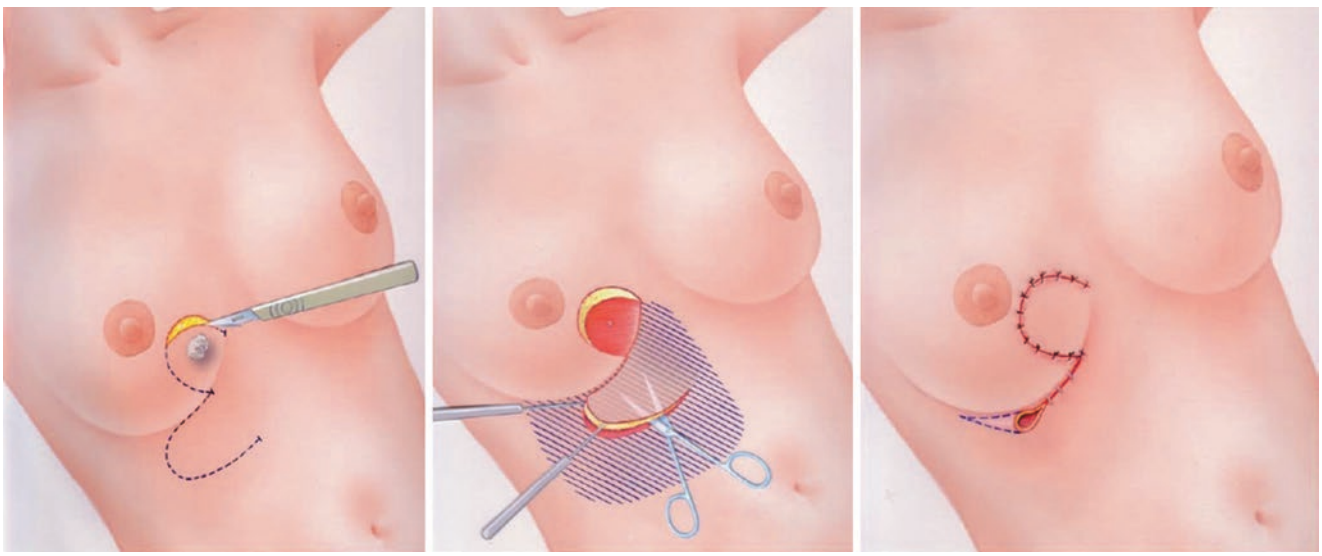

Fig. 28.6 Principles in targeted oncoplastic breast-conserving surgery: BCS thoracoepigastric flap. *BCS* breast-conserving surgery

during BCS with these five oncoplastic principles in 97%. The cosmetic results were good or excellent in 95%. A tumour-free resection margin of 1 mm was mandatory (according to German guidelines) and achieved in 91% during first surgery, while in 5% secondary mastectomy was required. Local recurrences were diagnosed in 1.9% with a median follow-up of 4.2 years.

Our understanding of breast cancer biology has advanced considerably since the initial trials comparing BCT and mastectomy more than 30 years ago. It is apparent that factors such as tumour biology and the availability of effective systemic treatment are at least as important as microscopic residual disease burden in determining local control of breast cancer. Adoption of no ink on tumour as

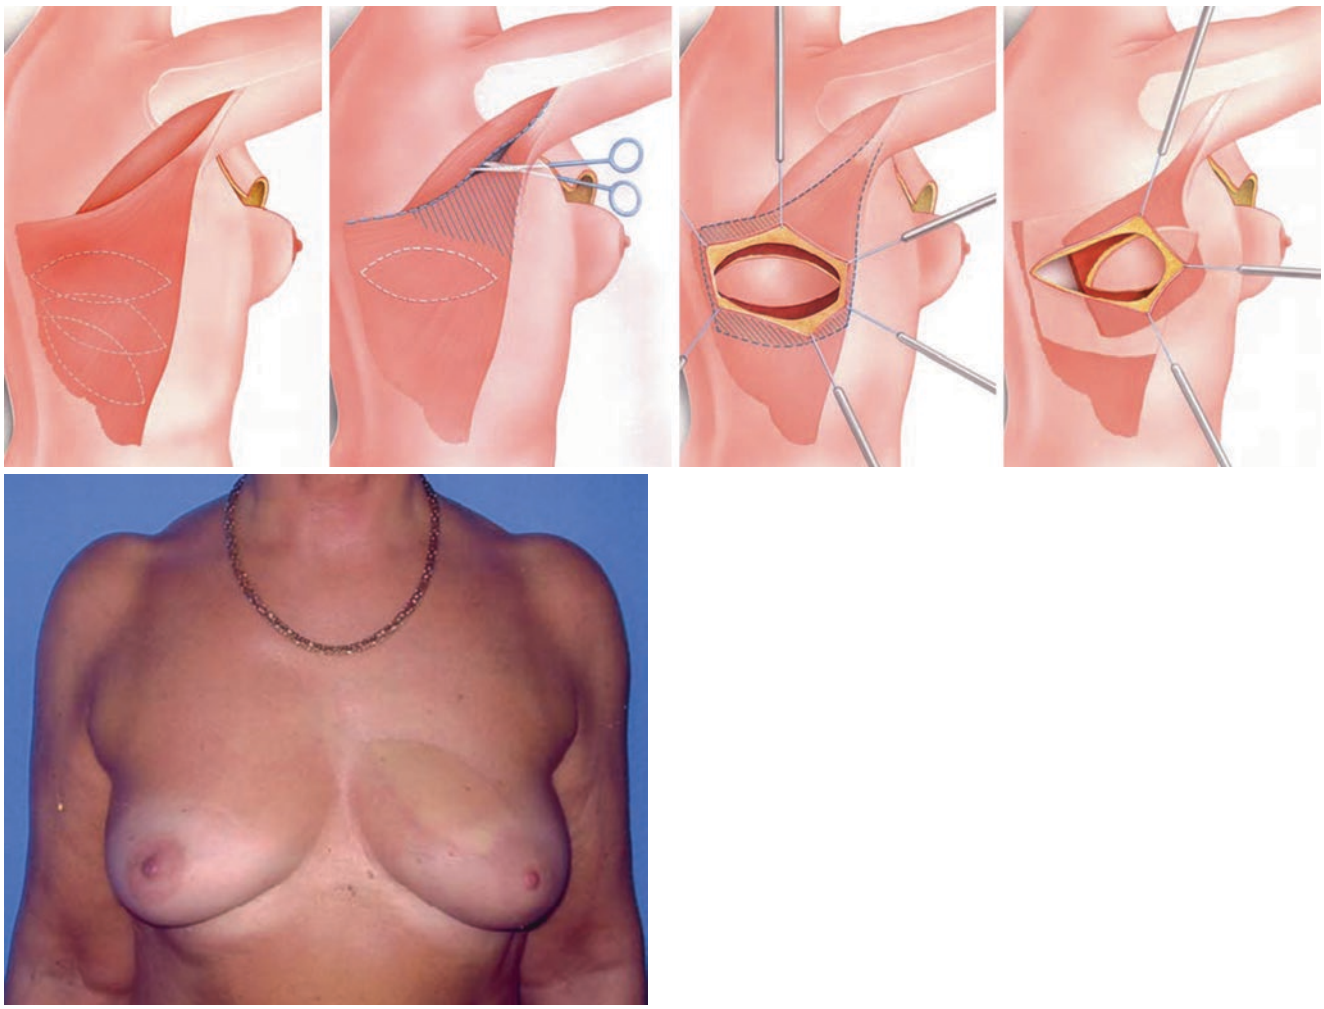

Fig. 28.7 Principles in targeted oncoplastic breast-conserving surgery: BCS latissimus dorsi flap. *BCS* breast-conserving surgery

the standard negative margin definition has clear potential to decrease the use of re-excision and large quadrantectomy-type resections. Adoption of a minimal margin definition removes the rational for the *old* concept of oncoplastic breast surgery—introduced 20 years ago. Further development of the traditional concept of oncoplastic breast surgery to a concept of *targeted* (*oncoplastic*) *breast surgery* with five defined oncoplastic principles allows the reconstruction of segmental resection defects during breast-conserving therapy with highest clinical applicability and results in favourable oncological and aesthetic outcomes. This approach might be useful in extending the indications for breast-conserving therapy. The adoption of a minimal margin definition does not remove the rational for a *new* concept of targeted oncoplastic breast surgery. Targeted oncoplastic breast surgery depends on the anatomical, pathological, and reconstructive aspects of breast cancer to achieve favourable local outcomes for the patients—combining oncological and aesthetic prerequisites [44].

28.1.4.2 Surgical Complications Following NACT

An aspect of NACT that has not yet been investigated thoroughly is the effect of preoperative treatment on surgical complications. The influence of new agents such as biologicals and dose-dense therapies on postoperative wound healing, wound infection, haematoma formation and the need for reoperation has still scarcely been studied. In a recent retrospective analysis [45], data were collected from 44,533 patients after breast surgery. A multivariable regression analysis was performed to identify predictors of postoperative wound complications; 2006 patients received NACT before surgery. Wound complication rates were generally low and comparable in the neoadjuvant treatment and primary surgery groups (3.4 vs. 3.1%). It was concluded that NACT does not influence postoperative wound healing, although there was a trend towards a higher rate of wound complications (4.0%) among patients who had mastectomy and immediate reconstruction after NACT. However, these rates may be an underestimate as postoperative complications

requiring reoperation were excluded. It is understandable that mastectomies with immediate or delayed reconstruction have higher postoperative complication rates than BCS [46]. In smaller series [47–49] of immediate breast reconstruction following NACT, complication rates after mastectomy and immediate autologous or expander/implant reconstruction with or without preceding NACT were compared and reported to be similar. Bearing in mind the small sample sizes, NACT did not, however, seem to affect postoperative complication rates.

Some reports have raised doubt about whether the use of preoperative bevacizumab is safe [50]. Bevacizumab in addition to chemotherapy increases the pCR rate. The GeparQuinto study [51] reported a non-significant increase in overall surgical complications after preoperative addition of bevacizumab (11.0 vs. 15.3%; $P = 0.12$), but revealed an increased risk for patients who required two or more operations to achieve clear margins for BCS [52]. Golshan et al. [53] reported an increased complication rate when performing immediate breast reconstruction using expanders. In a single-arm study, with only 51 patients enrolled, which evaluated neoadjuvant cisplatinum plus bevacizumab, no significant increases in wound healing complications following BCS were observed compared with the results of a previous study in which cisplatinum was given without bevacizumab. Nevertheless, loss of the reconstruction (implant or expander) was reported in four of eight patients. A further study [54] reported no difference in overall surgical complication rate among patients treated with neoadjuvant doxorubicin–cyclophosphamide–paclitaxel with or without bevacizumab. Patients in the two cohorts undergoing mastectomy with or without reconstruction (autologous tissue or implant/expander) were compared. Again, the rate of complications was higher when implants/expanders were used for immediate reconstruction following administration of bevacizumab in a cohort of 119 patients.

28.1.5 Locoregional Recurrence After NACT

In a meta-analysis [55] of nine randomized clinical trials, the clinical outcome of 3861 patients receiving the same systemic therapy either before or after surgery was compared. No significant difference in cancer-related death, disease progression, or distant disease recurrence was reported. A significant increase in LRR rate was observed in the neoadjuvant treatment arm (relative risk 1.22; $P = 0.015$). Four of the nine studies included in this meta-analysis allowed RT alone, without any breast surgery, when a complete clinical response was achieved. The NACT regimens administered in those studies are not comparable with those of the current standard of care, and clinical response was assessed by palpation and X-ray mammography. In addition, complete response was not proven histologically by biopsy before the decision to omit surgery was taken. Thus, an increase in LRR in the neoadjuvant arm is understandable.

Long-term follow-up results of the NSABP B-18 and B-27 trials have been published. These two studies included a total of 3088 patients undergoing NACT or adjuvant chemotherapy. All underwent surgery in the course of treatment. RT was limited to WBI following BCS. Chest wall RT following mastectomy or RT of regional lymph nodes was not allowed in the trial protocols, so an influence of unstandardized RT on locoregional control was avoided. The 10-year cumulative LRR rate after NACT was 12.3% for patients who had a mastectomy and 10.3% for those treated with BCS and consecutive WBI. Clinical tumour size greater than 5 cm in patients who had a mastectomy and age below 50 years in the BCS group had a significant impact on the risk of LRR by 10 years. Clinically node-positive (cN+) disease before NACT and pathological nodal involvement after NACT were independent predictors of LRR, irrespective of type of surgical therapy. Patients who failed to achieve downstaging of the axilla (cN + to ypN0) and breast pCR were at higher risk of LRR. Unfortunately, data concerning hormone receptor and HER2 status were not available, and it could not therefore be determined whether certain subgroups may benefit more or may be at increased risk of LRR after NACT. Moreover, the direct comparison of LRR rates between the two groups in NSABP B-18, which received the same type of chemotherapy (one group before and one after surgery), was not reported.

If subgroups at increased risk of LRR could be identified, this knowledge could be included when deciding on surgical treatment. In a recent meta-analysis [55] of 12,592 patients with breast cancer treated with initial surgery (BCS or mastectomy), it was stated that the risk of LRR may vary between tumour subtypes. Patients with triple-negative breast cancer or a HER2-positive phenotype have a higher risk of LRR than patients with luminal tumours. Lowery et al. [56] reported a LRR rate of 7.1% for BCS and 9.0% for mastectomy at a median follow-up of 57 months for patients with HER2-positive breast cancer, these patients showing the highest risk of LRR. Keeping in mind that these data were collected before the era of trastuzumab and that all NACT was excluded, these rates may not apply to modern NACT regimens. All patients who had BCS underwent adjuvant RT, and 44% of those having a mastectomy received chest wall RT. Adjuvant chemotherapy was administered to 48% of all patients.

Young age is also a risk factor for increased risk of local recurrence. However, it seems that this is especially true for young patients without a pCR. In one study [57], of women who did not achieve a pCR, the LRR rate among those aged 35 years or less was significantly higher than that among women aged 36–50 years ($P = 0.024$). However, there was no age-related difference among women who achieved a pCR.

Is it possible that microscopic residual tumour is left behind when BCS is performed within new margins? It could be speculated that such resistant residual tumour could increase the overall risk of LRR. The main target of NACT is shifting from merely downstaging to monitoring tumour response and tailoring therapy and predicting clinical outcome. At the San Antonio Breast Cancer Symposium 2011, the German Breast Group presented data from a meta-analysis of seven prospective neoadjuvant trials with a total of 6377 patients. LRR rates were analysed according to initial tumour stage, intrinsic tumour subtype, type of surgery, pCR rate, and nodal status. At a median follow-up of 46.2 months, 485 patients had experienced LRR. LRR rates for BCS were significantly lower than those for mastectomy. Not surprisingly, the percentage of women undergoing BCS declined with increasing initial clinical tumour (cT) category (ranging from 77.7% for cT1 to 19.1% for cT4d), and LRR rate rose with increasing tumour size after NACT (from 4.7% for ypT0 to 31.2% for ypT4d). The LRR rate was higher among patients with non-invasive residual disease (9.9 vs. 3.7%). Comparing tumour subtypes, despite achieving a pCR, luminal B/HER2-positive tumours had a higher LRR rate (8.1%) than all other subtypes. Among patients who did not achieve a pCR, triple-negative and non-luminal-like HER2-positive tumours both displayed an extraordinary LRR rate of about 18%.

Weksberg et al. [58] investigated the prognostic outcome of salvage therapy in patients with local recurrence after NACT and BCS. Data were analysed retrospectively for 1589 patients, of whom 448 had undergone surgery after NACT. Among these, 2.6% of patients initially treated with BCS and 5.8% treated with NACT and subsequent BCS experienced LRR at a median follow-up of 91 months. Higher nuclear grade, higher tumour stage, and larger number of involved lymph nodes in the NACT group may account for the difference in LRR rate itself. No significant differences in DFS, OS, and locoregional control were detected in the two groups following salvage treatment for isolated LRR.

Therefore, resection within new margins after NACT is safe and should be offered to more patients, enabling translation of the increasing pCR rates into higher BCS rates and avoidance of unnecessary mastectomies.

28.1.6 Management of the Axilla After NACT

The use and timing of sentinel lymph node biopsy (SLNB) in patients who have undergone NACT has been the subject of considerable debate. Initial concerns regarding the feasibility and accuracy of SLNB following chemotherapy were centred on the potential for altered lymphatic drainage as a result of lymphatic tissue fibrosis or vessel blockage by tumour emboli, as well as the possibility that the effects of chemotherapy might not be uniform throughout the nodal basin. Opponents of SLNB after NACT also argued that knowledge of the axillary node status before NACT was necessary to identify optimal candidates for adjuvant radiotherapy. For women presenting with clinically node-negative disease, these concerns have largely been addressed, and SLNB after NACT is now accepted as standard care [59]. More recent controversy has surrounded the use of SLNB after chemotherapy in patients who present with clinically positive needle biopsy-proven nodal metastases.

28.1.6.1 Clinically Node-Negative Disease

Numerous studies, including the NSABP B-27 trial [60], a large single-institution series from the MDACC [61], and several meta-analyses [62, 63] have established that sentinel lymph node (SLN) identification rates and false-negative rates after NACT are comparable to those reported in patients with breast cancer who undergo upfront surgery. In the MDACC experience, SLN identification rates were 97.4% for women who underwent SNLB after NACT ($n = 575$) and 98.7% for patients treated with upfront surgery ($n = 3, 171$; $P = 0.017$), and false-negative rates were similar: 5.9% versus 4.1% ($P = 0.39$). After a median follow-up duration of 47 months, regional disease recurrence had occurred in 0.9% of the patients who underwent upfront surgery and SLNB compared with 1.2% in the NACT group—a statistically insignificant difference. This study also demonstrated that NACT could be used to downstage disease in the axilla in patients presenting with clinically node-negative T2 and T3 breast tumours, resulting in fewer axillary node dissections without compromising locoregional control: SLN-positive rates compared with upfront surgery were 20.5% versus 36.5% ($P < 0.0001$) and 30.4% versus 51.4% ($P = 0.04$) for women with T2 and T3 tumours, respectively. These data are consistent with those from NSABP B-18 [10], a randomized trial of preoperative versus postoperative chemotherapy, which showed that patients who received preoperative chemotherapy were more likely to have pathologically negative lymph nodes compared with those who underwent surgery first (58% vs. 42%; $P < 0.0001$), demonstrating that NACT can eradicate nonpalpable nodal disease in some patients.

Despite the proven ability of NACT to downstage disease in the axilla, the relative importance of pretreatment nodal stage versus postchemotherapy nodal stage on locoregional recurrence (LRR) risk and the need for adjuvant radiotherapy remain uncertain. Updated data from a combined analysis of NSABP B-18 and B-27 [64], trials of NACT in patients with operable breast cancer that did not allow regional nodal radiotherapy and/or radiotherapy to the chest wall (radiation treatment of the breast was performed in patients who underwent lumpectomy), have provided important information regarding predictors of LRR in this setting. In both trials [10, 60], approximately 70% of patients treated in the NACT

groups were clinically node negative before treatment. At 10 years of follow-up in 3,088 patients who received NACT in these trials, LRR events had occurred in 335 (10.9%) [65]; patient age, clinical tumour size, clinical nodal status before NACT, and pathological nodal status and breast tumour response after NACT were independent overall predictors of LRR. Importantly, among the clinically node-negative patients treated with lumpectomy and breast radiotherapy after NACT, rates of regional nodal recurrence were low (0.5–2.3%) and were not influenced by pathological node status nor pathological breast tumour response. Among clinically node-negative patients treated with NACT followed by mastectomy, regional nodal recurrence rates were also low, irrespective of tumour size (2.3–6.2%); however, rates of chest wall recurrence were greater in patients with clinically negative nodes but pathologically node-positive disease and were negatively correlated with breast tumour response.

Taken together, these data demonstrate that SLNB after NACT in patients with clinically node-negative disease is feasible and accurate and that NACT decreases the number of patients with a positive SLN, thereby sparing patients the morbidity of ALND, without compromising subsequent treatment recommendations or locoregional control. These findings also raise questions about current recommendations that all patients receiving NACT should undergo axillary ultrasonography with biopsy of abnormal nodes [59].

28.1.6.2 Clinically Node-Positive Disease

The success of SLNB after NACT in patients presenting with clinically node-negative disease, combined with increasing rates of pCR demonstrated in trials using modern chemotherapy regimens and targeted therapies, has led to increased interest in the use of SLNB after NACT in patients who present with clinically positive nodes. This issue is particularly relevant for patients with ER-negative and/or HER2-positive disease treated with preoperative anti-HER2 therapy, in whom pCR rates exceed 50% [66, 67]. Early evidence that this approach might be feasible came from the NSABP B-27 trial [60], which included patients with both clinically negative and positive nodes, although histological documentation of pathological nodal status was not required before NACT. After NACT, 428 of 2411 (18%) patients underwent attempted SLN identification and removal before the required ALND—23.8% of the 428 patients in whom SLN biopsy was attempted had clinically positive nodes before NACT. Among the 343 patients in whom both SLNB and ALND were performed successfully, the overall false-negative rate was 10.7% (15 of 140 node-positive patients had a negative SLNB), with no significant difference according to pretreatment nodal status (P = 0.51). Similarly, a report from a French prospective multicentre trial of SLNB after NACT found no significant difference in the false-negative rates between patients who were clinically node positive (n = 65) versus clinically node negative (n = 130) at presentation (15% vs. 9.4%; P = 0.66) [68]. These observations were not supported by smaller, single-institution case series of SLNB after NACT in patients for whom positive nodal status was documented with pretreatment biopsy [69]. The largest of these series, from the MDACC, included 150 patients with biopsy-proven nodal metastasis; 111 of these patients also underwent SLNB and ALND after NACT, and the SLN identification rate was 93% and the false-negative rate was 20.8%, leading to the conclusion that ALND remained the standard of care in this setting [70].

Three multicentre studies addressing the feasibility of SLN after NACT in patients with clinically node-positive disease have, however, challenged the conclusion that ALND is required for all clinically node-positive patients [71–73]. The Sentinel Neoadjuvant (SENTINA) trial [74], a four-arm prospective multicentre trial by the German Breast Group, included 1737 patients who all received at least six cycles of anthracycline-based NACT. All clinically node-negative patients had upfront SLNB; those who had pathologically negative SLNs had no further axillary node surgery (arm A; n = 662), and those who were SLN positive underwent a second SLNB and ALND after NACT (arm B; n = 360). Clinically node-positive patients (n = 715) underwent NACT; those who converted to clinically node-negative disease (as documented by physical examination and ultrasonography of the axilla) underwent SLNB and ALND (arm C; n = 592, pre-NACT nodal status confirmed in 149 [25%]), and the women who remained clinically node positive had ALND (arm D, n = 123). Re-operative SLNB (arm B) resulted in the lowest SLN identification rate (60.8%) and an exceedingly high false-negative rate (51.6%), clearly demonstrating that SLNB should not be performed both before and after chemotherapy. SLN identification rates were also lower than expected in arm C (80.1%) and were associated with a false-negative rate of 14.2%, although the false-negative rate was lower when three or more SLNs were removed (7.3%)—both end points were improved when SLN mapping was performed using the dual mapping technique (with radioisotope and blue dye).

The importance of SLNB technique in patients with needle biopsy-proven nodal involvement was also highlighted in the American College of Surgeons Oncology Group (ACOSOG) Z1071 trial [72], a phase II study that enrolled 756 women with T0–T4, biopsy-proven N1 or N2 disease; 663 patients had clinical N1 disease, 649 of whom completed NACT and subsequently underwent SLNB and ALND. Surgeons were encouraged to use the dual mapping technique for SLN identification and to remove at least two SLNs. The SLN identification rate was 92.9%, similar to the rate reported for SLNB after NACT in clinically node-negative patients and superior to those reported in the SENTINA trial; however, the overall false-negative rate of

12.6% was similar to the German Breast Group experience in arm C of the SENTINA study despite the fact that axillary lymph node response to NACT was not considered in selecting patients for SLNB. To be consistent with the accepted false-negative rate in patients presenting with clinically negative nodes, the prespecified criteria for success in the Z1071 trial were a false-negative rate of ≤10%; thus, the study did not meet this end point. However, as reported in the SENTINA trial, when three or more SLNs were removed, the false-negative rate was 9.1%, demonstrating that surgical technique is critical when considering SLNB in this setting and that routine imaging of the axilla post NACT might not be necessary. These findings in biopsy-proven clinically node-positive breast cancer have now also been reproduced in the smaller Sentinel Node Biopsy Following Neoadjuvant Chemotherapy (SN FNAC) study [71]. In this study, removal of one SLN was associated with a false-negative rate of 18.2%, and removal of more than two SLNs was associated with a false-negative rate of 4.9%.

The relationship between the number of SLNs removed and the false-negative rate of the procedure is not a new concept. Nearly all early prospective trials of SLN biopsy in patients with early-stage breast cancer documented the same effect: lower false-negative rates with increasing numbers of nodes removed [75–78]. However, one must also consider that the median number of SLNs removed in the SENTINA trial was 2 [71–73], as it was in NSABP B-32 and other large prospective trials of upfront SLN biopsy, suggesting that three or more SLNs cannot be identified in many patients. Indeed, in 2014, the AMAROS trial of radiotherapy versus surgery in patients with a positive SLN demonstrated that only 382 (27%) of the patients randomized had three or more SLNs identified in the setting of upfront SLN biopsy [79]. Similarly, among 641 clinically N1 patients who converted to clinically node-negative disease in the Z1071 trial and among 592 patients in arm C of the SENTINA trial, 57% and 34% of patients, respectively, had three or more SLNs removed [55, 56]. Therefore, substantial numbers of patients who convert from clinically node-positive to clinically node-negative disease after NACT are unlikely to have three or more SLNs identified after NACT and, as demonstrated in all three studies to date [71–73], omitting ALND in these patients might be associated with an unacceptably high false-negative rate. Of note, no data support random sampling of nearby axillary lymph nodes to replace SLN mapping and identification of at least three nodes following NACT; thus, surgeons will need to monitor their own performance in this regard, and until data on the clinical significance of leaving axillary lymph node disease behind after NACT are available, patients should be informed that ALND could be indicated if SLN mapping is unsatisfactory.

28.1.7 Significance of Extent of Residual Nodal Disease

The relevance of the distinction between post-NACT isolated tumour cells (ypN0i+, <0.2 mm), micrometastatic disease (ypN1mi, 0.2–2.0 mm), and macrometastatic disease (ypN+, >2.0 mm) in SLNs is another factor that remains unclear. In patients who have not received NACT, the size of the SLN metastasis is correlated with the likelihood of additional nodal disease, and low-volume SLN disease does not always mandate completion axillary node dissection [74, 80, 81]. By contrast, according to the 7th Edition of the American Joint Committee on Cancer (AJCC) staging system [82], patients treated with NACT who are ypN0i+ or ypN1mi at SLNB are considered to have residual nodal disease, and ALND remains the standard of care. In the SN FNAC study [71], SLN metastases of any size were considered positive, and no correlation between the size of the SLN metastases and the rate of positive non-SLNs was found; however, if ypN0i+ SLN disease was considered SLN negative, the false-negative rate of the procedure would have increased from 8.4% to 13.3%. The Z1071 trial investigators also reported on a subset of 470 patients who had at least two SLNs identified and for whom pathological information regarding the presence of micrometastatic disease in the SLN, identified by immunohistochemistry or haematoxylin and eosin staining, was available [83]. When micrometastatic disease was included in the definition of residual nodal disease after NACT, the pCR rate decreased from 36.0 to 33.8% and the false-negative rate decreased from 11.3 to 8.7%. As ALND was performed in all patients in the Z1071, SENTINA, and SN FNAC trials, these studies provide no information regarding the clinical significance of leaving disease behind after NACT. An important consideration is that the potentially chemoresistant disease that persists after NACT might not be associated with the same outcomes demonstrated in the NSABP B-32 and Z0011 trials of upfront surgery, in which both micrometastatic and macrometastatic diseases remaining in the axilla did not compromise locoregional control or survival [74, 80, 81].

Failure to identify residual nodal disease after NACT might also have important implications for decisions regarding radiotherapy. In the updated analysis of NSABP B-18 and B-27 trials, clinically node-positive patients who received NACT and remained pathologically node positive experienced the highest rates of LRR following ALND, ranging from 15 to 22% after lumpectomy and radiotherapy of the breast and from 17 to 22% after mastectomy [65], implying that both groups should be considered for adjuvant radiotherapy: regional nodal radiotherapy in addition to breast radiotherapy for those who undergo BCS and chest wall radiotherapy for those treated with mastectomy. The question of whether completion ALND can be omitted in

favour of axillary radiotherapy in patients with positive SLNs after NACT is being addressed in the ongoing phase III A011202 trial, conducted by the Alliance for Clinical Trials in Oncology [84]. By contrast, in the NSABP trials, patients with clinically node-positive disease who had a pCR at mastectomy (ypT0N0) experienced excellent locoregional control (0% LRR at 10 years) [65], suggesting that response to NACT can be used to select patients who do not need postmastectomy radiotherapy. This concept is currently being tested in the NSABP B-51/Radiation Therapy Oncology Group (RTOG) 1304 (NRG 9353) trial, a phase III randomized trial of more versus less radiotherapy in women with clinically node-positive breast cancer who become pathologically node negative after NACT [85]. If additional radiotherapy in this setting does not affect the risk of LRR, NACT could become the new standard to facilitate a tailored approach to locoregional therapy in patients with operable node-positive breast cancer. For patients who remain node positive following NACT, accurate detection of residual disease is equally important, as these patients could potentially have some level of resistance to systemic therapy and, therefore, might be candidates for future trials of novel agents.

28.1.8 Conclusions

The use of NACT for the treatment of patients with breast cancer reduces the need for mastectomy and axillary dissection, decreasing the morbidity of surgery, without increasing the risk of LRR. Hormone receptor status and HER2 status can be used to select the patients most likely to experience a pCR with NACT. However, increasing rates of pCR with contemporary therapeutic agents (such as HER2-targeted therapies) have not been accompanied by a parallel increase in rates of BCS. Future trials of NACT should examine whether this pattern reflects an inability to accurately assess the extent of residual disease preoperatively or surgeon or patient preference. Improved understanding of the optimal negative margin width for BCS after NACT and the adoption of *targeted breast surgery* could also increase rates of BCS.

In patients with breast cancer who are clinically node negative at presentation, NACT often results in downstaging of axillary disease; SLNB after NACT provides an accurate indication of axillary lymph node involvement in this setting and can, therefore, guide the use of completion ALND, and this approach is associated with a low rate of LRR. The management of patients who are clinically node positive at presentation is in evolution—recent trials suggest SLNB is accurate if three or more sentinel nodes are obtained, but outcome data from patients treated with SLNB alone in this setting are lacking. Although false-negative rates for SLNB after upfront surgery of 10% are associated with a risk of LRR of <1%, whether this holds true for the potentially drug-resistant disease left behind after NACT remains unclear.

One of the great opportunities provided by NACT is the ability to tailor the extent of locoregional therapy based on the preoperative treatment response. The appropriate therapy will probably vary not only by response but also by ER, PR, and HER2 status; the failure to achieve pCR in patients with tumours that lack ER, PR, and HER2 could be indicative of a much higher risk of LRR than in patients with ER-positive tumours who receive at least 5 years of endocrine therapy or patients with HER2-positive disease who are treated with complete anti-HER2 therapy after NACT. Ongoing clinical trials will help to address these issues and to define the relative importance of pretreatment and posttreatment stage on the risk of locoregional recurrence.

The concept of *targeted breast surgery,* including five principles for breast-conserving surgery after NACT, is a recommended concept of surgical techniques optimizing local control and aesthetic outcome for patients—initially developed for primary BCS. Targeted breast surgery is a further development of the classical concept of oncoplastic breast surgery with wide local resection based on the new minimal resection margin width definition (*no ink on tumour*).

Surgical Treatment of the Primary Tumor in Patients with Metastatic Breast Cancer (Stage IV Disease)

29

Mattia Intra

The widespread uptake of breast cancer screening, together with heightened population awareness, means that most breast cancers in the Western world are detected at an early stage. Recent tumor registry studies from the United States and Europe have shown that metastatic breast cancer (BC) accounts for 4–5% of all cases [1–3]. However, in developing nations, the proportion of patients with metastatic BC at diagnosis is greater, ranging from 10% in Malaysia [4] to 24% in Nepal [5] and 44% in Nigerian women [6]. In early breast cancer, high-quality evidence from randomized controlled trials and meta-analyses is available to support the majority of treatments we perform. In comparison, there is a lack of level I evidence and accepted standard-of-care therapies available for patients with metastatic BC.

Metastatic BC is considered to be a fatal disease, regardless of whether distant metastases are discovered at initial presentation (de novo stage IV) or following apparently successful therapy of localized disease and an intervening disease-free interval (metachronous stage IV). As stage IV disease is considered incurable, the goals of treatment are only the prolongation of life and the palliation or prevention of symptoms. In both the situations de novo stage IV and metachronous stage IV, the primary and most important and effective treatment modality is systemic therapy. Recent rapid advances in medical therapy, with the discovery of new therapeutic targets and drugs directed at these targets, have led to the concept of stage IV BC as a chronic disease. With the ever-increasing medical therapy armamentarium, and perhaps with better palliative care, survival of patients with metastatic BC has improved steadily over the past two decades [7, 8]. Moreover, improvements in imaging technology, especially combined positron emission tomography with computed tomography (PET-CT), now enable the detection of minute foci of metastases that previously would have remained undetected. Today's patients with metastatic BC are frequently asymptomatic and systemically well controlled. They often have small primary breast cancers rather than locally advanced cancers. Consequently, the question of management of the primary tumor in women with de novo stage IV BC has attracted significant interest, particularly as loss of control at the primary site can have a profound effect on the quality of life. Retrospective data published over the past decade suggest that primary tumor resection and possibly radiotherapy (RT) may improve survival when used in conjunction with effective systemic therapy. These data have led to some new enthusiasm for the resection of asymptomatic primary tumors, in contrast to the classical, dogmatic approach of reserving resection only for palliation of symptomatic primary tumors.

29.1 Arguments Against Primary Surgery in Stage IV Breast Cancer

There are several, historical arguments against performing primary surgery in metastatic BC. Traditional teaching tells us that surgery may not provide any survival advantage, but may be associated with postoperative complications; by not performing surgery, we can avoid potential complications. How surgical procedures can carry inherent risk is well known. There is the possibility of hematoma, infection, and poor healing of the surgical site, particularly if combined with axillary surgery or postmastectomy reconstruction. There is a 16% risk of lymphedema for patients undergoing axillary dissection [9], which is roughly doubled by the addition of radiation following axillary dissection [10]. In the metastatic setting, this may only add to a patient's distress in the last few months or years of life. Moreover, complications from surgery may delay systemic treatment, which is of paramount importance in patients with metastatic disease. This delay in systemic therapy may adversely affect the control of distant disease in some patients. If mastectomy is performed, questions about breast reconstruction arise, which increases the risk of surgical complications and may further delay adjuvant

therapy [11]; other data suggest that delays in systemic therapy can negatively affect survival. Lohrisch et al. [12] found a decrease in survival when chemotherapy was started more than 12 weeks after surgery in patients with early-stage BC, and this is likely to be even more true of metastatic BC. Finally, women with metastatic disease who are offered primary site surgery are inquiring about (and anecdotally receiving) contralateral prophylactic mastectomy, a clearly inappropriate intervention for this patient population. However, the fact that patients consider it points to the need for definitive, unbiased information to guide treatment plans for a patient population that is highly motivated to pursue any and all options with a possibility of benefit. Apart from the risks and quality-of-life hazards of locoregional therapy for BC, it is also important to remember that this population of patients is often stretched to the limit in terms of out-of-pocket expenses for imaging and therapy, even when insurance plans are generous. Locoregional therapy adds considerably to this burden, which must be considered when arriving at a management plan for this vulnerable population of patients.

Another argument against primary surgery in stage IV BC is that the intact primary breast cancer is easily accessible and provides measurable disease that can be used to gauge the response to systemic treatment; removing this makes the clinical assessment of response to therapy more difficult. Patients with stage IV BC may represent an anesthetic challenge because of debilitation, as well as a surgical challenge because of locally advanced cancer with bulky lymph node involvement; the likelihood of adverse outcomes may be increased. Additionally, in a rodent cancer model, the primary tumor has been shown to inhibit its remote metastases. Following excision of the tumor, neovascularization and growth of the metastases occurred; it is feared that perhaps this could also happen in patients after primary surgery in metastatic BC [13].

29.2 Arguments in Favor of Primary Surgery in Stage IV Breast Cancer

The validity of these arguments against primary surgery in metastatic BC has been apparently challenged. First of all, there have been several studies indicating improvement in survival of women with metastatic BC over the past three decades [8, 14, 15]. A single-institution review of women diagnosed with metastatic disease treated from 1974 to 1979 showed a median survival of 15 months compared with those treated from 1995 to 2000 who had a median survival of 58 months [3]. Similarly, Andre et al. [8] reported temporal trends in improvement of survival for patients with metastatic disease based on treatment period, comparing the intervals 1994–2000 and 1987–1993. Although some of these improvements are undoubted because of better systemic therapy, lead time bias related to more sensitive imaging and therefore earlier diagnosis of metastatic disease in later periods are also likely contributing factors, given the retrospective nature of these studies. More recently, Dawood et al. [15] examined the outcomes between patients with de novo stage IV breast cancer and those who experienced metachronous distant relapse. From a large cohort of patients examined from a single institution, they found the median survival for patients who presented with de novo stage IV breast cancer was 12 months longer than in women with relapsed breast cancer. This difference was statistically significant in both univariate and multivariate analyses. The authors also noted that disease-free interval was also associated with outcomes. Specifically, those patients whose disease relapsed with shorter disease-free interval had worse outcomes when compared with those patients who presented with de novo stage IV disease. The reasons for this difference in outcomes maybe partially related to the fact that women with de novo stage IV disease are treatment naïve and therefore may respond better to systemic therapy, whereas those with metastatic relapse have demonstrated therapeutic resistance of their tumors in the adjuvant setting. There may also be biological differences dictated by the presence of the primary tumor in de novo stage IV disease, as suggested by Retzky et al. [16], vs. reactivation of dormant, resistant clones in metachronous metastases; however, present knowledge regarding interactions between the primary tumor and metastatic sites in humans, and any influence these may have on the course of disease, is limited.

The second argument in favor of primary surgery in metastatic BC comes from evidences accumulated over the past 15 years in non-breast cancer treatment, suggesting that a reduction in tumor burden at the primary site may add to the efficacy of systemic therapy and aid survival. These include a randomized trial of patients with de novo stage IV renal cell carcinoma, which demonstrated a modest but significant survival advantage for the nephrectomy group [17, 18]. An improved survival with resection of primary disease with or without resection of distant disease has also been observed in advanced stages of ovarian cancer [19], in which tumor debulking in the abdominal cavity has become a standard component of overall treatment strategy, despite the lack of a randomized trial testing this approach. Thus, based on retrospective data, these cancers are frequently managed with tumor debulking before chemotherapy [20, 21], drawing on the theory that a smaller tumor burden increases the efficacy of chemotherapy [22]. Again, in colorectal and gastric cancer and in melanoma and sarcoma, resection of the primary tumor, tumor debulking, tumor burden reduction, metastasectomy, re-metastasectomy, multiple metastasectomies, and combined surgery for primary and secondary tumor are widely accepted and routinely performed in clinical practice, being accepted their role in improving survival and quality of life [23–27].

Another theoretical benefit from resection of the primary tumor in patients with overt metastases can be supported along several lines of investigation about the different possible models of progression and metastatic dissemination in BC, ranging from the potential role of BC as a source of tumor stem cells with enhanced metastatic potential [28, 29] to the possibility that tumor-induced immunosuppression is facilitated by the intact primary tumor [30, 31]. It is well known that the progression and metastatic dissemination in breast cancer are a highly selective process that depends on specialized properties of tumor cells (genetically predetermined) and multiple interactions of metastatic cells (seed) with homeostatic mechanism (soil) that tumor cells can exploit. The ongoing seeding from both the primary tumor and distant sites could be an important mechanism of continued tumor growth and metastases. Under this self-seeding theory, tumor cells have the property to escape from the primary tumor and seed distant site but also may metastasize back to the site of the primary tumor [28]. Decreasing the tumor burden could also increase the efficacy of medical treatment by reducing the chances of a resistant clone appearing, and a certain degree of immunomodulation may be achieved by eliminating the immunosuppression associated with the presence of the primary tumor [31]. The newer concepts of the metastatic progression in BC seem to support the concept that the resection of the primary tumor in this scenario would have clinical relevance. In fact, the removal of the primary tumor could theoretically reduce either self-seeding, tumor cell dissemination, or the population of native cancer stem cells, finally making more effective the systemic therapy. Conversely, there has been a concern, based on laboratory data, that primary tumor resection may accelerate the growth of metastatic lesions, but this has not been demonstrated in humans. Although these laboratory data suggest a biological basis for improved survival with resection of the primary tumor in the setting of metastatic disease, these specific models have not been validated in humans. In conclusion, it would be naïve to believe that surgery will benefit all women with metastatic breast cancer [32], but in theory no clinical or biological reason exists to exclude a priori the surgery in all patients with stage IV breast cancer.

Finally, there are important quality-of-life (QOL) hazards that relate to the primary tumor, regardless of whether primary site local treatment is used. If the intact primary tumor progresses, the QOL effect of uncontrolled chest wall disease can be disastrous for a minority of women [33, 34]. Actually, for most women with intact primary tumors and distant disease that is responsive to systemic therapy, the primary tumor tends to remain controlled and asymptomatic with medical therapy [35]. So, if all women were subjected to primary site local treatment, most of them would experience the QOL risks of surgery and potentially RT, including those who would not have developed uncontrolled local disease during the remainder of their lives. Therefore, the analysis of the QOL effect has to be very thoughtful, weighing the possibility of uncontrolled local disease in a minority of women against the potentially unnecessary costs of primary site local treatment in all women.

29.3 Retrospective Studies and Meta-analysis on Primary Tumor Resection

Based on these considerations and mainly following the publication of a randomized trial demonstrating the value of primary tumor resection in stage IV renal cell carcinoma, a number of retrospective studies were performed to examine the effect of surgical resection of the primary tumor on survival in the setting of metastatic BC [1, 2, 4, 33, 36–46]. These studies have come from single institutions and large data bases from the United States, Europe, and Asia. The type of local therapy has largely been a surgery alone, although a few authors have been able to evaluate surgery plus RT [47–49]. The survival outcomes in these retrospective analyses have been the subject of several reviews and meta-analyses [50–54].

A large meta-analysis by Petrelli and Barni published in 2012 [51] included 15 retrospective case series and found that surgery of the primary tumor was independently associated with longer survival, with a hazard ratio (HR) of 0.69 ($P < 0.00001$) (Fig. 29.1). On overall, surgery reduced the risk of death by 30%, especially when it was associated with systemic therapy and RT in a multimodality strategy. The survival benefit was independent of age, tumor burden, type of surgery, margin status, site of metastases, hormone receptor status, and HER2 status; the use of systemic therapy and RT was significantly associated with survival.

A similar literature has developed on the use of primary RT for the primary site, showing a similar magnitude of survival benefit. The RT studies have come mainly from single institutions in France and Canada. The first and largest was reported by Le Scodan et al. [47]. These investigators identified 581 patients with de novo stage IV BC treated between 1984 and 2004, 320 of whom received RT, with 41 women receiving both surgery and RT and 30 receiving only surgery. Nodal fields were included for most patients, and most of those receiving RT were given a boost dose to the tumor site. The overall survival rate was 43% in the group receiving locoregional therapy vs. 27% in those who did not, for an adjusted HR = 0.7 (95% CI: 0.58–0.85). A second French study of 236 patients described similar differences in outcomes with the use of primary RT to the primary site, but adjusted estimates of overall survival showed no significant advantage for the primary site local treatment group [48]. The value of postoperative RT has been difficult to assess in these retrospective studies, as large databases such as the

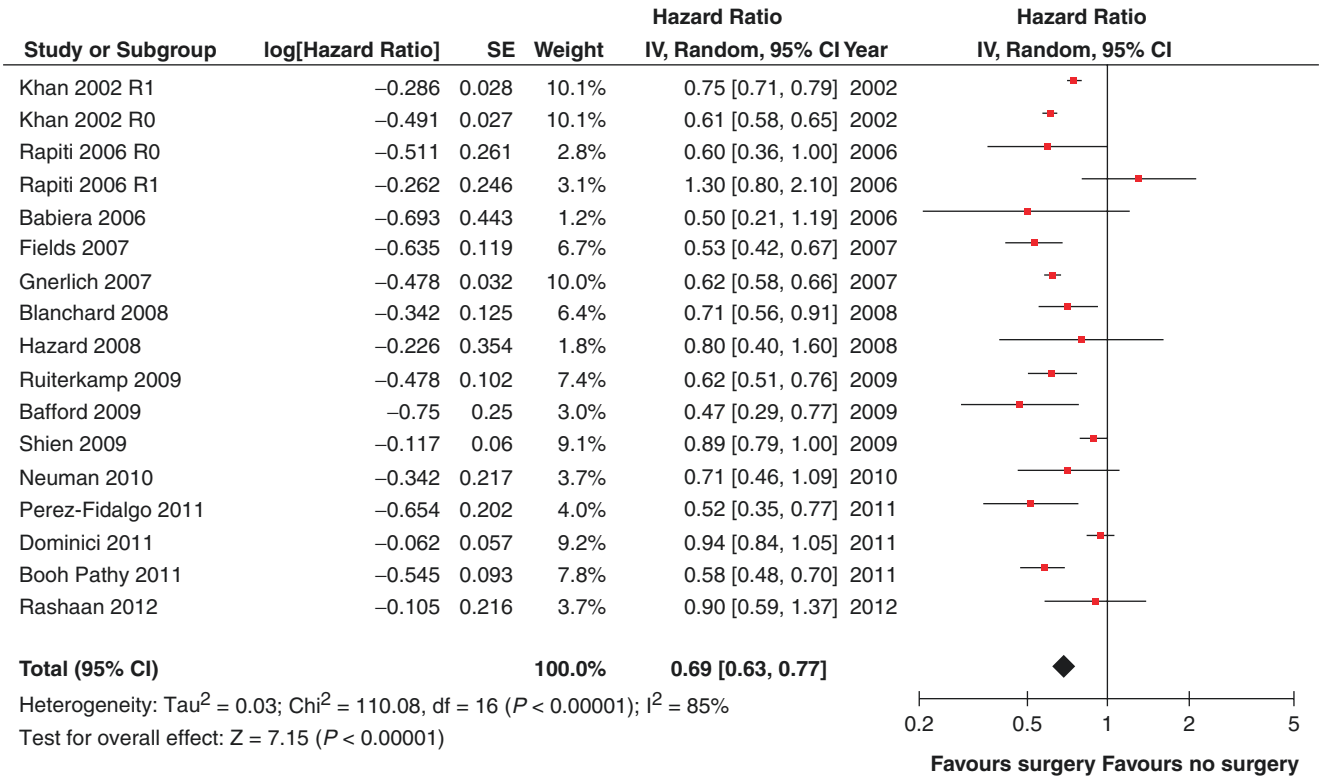

Fig. 29.1 Meta-analysis on 15 retrospective case series, from Petrelli et al. [51]

National Cancer Database (NCDB) and the Surveillance, Epidemiology, and End Results (SEER) did not distinguish between RT to the primary and metastatic sites. The data that are available do not allow clear conclusions and do not show a significant advantage to the combination of surgery and RT to the primary site.

A larger systematic review and meta-analysis were published in 2016 by Headon et al. [55]. The analysis included 16 studies and compared 15,368 stage IV BC patients submitted to surgery of the intact primary tumor to 14,313 not operated patients. In this meta-analysis, a pooled hazard ratio of 0.63 (95% confidence interval, 0.58–0.7; $P < 0.0001$) was revealed, equating to a 37% reduction in risk of mortality in patients that underwent surgical resection of the primary tumor (Fig. 29.2). The conclusions, consistent to what previously reported, are that surgery of the primary tumor in stage IV BC apparently offers a survival benefit in metastatic patients.

29.4 SEER (Surveillance, Epidemiology, and End Results) Data on Primary Tumor Resection

In 2016, four different analyses on primary site local therapy in stage IV BC, based on SEER data, were published. Eng et al. [56] retrieved the records of 25,323 women diagnosed with primary stage IV BC in the SEER 18 registries database from 1990 to 2012. For each case, information on age at diagnosis, tumor size, nodal status, estrogen receptor status, progesterone receptor status, ethnicity, cause of death, and date of death were extracted. The Cox proportional hazard model was used to estimate the unadjusted and adjusted hazard ratio (HR) of death due to stage IV BC, according to age group. Among 25,323 women with stage IV BC, 2542 (10.0%) were diagnosed at age 40 or below, 5562 (22.0%) were diagnosed between ages 41 and 50, and 17,219 (68.0%) were diagnosed between ages 51 and 70. After a mean follow-up of 2.2 years, 16,387 (64.7%) women died of breast cancer (median survival 2.3 years). The 10-year actuarial breast cancer-specific survival rate was 15.7% for women ages 40 and below, 14.9% for women ages 41–50, and 11.7% for women ages 51 to 70 ($p < 0.0001$). In an adjusted analysis, the risk of death from BC at 10 years was significantly lower for women ages 40 and below (HR 0.78; 95% CI, 0.74–0.82; $p < 0.0001$) and for women ages 41–50 (HR 0.82; 95% CI, 0.79–0.85; $p < 0.0001$), compared to women ages 51–70. The authors concluded that approximately 13% of women with primary stage IV breast cancer survive 10 years after diagnosis. Women diagnosed with stage IV BC before age 50 have better survival at 10 years compared to older women.

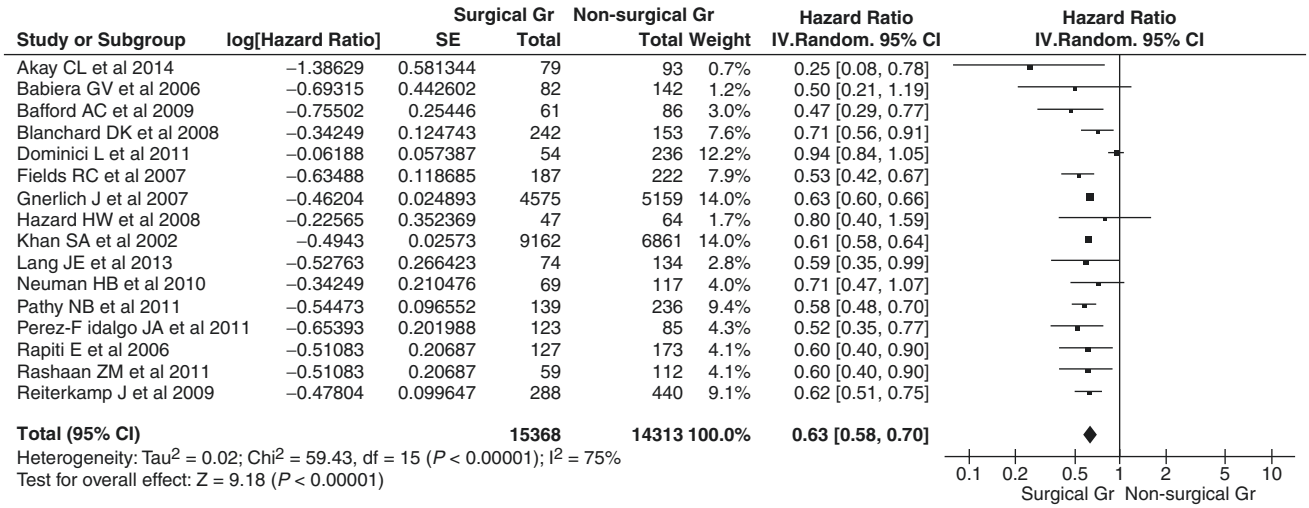

Fig. 29.2 Meta-analysis on 16 retrospective case series, from Headon et al. [55]

Similarly, Warschkow et al. [57] assessed the effect of primary tumor surgery on overall and cancer-specific mortality using risk-adjusted Cox proportional hazard regression modeling and stratified propensity score matching in metastatic BC patients identified in the SEER registry between 1998 and 2009. Overall, 16,247 women with metastatic BC were included. Of those, 7600 women underwent primary tumor surgery although 8647 did not have any surgery at all. Primary tumor surgery decreased from 62.0% in 1998 to 39.1% in 2009 ($P < 0.001$). Primary tumor surgery was associated with decreased overall mortality (hazard ratio (HR) = 0.53, 95% CI 0.50–0.55, $P < 0.001$) and cancer-specific mortality (HR = 0.51, 95% CI 0.48–0.54, $P < 0.001$) in the propensity score-matched model. The benefit of primary tumor surgery increased from 1998 to 2009 for overall mortality (1998, HR = 0.72, 95% CI 0.59–0.89; 2009, HR = 0.42, 95% CI 0.35–0.50) and cancer-specific mortality (1998, HR = 0.72, 95% CI 0.58–0.89; 2009, HR = 0.40, 95% CI 0.33–0.48). In conclusion, the study provided evidence of a favorable impact of primary tumor surgery on mortality in metastatic BC patients. Most importantly, the benefit of primary tumor surgery increased over time from 1998 to 2009.

In order to evaluate the patterns of receipt of initial breast surgery for female patients with stage IV BC in the United States, with particular attention to women who survived at least 10 years, Thomas et al. [58] analyzed a retrospective cohort of patients using data from the SEER program. Female patients diagnosed as having stage IV BC between 1988 and 2011 and who did not receive RT as part of the first course of treatment were included (n = 21,372). Kaplan-Meier estimates of median survival and descriptive statistics were used to compare patient and tumor characteristics by receipt of breast surgery at diagnosis. A Royston-Parmar survival model and logistic regression analysis assessed demographic and clinical factors associated with survival and prolonged survival (of at least 10 years). Mail outcome of the analysis was differences in survival, particularly survival of at least 10 years, by receipt of initial surgery to the primary tumor. Among the 21,372 patients, the median survival increased from 20 months (1988–1991) to 26 months (2007–2011). During this time, the rate of surgery declined (odds ratio [OR], 0.16; 95% CI, 0.12–0.21). Even so, receipt of surgery was associated with improved survival in multivariate analysis, which controlled for patient and clinical characteristics, along with time period (hazard ratio, 0.60; 95% CI, 0.57–0.63). For women diagnosed as having cancer before 2002 (n = 7504), survival of at least 10 years was seen in 9.6% (n = 353) and 2.9% (n = 107) of those who did and did not receive surgery, respectively (OR, 3.61; 95% CI, 2.89–4.50). In multivariate analysis, survival of at least 10 years was associated with receipt of surgery (odds ratio, 2.80; 95% CI, 2.08–3.77), hormone receptor-positive disease (OR, 1.76; 95% CI, 1.25–2.48), older age (OR, 0.41; 95% CI, 0.32–0.54), larger tumor size (OR, 0.37; 95% CI, 0.27–0.51), marital status of being separated at the time of diagnosis (OR, 0.67; 95% CI, 0.51–0.88), and more recent year of diagnosis (OR, 1.43; 95% CI, 1.02–1.99). In conclusion, survival in stage IV BC was improved and was increasingly of prolonged duration, particularly for some women undergoing initial breast surgery.

Finally, Tan et al. [59] used the SEER database to explore the impact of surgery on the survival of patients with stage IV BC and included 10,441 eligible stage IV BC patients from 2004 to 2008. They were divided into four groups as follows: R0 group (patients who underwent primary site and distant metastatic site resection), primary site resection group, metastases resection group, and no resection group. The four groups achieved a median survival time of 51, 43, 31, and 21 months, respectively, $P < 0.001$. The Cox proportional hazard model showed that the R0 group, primary

resection group, and metastases resection group had a good survival benefit, with hazard ratios of 0.558 (95% CI, 0.471–0.661), 0.566 (95% CI, 0.557–0.625), and 0.782 (95% CI, 0.693–0.883), respectively. In the hormone receptor (HR)-positive population, the R0 group (median survival time = 66 m, 5-year OS = 54.1%) gained an additional survival benefit compared with the primary resection group (median survival time = 52 m; 5-year OS = 44.9%; $P < 0.001$). The metastases resection group (median survival time = 38 m; 5-year OS = 31.7%) survived longer than the no resection group (median survival time = 28 m; 5-year OS = 22.0%; $P < 0.001$). In the HR-negative population, the R0 group and primary resection group had a similar survival ($P = 0.691$), and the metastases resection group had a similar outcome to that of the no resection group ($P = 0.526$) (Fig. 29.3). In conclusion, patients who underwent surgery for stage IV BC showed better overall survival than the no resection group, especially when cytoreductive surgery is performed in HR+ stage IV BC patients.

29.5 Potential Biases of Retrospective Studies and Meta-analysis

Many potential biases could have affect and spoiled the enthusiastic results of all the retrospective studies, including meta-analysis. First of all, the timing of surgery on the primary tumor in relation to the diagnosis of metastases, and the use of systemic therapy, has not always been specified in the published retrospective literature, although several authors have attempted to address it [41, 46, 60, 61], with varying conclusions. This is a source of bias because women who are

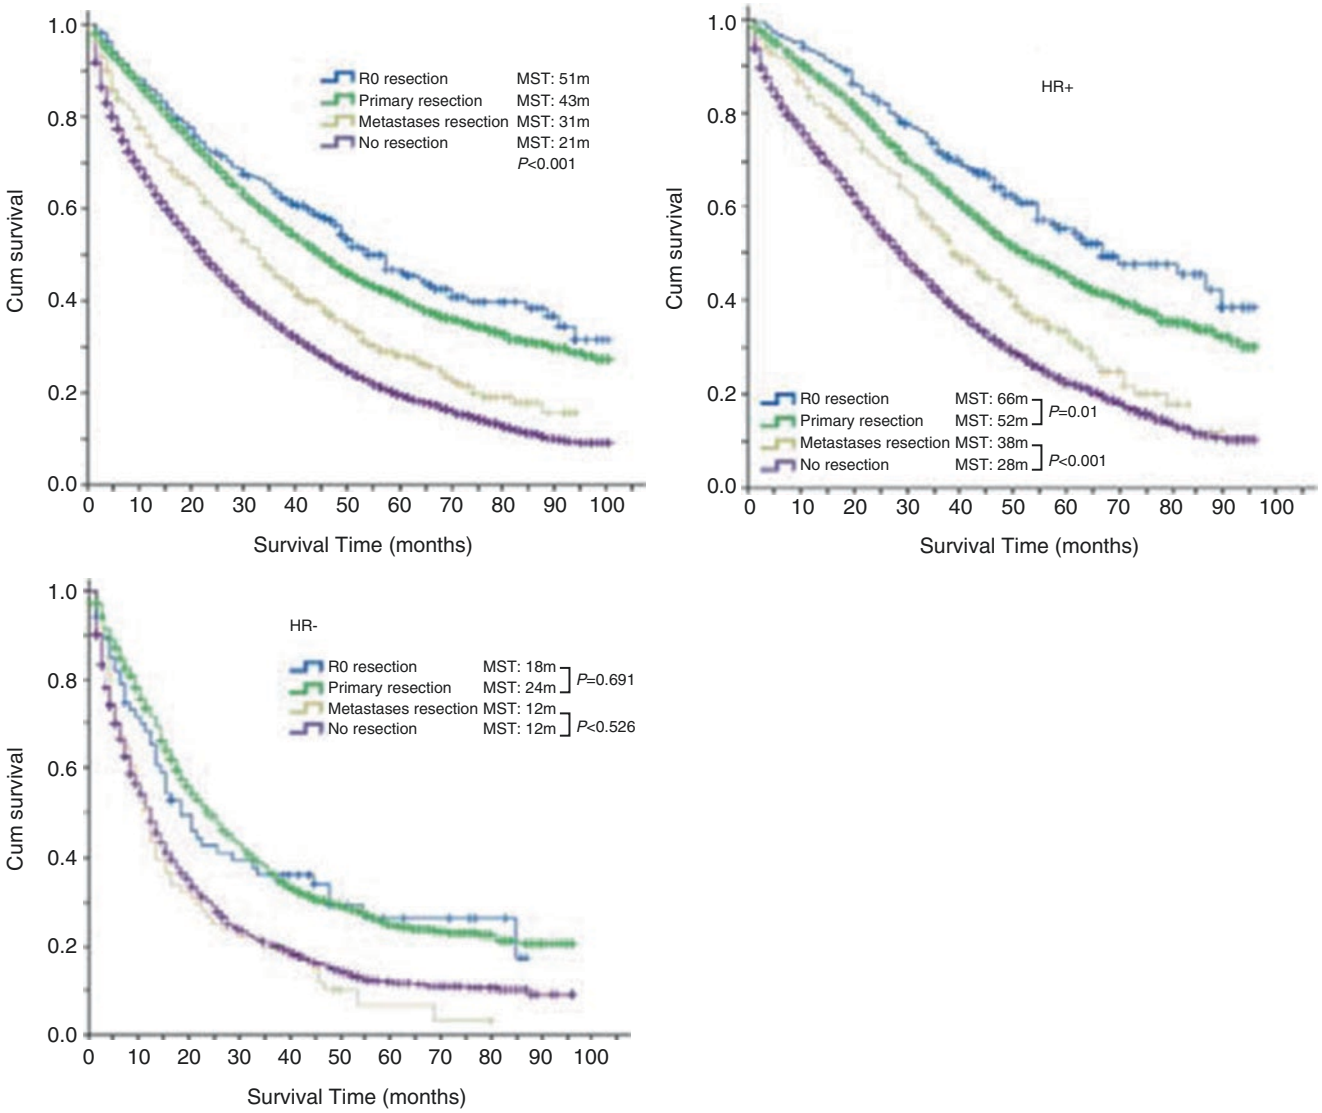

Fig. 29.3 (**a**) Overall survival curves in four groups, (**b**) Kaplan-Meier survival curves of the four groups in the HR+ population (**c**) and in HR-population, from Tan et al. [59]

diagnosed with metastases only after they have undergone surgery for the primary tumor most likely have asymptomatic (and therefore lower-volume) metastases. In contrast, those who present with symptomatic metastases, discovered before surgery, are likely to have a higher burden of distant disease. In reviewing the available literature, we see that there is a substantial fraction of women with T1–T2 tumors, raising the possibility that these women were operated on with the assumption of nonmetastatic disease, were diagnosed with metastases postoperatively, and were then classified as having stage IV disease during the abstraction process by local tumor registrars. Other sources of bias exist in the retrospective data although all studies have attempted to control for these using multivariate regression. In fact, single-institution studies are limited by institutional biases and small numbers of well-selected patients, often treated during a long period of time and with different, and differently effective, medical therapies. In addition, some studies were multi-adjusted with exclusion of patients with short survival, delayed metastatic disease, and more advanced tumors.

Although the meta-analysis seems to definitively confirm the positive impact of surgery of the primary tumor on survival in stage IV patients, it well known that the assumption that a meta-analysis uniformly represents the final and accurate viewpoint of an area of research is not warranted. A meta-analysis combines similar trials in order to obtain a larger number of patients to improve the evaluation of whether statistically reliable differences exist between comparison groups. Meta-analyses are by no means perfect. The conclusions made by the authors of a meta-analysis are subject to the same potential for bias as the smallest of clinical studies included in it. On some occasions, a large clinical trial has subsequently been performed evaluating the same clinical question with an outcome quite different from the initial meta-analysis, and discrepancies between meta-analyses and subsequent large randomized clinical trials are documented in literature [62]. In all the retrospective studies on stage IV BC included in the recent meta-analysis, women who received surgery tended to be younger [33, 36, 37, 39, 40, 44, 46], tended to have smaller tumors [2, 4, 36, 38–40, 42], tended to have fewer comorbidities and better performance status [2, 44, 45], tended to have a lower burden of metastatic disease [2, 36–38, 41, 42, 44–46], were less likely to have visceral metastases [2, 36, 38, 43, 45], and were likely to have better access to care [38, 40]. Meta-analysis simply reflects the biases of the retrospective studies considered in it.

Finally, studies based on large population-based data sets such as administrative claim data and tumor registry data (SEER data on metastatic BC) have become increasingly common in surgical oncology research. These data sets can be acquired relatively easily, and they offer larger sample sizes and improved generalizability compared with institutional data. There are, however, significant limitations that must be considered in the analysis and interpretation of such data. Invalid conclusions can result when insufficient attention is paid to issues such as data quality and depth, potential sources of bias, missing data, type I error, and the assessment of statistical significance [62]. In fact, the population database studies on metastatic BC incorporated large cohorts of very heterogeneous patients treated during a long period of time and provided the most generalizable conclusions, but they were limited by the clinical variables recorded (HER-2/neu status, indications for the procedure, the specific procedure performed, time of surgery, surgical margin status, systemic therapy, and local RT). So, registry data should be interpreted with caution and good understanding of its limitations.

In conclusion, these consistent biases related to retrospective data and large population-based registries on metastatic BC, including meta-analysis, raise real questions as to whether the better survival of women undergoing primary site local treatment is a cause-and-effect relationship or simply means that physicians are good at picking out patients who are likely to survive longer and definitively selecting patients with the best prognosis at all. Therefore, any conclusions reached from these series should be considered exploratory, and physicians should therefore exercise appropriate caution in adopting these data to their therapeutic strategies, as the survival value of primary site local treatment clearly remains to be proven.

29.6 The Clinical Trials

The initial wave of retrospective data suggesting a survival advantage to primary tumor resection, the recognition of consistent biases observed in the published retrospective analyses, and the potential for harm from surgical and RT interventions led to the launching of seven randomized trials in different countries (Table 29.1). Of these, two trials are ongoing (Japan and Austria), two have been completed (India and Turkey), one has just completed enrollment (the Unites States and Canada), one has terminated for lack of enrollment (the Netherlands), and another was withdrawn before enrollment (Thailand). The two completed trials were presented at the San Antonio Breast Cancer Symposium (SABCS) in 2013 [63, 64, 66], and one (India) was recently published [64]. These presentations can be viewed at http://www.sabcs.org/PastSymposia/Index.asp#SABCS2013. Their major features are compared in the Table 29.2. In addition to the main question of whether locoregional therapy is beneficial to women with stage IV BC, these trials address the many ancillary questions regarding the selection of patients who may benefit from resection of the primary tumor, the value of surgery alone vs. surgery plus RT, the type of surgery (mastectomy vs. tumorectomy), and the optimal timing of surgery.

Table 29.1 Completed and ongoing randomized trials testing locoregional therapy with systemic therapy vs. systemic therapy alone

Country	Accrual period	Sample size	Initial therapy	Radiotherapy	Status
India [63, 64] NCT00193778	2005–2012	350	Chemotherapy	If indicated	Closed, published
Japan [65] JCOG 1017	2011–2016	410	Systemic therapy	Not addressed	Enrolling
US and Canada EA2108 NCT01242800	2011–2015	368	Systemic therapy	Per standards for stages I–III	Closed July 2015
Turkey [66, 67] NCT00557986	2008–2012	271	Surgery	For breast conservation	Closed, F-up immature
Netherlands [68] SUMBIT trial NCT01392586	2011–2016	516	Surgery	For positive margins or palliation	Closed. Lack of enrollment
Austria POSYTIVE trial NCT01015625	2010–2019	254	Surgery	Per standards for stages I–III	Enrolling

Table 29.2 Comparison of randomized Indian and Turkish trials presented at SABCS 2013

	Tata memorial (2005–2012)	Turkey MF 07-01 (2008–2012)
Randomization time point	After systemic therapy	At diagnosis
Number randomized	350	271
Primary end point	Overall survival	Overall survival
Stratification	Number and type of metastases and hormone receptor	None described
Preplanned subset analysis	Age, ER and HER2 status, number, and type of metastases	None described
Tumor size	Not described	More T2 and T4 tumors in systemic therapy arm
Receptor status	Balanced	More triple-negative tumors in systemic therapy arm
Metastatic Burden	Balanced >3 lesions	Single organ site more frequent in surgical arm
Bone-only metastases	Balanced	Fewer in systemic therapy arm
Hazard ratio for survival	1.04 (95% CI: 0.8–1.3)	0.76 (95% CI: 0.49–1.16)
Hazard ratio for local control	0.16 (95% CI: 0.10–0.26)	Too few events

29.7 Trials Requiring Randomization to Local Therapy After Systemic Therapy

The rationale for initial systemic therapy is based on the notion that PSLT can provide survival value only if disease at distant sites is responsive to systemic therapy. There are four trials that have been initiated that adopt this approach.

The first trial to open was in India, at the Tata Memorial Cancer Institute in Mumbai, in 2005 (NCT00193778), and was published in 2015 [64]. In this open-label, randomized controlled trial, previously untreated patients (≤65 years of age with an estimated remaining life expectancy of at least 1 year) presenting with de novo metastatic BC were recruited. Patients were randomly assigned (1:1) to receive locoregional treatment directed at their primary breast tumor and axillary lymph nodes or no locoregional treatment. Randomization was stratified by site of distant metastases (bone, viscera, or both), number of metastases (more than 3 vs. <3), and hormone receptor status of the tumor. Use of induction endocrine therapy occurred in 4% of patients in each arm. Patients with resectable primary tumor in the breast that could be treated with endocrine therapy were randomly assigned upfront, whereas those with an unresectable primary tumor were planned for chemotherapy before randomization. Of the patients who had chemotherapy before randomization, they randomly assigned patients who had an objective tumor response after six to eight cycles of chemotherapy. The primary end point was an overall survival analyzed by intention to treat. The trial was powered to detect a 6-month improvement in 2-year survival (from 18 to 24 months). Between February 2005 and January 2013, of the 716 women presenting with de novo metastatic BC, 350 patients were randomly assigned: 173 to locoregional treatment and 177 to no locoregional treatment. At data cutoff of November 2013, median follow-up was 23 months (IQR 12.2–38.7) with 235 deaths (locoregional treatment $n = 118$, no locoregional treatment $n = 117$). Median overall survival was 19.2 months (95% CI, 15.98–22.46) in the locoregional treatment group and 20.5 months (16.96–23.98) in the no locoregional treatment group (HR 1.04; 95% CI, 0.81–1.34; $p = 0.79$), and the corresponding 2-year overall survival was 41.9% (95% CI, 33.9–49.7) in the locoregional treatment group and 43.0% (35.2–50.8) in the no locoregional treatment group (Fig. 29.4). The only

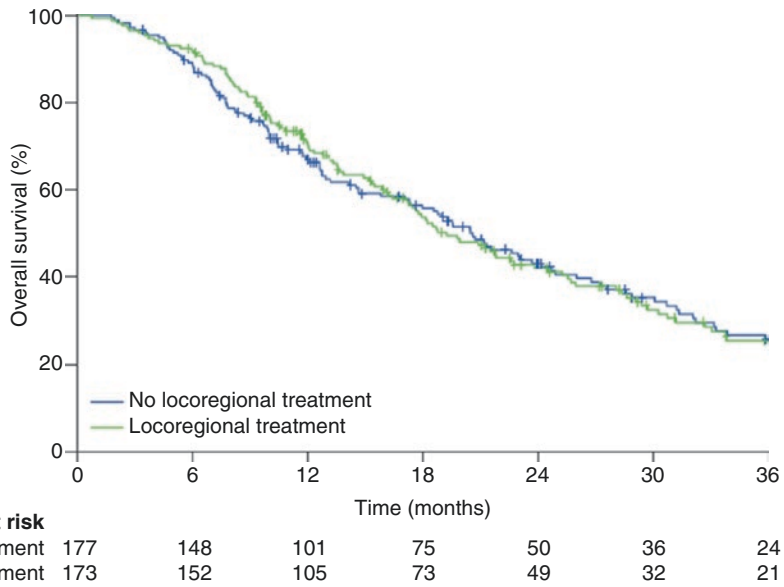

Fig. 29.4 Kaplan-Meier plot of overall survival (From: Badwe et al. [64])

adverse event noted was wound infection related to surgery in one patient in the locoregional treatment group. The authors concluded that there is no evidence to suggest that locoregional treatment of the primary tumor affects overall survival in patients with metastatic BC at initial presentation who have responded to frontline chemotherapy and this procedure should not be part of routine practice. Planned subset analyses examined survival outcomes for premenopausal vs. postmenopausal women, those with bone-only metastases vs. those with bone plus visceral metastases, more than 3 vs. 1–3 metastatic lesions, and hormone receptor or HER2 subsets, with no significant differences noted. However, where the odds ratio deviated from unity, it favored the systemic therapy only arm (1.4 for bone-only disease and 1.6 for 3 or fewer metastases) (Fig. 29.5). It is noteworthy that the usual approach to systemic therapy for the population in this trial (per Indian standards) was that following induction, therapy was not continuous. Therapy was suspended following good response or stable disease and was resumed on progression. This may explain the difference in 3-year survival seen in this trial and the registry trial in the United States [69] (TBCRC 0013, discussed later). As expected of course, the local progression-free survival rate was significantly better in the surgical group (80% at 5 years compared with 20% in the nonsurgical group, $P < 0.001$).

Currently, two trials with similar design are ongoing. In Japan, JCOG 1017 [65] seeks to enroll 410 patients with newly diagnosed metastatic BC to compare the efficacy of primary tumor resection plus systemic therapy vs. systemic therapy alone. After 3 months of systemic therapy, women who show no disease progression are randomized to undergo surgery or to continue systemic therapy; RT is not required. The primary outcome is overall survival. Secondary outcomes are local recurrence rate, local control rate, and effect on distant metastasis after resection of the primary site. More than 350 patients have been enrolled to date.

In the United States and Canada, the Eastern Cooperative Oncology Group EA2108 (NCT01242800) recruited 383 patients with metastatic BC (revised downward from 880 patients because of slow enrollment), and the trial was closed on July 30, 2015. All patients receive induction systemic therapy at the discretion of the treating physician, consisting of endocrine, cytotoxic, or biologic regimens appropriate to the patient's age and tumor type. Patients without progression of disease after 16–32 weeks of treatment were randomized to either locoregional therapy including surgery and RT (to mirror standards of treatment for patients with nonmetastatic disease) or the continuation of systemic therapy. Randomization was stratified by the type of induction systemic therapy (endocrine therapy, chemotherapy, or chemotherapy with anti-HER2 agents), as that would also reflect the biological subtype of the tumor. It was estimated that 80% of registered patients would respond or demonstrate stable disease and would proceed to randomization, and a crossover of 15% was built into the design (anticipating that some patients would not accept the locoregional therapy arm that they are assigned to). Therapy for the primary site was allowed for palliation, later in the course of disease, for women who were randomized to the systemic therapy–alone arm. The primary outcome is survival; the trial is powered to detect an overall survival difference of 19% at 3 years (from 30 to 49%). The secondary outcomes are local progression-free survival and quality of life, and biological samples are being banked for correlative studies. The fraction of patients dropping out for disease progression during induction systemic therapy, and the fraction of crossing over, is within the expected range. Results are expected by 2017.

29.8 Trials Requiring Randomization to Locoregional Therapy Before Systemic Therapy

Some have argued that randomization to, and delivery of, locoregional therapy before systemic therapy is a purer test of the potential benefit of primary site local treatment in the metastatic setting, as it avoids selection of only those patients who respond to systemic therapy. Although this approach avoids the "bias" of including only responders to systemic therapy, it also means that primary site local treatment is provided to some patients whose tumors are unresponsive to systemic therapy at distant sites and therefore will die early owing to their distant disease. The first trial with this design was opened by the Turkish Federation of Breast Diseases (NCT00557986) and has completed enrollment, with early data reported at SABCS 2013 [67]. The design included randomization to surgery before systemic therapy or systemic therapy alone with RT to the primary site in cases of breast conservation. The trial was powered to detect an improvement in the 3-year survival rate from 17 to 35%. A total of 271 evaluable women were recruited. The primary outcome was overall survival, with secondary outcomes related to progression-free survival, quality-of-life measures, and morbidity related to locoregional therapy. The trial was reported at SABCS 2013 with a median follow-up of 18 months and 31% of the population having died [66]. No significant survival advantage was observed at the time of reporting, with a median survival of 42 vs. 46 months, favoring surgery (HR = 0.76; 95% CI, 0.49–1.16; $P = 0.2$). Multiple unplanned subset analyses revealed only the possibility of an advantage with surgery for women with solitary bony metastases (33 women in the primary site local treatment arm and 20 in the control arm; HR = 0.23, $P = 0.02$), but these were not biopsy proven at entry. There were insufficient local recurrences for analysis.

The SUMBIT trial in the Netherlands (NCT01392586) was similarly structured but closed after enrollment of ten patients [68]. The POSYTIVE trial in Austria (NCT01015625) has a roughly similar design and aims to recruit 254 patients with synchronous metastatic breast cancer and randomly assign them to receive either PSLT (lumpectomy or mastectomy + axillary surgery/± RT) vs. nothing. This has recently been revised to allow systemic therapy before randomization. Primary outcomes are median survival. Secondary outcomes are time to distant progression and time to local progression.

29.9 Prospective Registry Study TBCRC 0313

A prospective study entitled "A Prospective Analysis of Surgery in Patients Presenting with Stage IV Breast Cancer" is a multi-institutional data registry [69]. The objective is to

characterize patients with stage IV BC while documenting clinical management outcomes. The planned total enrollment is 100 patients. Its primary aims are to document response to first-line therapy, frequency of surgical referral, and proportion of patients undergoing surgery, determine the incidence of uncontrolled local disease and frequency of surgical palliation, and correlate molecular characteristics of primary tumor with conventional prognostic factors. A number of correlative molecular studies of circulating tumor cells and analyses of primary and metastatic tumor samples are planned. The analysis of registered patients with stage IV disease follows two tracks: one for those with an intact primary and one for those with the primary tumor resected and metastases discovered within 3 months of surgery. Local and distant disease will be carefully monitored in women with responsive and nonresponsive disease, and the use of research biopsies during therapy will provide samples to generate biological hypotheses related to interactions between responding and nonresponding primary and metastatic sites, the frequency and effect of uncontrolled chest wall disease, quality of life, and other issues. As reported at the San Antonio Breast Cancer Symposium in 2013, the 3-year survival rate of 39 women who were responsive to induction systemic therapy and received surgery was 81%, whereas the survival rate of responders who did not receive surgery was 79%. Although the numbers are small, it is also of interest that among 15 women who were diagnosed with metastases following surgical therapy for the primary tumor, the 3-year survival rate was 87%. These numbers are remarkably different from the survival experience in the Tata Memorial trial (3-year survival rate of 25%) and point to the differences in the biological and therapeutic environment between Indian and US populations.

29.10 Recommendations

Although retrospective data suggest that locoregional therapy for the primary tumor may provide a survival advantage in women with metastatic BC and an intact primary tumor, this is not confirmed by randomized trials. The biases of the retrospective data include the use of surgery in younger women with smaller tumors, single sites of metastasis, and less visceral disease. The publication of data from the Tata Memorial [64] and Turkish Federation [67] trials provides information on patients treated prospectively. These and ongoing trials will allow us to evaluate the role of surgery alone or surgery plus RT and will allow us to reach solid conclusions regarding the role of locoregional therapy, how extensive it should be, and its timing in stage IV breast cancer.

Until additional unbiased data are available, surgery and RT to patients with stage IV with an intact, asymptomatic primary tumor cannot be recommended outside a clinical trial. In particular, there is no basis for recommending surgery to women with distant disease (a) if the distant disease is not well controlled, as survival will likely not be long enough for the primary site to become a problem, or (b) both local and distant sites are well controlled, in which case, the primary site is likely to remain well controlled for the patient's life span. A possible exception to these rules may be a patient who would be rendered as having stage IV NED by resection of the primary tumor, although this too is based on highly selected series. For a patient whose distant disease is controlled but the primary site is progressing, surgery provides a reasonable approach [70].

Locoregional therapy for the primary tumor should be offered to patients only with full disclosure of the lack of evidence of a survival benefit. If a clinical trial is available and the patient is willing to consider it, that is clearly the most rational choice. If primary site local treatment is decided on following the considerations described earlier, the subset of patients that may benefit from more aggressive local therapy ("ideal" patients for primary site local treatment), based on the data from retrospective series and population database studies, includes young patients with good performance status (women diagnosed with stage IV breast cancer before age 50 have better survival at 10 years compared to older women) [56], smaller primary tumor, ER-/PR-positive or HER-2/neu amplified tumor (in which more effective targeted therapies are available), oligometastatic disease (solitary and or low-volume metastatic disease) [59], and possibly with metastatic spread limited to the skeleton [36, 37, 71].

If primary site local treatment is planned, either mastectomy or lumpectomy is appropriate, but of course breast conservation (if feasible) is clearly the least harmful option, and the odds of successful breast conservation can be maximized by the use of effective systemic therapy preoperatively. In case of breast-conserving surgery (BCS), resection margins were strongly considered in the past as important prognostic factor of local recurrence and survival. The original report by Khan et al. found that for BCS or mastectomy patients, the median 3-year survival was 35–36% for patients with clear margins, 26% for those with positive margins, and 17% in nonsurgical patients ($p < 0.0001$) [1]. Two further tumor registry studies [36, 72] and an institutional study from Malaysia [4] also demonstrated that survival was improved in patients with negative margins. These findings may be easily explained by differences between groups, and currently the true significance of the resection margins in BCS has been strongly resized, either in early breast cancer [73] or in metastatic BC. So, although we should always aspire to clear surgical margins when we perform BCS in metastatic BC, this is not mandatory and a re-excision for involvement of the resection margins should be always

avoided. In case of mastectomy, plastic reconstruction is not absolutely contraindicated and must be evaluated case by case, considering the possible immunodepression related to larger reconstructive surgery.

The data on axillary surgery are extremely limited, but if surgery is undertaken, removal only of all gross and symptomatic disease seems prudent. Out of these, routine axillary dissection, axillary nodal samples, and sentinel lymph node biopsy should be categorically avoided, being unnecessary neither for prognostic information nor for local control of the disease.

The evidence supporting the use of postoperative RT is weak [47, 48], at best, and cannot be recommended presently. Primary RT can be considered with the same caveats as surgical resection, particularly if the surgical procedure required would be mastectomy. Although whether RT should follow surgery is unproven, its use may be justified if the risk of early local recurrence and uncontrolled chest wall disease is high.

Conclusions

Stage IV disease is a chronic and incurable disease, and the goals of treatment are only the prolongation of life and the palliation or prevention of symptoms. In stage IV breast cancer patients, the primary and most important and effective treatment modality still remains a systemic therapy. The retrospective data suggest that locoregional therapy for the primary tumor may provide a survival advantage in women with metastatic BC and an intact primary tumor, but this is not confirmed by randomized trials. The publication of data from the Tata Memorial [64] and Turkish Federation [67] trials provides information on patients treated prospectively. These and other ongoing trials will allow us to evaluate the role of surgery alone or surgery plus RT and will allow us to reach solid conclusions regarding the role of locoregional therapy, how extensive it should be, and its timing in stage IV breast cancer. Until additional unbiased data are available, surgery and RT to patients with stage IV with an intact, asymptomatic primary tumor shouldn't be routinely performed or recommended outside a clinical trial. Only for selected patient whose distant disease is controlled by systemic therapy but the primary site is progressing, surgery provides a reasonable approach.

Breast Cancer in Lymphoma Survivors

30

Mattia Intra and Denise Mattar Fanianos

30.1 Lymphoma Survivors

Non-Hodgkin lymphoma (NHL) is the most common hematologic malignancy in the world [1]. It is more common in developed countries, with an estimated 70,800 new cases in the United States (US) in 2014. Accounting for 4.3% of all cancers in the US, NHL ranks as the seventh most common cancer among males and the sixth most common cancer among females. NHL consists of more than 40 major subtypes with distinct genetic, morphologic, and clinical features. The incidence of NHL subtypes also varies by age, sex, ethnicity, and geographic region [2, 3]. Hodgkin lymphoma (HL) affects approximately 9050 new patients in the US each year [4], representing approximately 11.2% of all lymphomas. The disease has a bimodal distribution with an increased incidence in young adults as well as in patients 55 years and older [5].

Since the late 1960s, when combination chemotherapy and high-energy radiation therapy were introduced for the treatment of lymphomas, survival of patients has improved dramatically over the time, increasing from 87% in 1975 through 1979 to 97% in 2003 through 2009 [6]. In recent statistics [7], the American Cancer Society and the National Cancer Institute collaborated to estimate the number of current and future cancer survivors using data from the Surveillance, Epidemiology, and End Results (SEER) cancer registries. Incidence and survival were modeled by cancer type, sex, and age group using invasive malignant cases diagnosed from 1975 through 2012 from the nine oldest registries in the population-based SEER program. Among more than 15.5 million Americans with a history of cancer alive on January 1, 2016, there are an estimated 219,570 HL survivors and 686,370 NHL survivors. Although both HL and NHL occur in children and adults, the majority of HL cases (64%) are diagnosed before the age of 50 years, whereas most NHL cases (85%) occur in those aged 50 years and older.

30.1.1 Treatment and Survival for HL and NHL

There are two major types of HL. Classical HL (CHL) is the most common and is characterized by the presence of Reed-Sternberg cells. Nodular lymphocyte-predominant HL (NLPHL), which is characterized by "popcorn cells," comprises only about 5% of cases [8]. NLPHL is a more indolent disease with a generally favorable prognosis [9]. CHL is generally treated with multiagent chemotherapy (88%), sometimes in combination with radiation therapy (RT) (30% among chemotherapy recipients), although the use of RT is declining [10]. If these treatments are not effective, stem cell transplantation and the targeted drug brentuximab vedotin may be options. For patients with NLPHL, radiation alone may be appropriate for early-stage disease. For those with later-stage disease, chemotherapy plus RT as well as the monoclonal antibody rituximab may be recommended. The 5-year and 10-year survival rates for HL are 86% and 80%, respectively. The 5-year survival rate is 94% for NLPHL and 85% for CHL [7].

The most common types of NHL are Diffuse Large B-Cell Limphoma (DLBCL), representing 37% of cases, and follicular lymphoma, representing 20% of cases [8]. Although DLBCLs grow quickly, most patients with localized disease and about 50% of those with advanced-stage disease are cured [11, 12]. In contrast, follicular lymphomas tend to grow slowly and often do not require treatment until symptoms develop, but many are not curable [13]. Some cases of follicular lymphoma transform into DLBCL. The first course of treatment for all NHL subtypes combined is usually chemotherapy, either alone (58%) or in combination with RT (11%). Approximately 17% of patients receive no treatment. A monoclonal antibody like rituximab is often given along with chemotherapy for B-cell lymphomas and for some T-cell lymphomas. The 5-year survival rate is 86% for fol-

licular lymphoma and 61% for DLBCL; 10-year survival rate declines to 77% and 53%, respectively [7].

30.2 Risk of Breast Cancer in Lymphoma Survivors

The improving of the survival in lymphoma patients using combined modalities of treatment, in which RT has a fundamental part, led to observe in this population new problems over the time, often more important than the lymphoma itself. In fact, cure has come at a price, because the treatment of lymphoma has been shown to increase the risk of subsequent malignant neoplasms and other late effects considerably [14–36]. Although very high relative risks have been observed for leukemia (especially among patients who were treated with alkylating agents) and NHL (which was not previously associated with a particular type of therapy), second solid cancers, the occurrence of which is related primarily to RT, contribute most to the absolute excess risk of a second cancer among survivors of HL. At 5–10 years after treatment, the relative risk of solid cancer is significantly higher among survivors of HL than in the general population, and this higher risk persists for at least 25 years [24, 32, 33]. Few studies have investigated the evolution of a risk of a second solid cancer beyond 25 years after treatment [20, 24, 26, 29]. On the basis of increased knowledge of late effects, the treatment of HL has changed, with a trend toward the use of smaller radiation target volumes, lower radiation doses, and more effective, generally less toxic chemotherapy schemes ([37], [38]). However, the effect of these changes on the risk of a second cancer is still unknown.

In a recent study, Schaapveld et al. [39] investigated the long-term risk of a second cancer and changes in risk over time in a large cohort of survivors of HL. The analysis evaluated 3905 persons in the Netherlands who had survived for at least 5 years after the initiation of treatment for HL. Patients had received treatment between 1965 and 2000, when they were 15–50 years of age. The risk of a second cancer among these patients was compared with the risk that was expected on the basis of cancer incidence in the general population, and treatment-specific risks were compared within the cohort. With a median follow-up of 19.1 years, 1055 second cancers were diagnosed in 908 patients, resulting in a standardized incidence ratio (SIR) of 4.6 (95% confidence interval [CI], 4.3–4.9) in the study cohort as compared with the general population. Breast cancer contributed most to the overall absolute excess risk (24.9 cases of breast cancer per 10,000 person-years among men and women), representing 20.4% of the excess risk of any second cancer (121.8 cases per 10,000 person-years) in the cohort; the absolute excess risk of breast cancer among women was 54.3 cases per 10,000 person-years, representing 40.5% of the excess risk of any second cancer (134.0 cases per 10,000 person-years) among women in the cohort. The risk was still elevated 35 years or more after treatment (SIR, 3.9; 95% CI, 2.8–5.4), and the cumulative incidence of a second cancer in the study cohort at 40 years was 48.5% (95% CI, 45.4–51.5). At 30 years, the cumulative incidence of breast cancer among women in the study cohort was 16.6% (95% CI, 14.1–19.2). The cumulative incidence of second solid cancers did not differ according to study period (1965–1976, 1977–1988, or 1989–2000) (P = 0.71 for heterogeneity) (Fig. 30.1). Although the risk of breast cancer was lower among patients who were treated with supradiaphragmatic-field RT not including the axilla than among those who were exposed to mantle-field irradiation (hazard ratio, 0.37; 95% CI, 0.19–0.72), the risk of breast cancer was not lower among patients treated in the 1989–2000 study period than among those treated in the two earlier periods. The authors concluded that the risk of second solid cancers did not appear to be lower among patients treated in the most recent calendar period studied (1989–2000) than among those treated in earlier periods.

Of course, because of the long latency required to observe second solid cancers and the rapid evolution of RT techniques, many estimates of radiation-related second cancer risk reflect outcomes of treatment no longer in use, and published risk estimates are largely based on patients treated with 35 Gy to mantle, extended-field, or subtotal nodal RT fields in the 1960s through the 1980s. Since that time, lymphoma treatment has progressed to use smaller involved-field RT fields [40, 41]. Recent clinical trial results suggest that low-dose (20 Gy) RT may emerge as standard treatment for adult lymphoma, and these new effective RT techniques probably will reduce in the future the absolute risk of secondary breast cancer expected [42–44]. The ongoing European Organization for Research and Treatment of Cancer (EORTC) H10 study aims to assess whether early assessment of response by repeat fluorodeoxyglucose positron emission tomography (FDG-PET) scans after two cycles of ABVD could help to better determine whether radiotherapy is needed in the treatment for stage I/II supradiaphragmatic Hodgkin lymphoma. This trial also introduces the concept, later published as EORTC-GELA, Groupe d'Etude des Lymphomes de l'Adulte guidelines, of initially involved "nodes" and not "field" irradiation. This concept relies on coregistered prechemotherapy and post-chemotherapy computed tomography-FDG-PET scans with intravenous contrast [45, 46].

In conclusion, improvements of RT techniques such as respiratory-gated RT and intensity-modulated RT should allow better protection of normal tissues (breast, lung, and heart) during RT for lymphoma [47]. These improvements, combined with the reduction of radiation field size (replacement of mantle-field RT by involved-field and involved-node

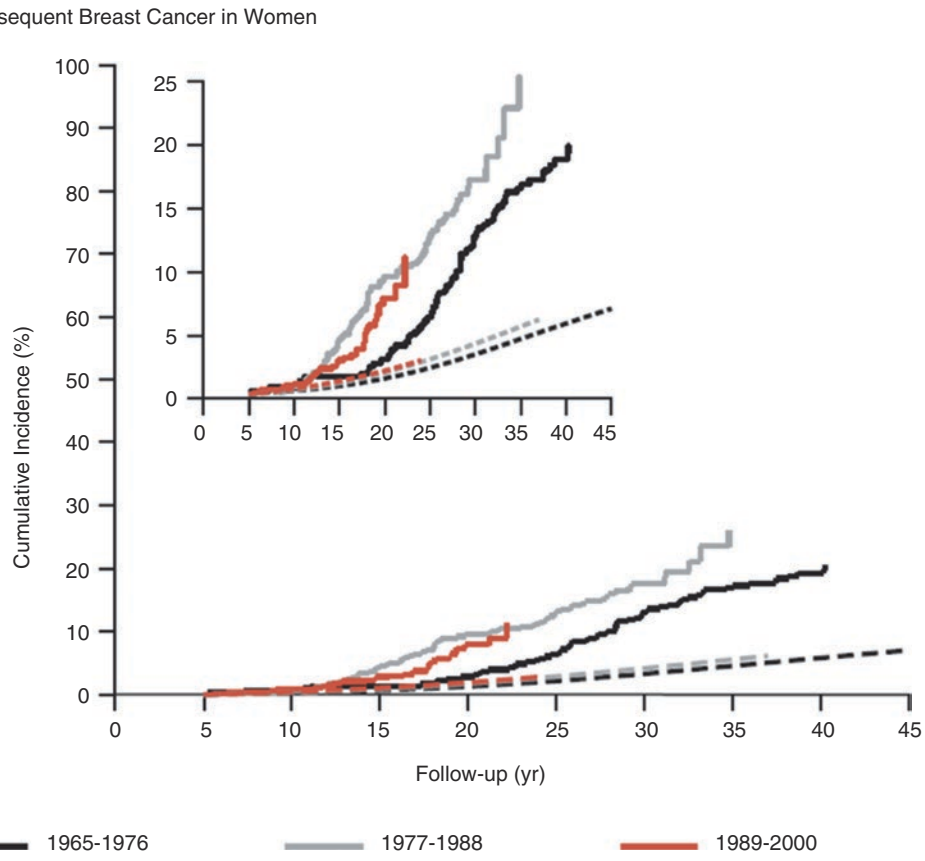

Fig. 30.1 Cumulative incidence of subsequent breast cancer in women. *Solid lines* represent the observed incidence and *dashed lines* the expected incidence in the general population. The *insets* show the same data on enlarged *y* axes (From: Second Cancer Risk Up to 40 Years after Treatment for Hodgkin lymphoma. M Schaapveld, B Aleman, AM van Eggermond. NEJM. 2015;373: 2499–511)

RT) [46], should minimize secondary breast cancer incidence in future decades.

30.3 Impact of Early Breast Cancer Screening on Mortality Among Lymphoma Survivors

Survivors of lymphoma are at increased risk for delayed morbidity related to their treatment, and increasing effort is being directed toward preventing or ameliorating late-treatment toxicity. One potentially modifiable late effect is mortality because of breast cancer among women treated with thoracic RT. In particular, adolescent females treated with thoracic RT for HL have been shown to have statistically significantly elevated risks of breast cancer [22, 48, 49], and consensus guidelines recommend the early initiation of breast cancer screening among these survivors [50]. In fact, these women must be considered as a population at very high risk of breast cancer, and, according to the age, mammary density, and menopausal status, a personalized program of breast cancer early detection should be routinely planned. Careful breast surveillance with yearly breast palpation and imaging is mandatory to provide early diagnosis of breast cancer. Unfortunately, lack of supporting evidence is a major limitation of these guidelines, however. The efficiency of screening with annual mammography in this particular population was reported in several studies [51]. Breast MRI should also help to better screen these women and was recommended as an adjunct to annual mammography for women who have been treated with radiotherapy for supradiaphragmatic HL, starting at age 25 or 8 years after completion of radiotherapy [52, 53].

A recent update of UK guidelines for the follow-up of pediatric cancer survivors, for example, could not identify a single study examining the benefits or harms of specific screening programs, including the early initiation of breast cancer screening in high-risk survivors [54]. This lack of evidence may in part account for the observation that 55–85% of eligible survivors in the US and Canada do not undergo breast cancer screening [55, 56]. While the effectiveness of early breast cancer screening should ideally be evaluated in a randomized trial, no such trial will be undertaken in the foreseeable future. To address this clinical uncertainty, Hodgson et al. [57] conducted simulations under a range of clinically plausible conditions to quantify the potential benefit of early breast cancer screening using different screening modalities among women treated with mediastinal RT for HL in adolescence. A mathematical model of breast cancer development was used to evaluate the marginal benefit of early-initiated screening of female survivors of adolescent HL starting at age 25 years on breast cancer mortality compared with

screening initiated at age 40 years. Sensitivity analyses were performed to evaluate the robustness of the estimates over a plausible range of conditions. For survivors treated at age 15 years, the absolute risk of breast cancer mortality by age 75 years was predicted to decrease from 16.65% with no early screening to 16.28% (annual mammography), 15.40% (annual MRI), 15.38% (same-day annual mammography and MRI), and 15.37% (alternating mammography and MRI every 6 months). Approximately 80 patients would need to be invited to MRI-based screening to prevent one breast cancer death. In sensitivity analyses, the number needed to invite to MRI-based screening to prevent one breast cancer death ranged from 71 to 333. Combinations of MRI plus mammography were predicted to produce 99.52 false positives per 1000 screenings done between age 25 and 39 years. The authors concluded that these findings are the first to indicate that early MRI-based screening should reduce breast cancer mortality among women treated with RT for adolescent HL. The magnitude of this benefit is superior to that described for other accepted screening indications although MRI can produce a substantial rate of false-positive results.

30.4 Breast Cancer Characteristics in Lymphoma Survivors

It is unknown whether breast cancer characteristics among young women treated with RT for lymphoma differ from sporadic breast cancer. In lymphoma survivors, there was a high rate of bilateral cancers, compared with sporadic breast cancer (from 7% to 25%) [58–60], easily explained by the symmetrical distribution of radiation dose in the two breasts during mantle-field or mediastinal RT. Clinical and pathologic characteristics of breast cancer after lymphoma have been previously detailed by several authors [58, 61–68], but only one of the above studies directly compared the characteristics and prognosis of breast cancers after lymphoma in a series of age-matched first primary breast cancer [63]. It seemed that the features and prognosis of breast cancer after lymphoma were quite similar to those of sporadic cases. In the series of the Institut Curie [64], breast cancers were diagnosed at a relatively young age (median, 43 years) compared with the general French population (median, 61 years), and overall survival and locoregional control rates seemed to be inferior to those in nonmetastatic invasive sporadic breast cancers: with a median follow-up of 7 years, the 5-year overall survival rate and locoregional control rate were, respectively, 74.5% (95% CI, 64–88%) and 82% (95% CI, 72–93.5%) for invasive carcinoma. This difference in overall survival may be partially explained by an increase in the number of deaths due to cardiovascular diseases and nonbreast cancers secondary to treatments of lymphoma. Broeks et al. [65, 66] recently suggested that radiation-associated breast cancer may be different from other tumors on the basis of their expression profile. They compared microarray-based gene expression in 22 breast cancers after HL with a set of 20 control breast cancers. Radiation-induced breast cancer seemed to be characterized by a high degree of proliferation and a more aggressive tumor type; they reported a higher chromosomal instability and higher expression of proliferation marker Ki-67 in tumors occurring in previously irradiated breasts.

Dores et al. [67] evaluated the risk of invasive breast cancer among female 5-year survivors of HL diagnosed before 35 years of age who received RT as part of initial therapy for HL and who were reported to one of nine cancer registry areas of the SEER Program in the US during 1973–2000 and followed through 2005. Compared with breast cancer in the general population, risks of estrogen receptor (ER)-positive/progesterone receptor (PR)-positive and ER-negative/PR-negative breast cancer in young, irradiated HL survivors were increased fivefold (95% confidence interval (CI) = 3.81–6.35) and ninefold (95% CI = 6.93–12.25), respectively. Among 15-year survivors, relative risk of ER-negative/PR-negative BC exceeded by twofold ($P = 0.002$) than that of ER-positive/PR-positive breast cancer. Finally, the authors concluded that RT may disproportionately contribute to the development of breast cancer with adverse prognostic features among young HL survivors.

30.5 Treatment of Breast Cancer in Lymphoma Survivors

The surgical treatment of breast cancer patients with a history of malignant lymphoma treated with RT represents a challenge. According to the American College of Radiology appropriateness criteria on conservative surgery and radiation [68], a previous history of RT (e.g., for the treatment of ML) that delivered a significant dose to the breast and for which retreatment would result in an excessively high total radiation dose to the breast tissue is a contraindication for a BCS. High radiation doses to the breast result in unacceptable long-term toxicity and poor cosmetic rates, and indeed most authors consider these patients at significant risk of complications (fibrosis, skin and soft tissue necrosis, rib fractures, potential lung and heart toxicities) [62, 69–71] and do not candidate them for BCS and adjuvant RT. The study from Stanford [62] reported one of two women, who underwent lumpectomy and breast RT, and had a severe tissue necrosis developed in her lateral breast and chest wall at the area of overlap with the previous mantle field. In contrast, other reports [58, 72–75] support BCS followed by external beam radiation when breast cancer develops many years after RT for lymphoma. So, at present, no consensus exists regarding the correct management of breast cancer after RT

for lymphoma, and, given the discordant results and the small number of women treated with BCS, mastectomy continues to be recommended as the standard treatment.

There are few studies in the literature that compare BCS and mastectomy in the setting of breast cancer patients previously treated with RT for lymphoma [64, 76, 77]. The retrospective study by Haberer et al. [64] evaluated outcomes of 72 women who developed either ductal carcinoma in situ or stage I–III invasive carcinoma of the breast after HL between 1978 and 2009 at the Institut Curie. In this large series, median age at HL diagnosis was 23 years (range, 14–53 years). Median total dose received by the mediastinum was 40 Gy, mostly by a mantle-field technique. Breast cancers occurred after a median interval of 21 years (range, 5–40 years). Ductal invasive carcinoma and ductal carcinoma in situ represented, respectively, 51 cases (71%) and 14 cases (19%). Invasive breast cancers consisted of 47 cT0–2 tumors (82%), 5 cN1–3 tumors (9%), and 20 grade 3 tumors (35%). Locoregional treatment for breast cancer consisted of mastectomy with [3] or without [36] RT in 39 patients and lumpectomy with [30] or without [2] adjuvant RT in 32 patients. The isocentric lateral decubitus radiation technique was used in 17 patients after BCS (57%). With a median follow-up of 7 years, 5-year overall survival rate and locoregional control rate were, respectively, 74.5% (95% CI, 64–88%) and 82% (95% CI, 72–93%) for invasive carcinoma and 100% (95% CI, 100–100%) and 92% (95% CI, 79–100%) for in situ carcinoma. In patients with invasive tumors, the 5-year distant disease-free survival rate was 79% (95% CI, 69–91%), and 13 patients died of progressive breast cancer. Contralateral breast cancer was diagnosed in ten patients (14%). The authors concluded that BCS can be an option for breast cancer that occur after HL, despite prior thoracic irradiation. It should consist of lumpectomy and adjuvant breast RT with use of adequate techniques, such as the lateral decubitus isocentric position, to protect the underlying heart and lung.

More recently, Cutuli et al. [78] have published a multicentric international retrospective study on 189 women previously treated for HD by RT and/or chemotherapy that subsequently developed 214 breast cancer. Median age at HD diagnosis was 25 years (34% were less than 20). Median interval between HD and breast cancer was 18.6 years, with a 42-year median age at first BC. According to the TNM classification, there were 30 (14%) T0 (non-palpable lesions), 86 (40%) T1, 56 (26%) T2, 13 (6%) T3T4, and 29 (14%) Tx. There were 25 (13.2%) contralateral breast cancers. 160 (75%) and 15 (7%) tumors were infiltrating ductal and lobular carcinomas, 7 (3.3%) were other subtypes, and 27 (22%) were DCIS. The rate of axillary nodal involvement was 32%. Among 203 operated tumors, 79 (39%) were treated by BCS, with RT in 56 (71%) cases. With a 50-month median follow-up, local recurrence occurred in 12% of the tumors (9% after mastectomy, 21% after lumpectomy alone, and 13.7% after lumpectomy with RT). Metastasis occurred in 47 (26%) patients. The risk factors were pN+, pT, high SBR grade, and young age (<50 years). The 10-year overall and specific survival rates were 53% and 63.5%, respectively. The 10-year specific survival rates were 79% for pT0T1T2, 48% for pT3T4 ($p = 0.0002$), and 79% for pN0 versus 38.5% for pN+ ($p = 0.00026$). Among 67 deaths, 43 (73%) were due to breast cancer. Comparing BCS to mastectomy group, the authors reported a similar 5- and 10-year breast cancer survival between the two groups of treatment (75.8% and 70.7% after BCS and 76.6% and 63.7% after mastectomy, respectively). No remarkable unfavorable side effects of this treatment were observed. Other small retrospective studies have been published addressing the effect of WBRT in patients who have been previously treated with RT for lymphoma and supporting the use of whole breast radiation therapy (WBRT) after breast-conserving surgery (BCS) as re-irradiation with limited toxicity and good tolerance, especially in case of long interval of time between lymphoma and breast cancer [62, 73, 79–82]. Deutsch et al. [73] reported 12 patients with breast cancer developing after previous RT for HD treated by BCS followed by WBRT. With a median follow-up of 46 months, the authors reported two deaths due to distant disease. No patients developed local recurrence, and 100% of patients had excellent cosmetic results.

To avoid the risk of cumulative doses of RT to the thoracic wall, reason why total mastectomy has been historically considered the standard of therapy for these patients, especially in case of young patients and short interval between lymphoma and breast cancer diagnosis [83], one of the conservative options is to treat just the tumor bed. The irradiation of a small volume of the breast and adjacent structures could minimize the risk of complications [84–92]. Advances in RT devices and the development of different forms of partial breast irradiation (PBI) techniques, such as interstitial or intracavitary brachytherapy (MammoSite applicator), intraoperative radiotherapy with electrons (IOERT), intraoperative orthovoltage device (Intrabeam), and 3-D conformal or intensity-modulated external beam RT, could represent safe alternatives to avoid unnecessary mastectomies and provide a breast-conserving option for these patients, improving the local control of the disease. All of these techniques have similar indications but different applications. In particular, they differ in the source of radiation (e.g., X-ray, iridium-192, photons) and the amount of breast volume treated [93–101]. Data from recent reports consider PBI as a real alternative to mastectomy for these patients, given that the irradiation of a small volume of the breast minimizes the risk of complications, and report excellent outcomes and local control in carefully selected patients. An early series by Chadha et al. [102] examined the feasibility of partial breast brachytherapy as the primary treatment for breast cancer diagnosed after mantle

RT for HL. Although the study included a very specific group of five BC patients (<1 cm), no evidence of recurrence was reported. Moreover, the reported toxicity never exceeded grade 2, and cosmetic outcome was reported as excellent in all patients with no severe late sequelae from the repeat course of RT.

In a previous report of our group, Intra et al. [103] performed a retrospective review to assess the potential of performing BCS and intraoperative radiotherapy with electrons (IOERT) in 43 patients affected by early breast cancer, previously treated with mantle radiation for lymphoma. Median age at diagnosis of lymphoma was 26 years (49% were less than 25). Median interval between lymphoma and breast cancer occurrence was 19 years. A total dose of 21 Gy (prescribed at 90% isodose) in 39 patients (91%), 17 Gy (prescribed at 100% isodose) in 1 patient, and 18 Gy (prescribed at 90% isodose) was delivered. IOERT was well tolerated in all patients without any unusual acute or late reactions. After a median follow-up of 52 months, local recurrence occurred in 9% of the patients and metastases in 7% patients. In this series, intraoperative technique offered the advantage of a very precise targeting of the tumor bed, sparing normal breast tissue and surrounding vital organs from a second course of irradiation. IOERT allowed a breast conservative treatment in selected breast cancer patients, independently of the interval between mantle RT and surgery, without acute, intermediate, and late side effects, so decreasing the number of avoidable mastectomies and achieving a good local control of the disease. Unfortunately, no reports have been published yet comparing PBI techniques and WBRT as re-irradiation therapy during BCS in patients with history of RT for lymphoma.

30.6 Treatment of Breast Cancer in Lymphoma Survivors at the European Institute of Oncology (EIO)

In order to evaluate the long-term survival outcomes with BCS and mastectomy in the management of breast cancer patients with a history of lymphoma treated with RT and the role of WBRT and PBI during BCS from a total number of 155 lymphoma survivor patients who developed breast cancer and were treated at the EIO from September 1994 to December 2012, we retrospectively reviewed the medical records of 113 consecutive patients diagnosed with operable breast cancer previously submitted to RT for lymphoma. Thirty-two patients were excluded from the analysis given that no history of RT for lymphoma was retrieved. We excluded patients diagnosed with intraductal carcinoma (DCIS) or inflammatory breast cancer and those with concomitant diagnosis of lymphoma and breast cancer. We also excluded patients with clinical evidence of metastatic disease at the time of breast cancer diagnosis.

30.6.1 Malignant Lymphoma Data

For the entire cohort, lymphoma characteristics and treatment modalities were extracted from each patient's medical record. Type of lymphoma, age at diagnosis, interval time between lymphoma diagnosis and the occurrence of breast cancer, and the percentage of patients treated with chemotherapeutic agents were obtained. Detailed information of RT fields used on lymphoma treatment was also collected: mantle-field radiation included the primary lymph node regions of the neck, supraclavicular, infraclavicular, axillary, and mediastinal areas. Other RT fields included the involved supradiaphragmatic lymph node site or the involved supradiaphragmatic lymph node.

30.6.2 Breast Cancer Data

Clinical data collected included type of surgery, age at breast cancer diagnosis, percentage of contralateral breast cancer, and adjuvant therapy received. Breast surgical treatment consisted of either quadrantectomy ± RT or mastectomy followed or not by postoperative RT. Axillary staging was performed using sentinel lymph node (SLN) biopsy followed by axillary lymph node dissection (ALND) in case of macrometastatic SLN or primary axillary clearance in patients with preoperative assessment of axillary involvement. According to our policy at that time, in case of isolated tumor cells (ITCs) or micrometastasis of SLN, axillary dissection was omitted. Re-irradiation was administered after or during surgery by either whole breast radiation therapy (WBRT) or intraoperative radiotherapy with electrons (IOERT). WBRT consisted of a classical course of postoperative fractionated irradiation of the entire breast followed by a boost on the tumor bed. IOERT during BCS was delivered in a full-dose course directly to the tumor bed during the intervention, according to our standardized technique previously described [104].

Pathological data was retrieved directly from the pathological reports and include histological subtype, size of tumor (T), number of positive lymph nodes (N), estrogen/progesterone receptor status (ER, PgR), Her-2/neu status, proliferative index (Ki-67), nuclear grade (G), and presence or absence of perivascular invasion (PVI).

Patients were followed up with physical examination with blood tests every 6 months, breast and axillary ultrasound every 6 months, annual mammography, and further systemic evaluations only in case of symptoms. When possible, the status of women not presenting at the institute for scheduled follow-up visits for more than 1 year was obtained

by telephone contact. From follow-up data, we identified local and axillary failures, contralateral breast tumor occurrence, distant metastasis, and death. To evaluate acute and late radiation morbidity, the Radiation Therapy Oncology Group (RTOG) and European Organization for Research and Treatment of Cancer (EORTC) scoring scheme ([105]) was applied on the first and seventh day of the radiosurgical treatment and every 6 months during follow-up.

30.6.3 Statistical Analysis

Differences in the distribution of subject characteristics between patients receiving BCS and patients receiving mastectomy were evaluated by the chi-square test. The end points evaluated were disease-free survival (DFS), overall survival (OS), cumulative incidence of locoregional recurrence (CI-LR), and distant metastasis (CI-DM), all measured from the date of surgery. DFS was defined as the time from surgery to events such as relapse (including ipsilateral breast recurrence), appearance of a second primary cancer (including contralateral breast cancer), or death, whichever occurred first. OS was defined as the time from surgery until the date of death (from any cause). The DFS and OS functions were estimated using the Kaplan–Meier method. The log-rank test was used to assess differences between groups. The CI-LR and CI-DM were defined as the time from the date of surgery to a locoregional recurrence and a distant metastasis, respectively. The CI-LR and CI-DM curves functions were estimated according to methods described by Kalbfleisch and Prentice [106], taking into account the competing causes of recurrence. The Gray's test was used to assess cumulative incidence differences between groups [107]. All analyses were carried out with the SAS software (SAS Institute, Cary, NC) and the R software (http://cran.r-project.org/) with the cmprsk package developed by Gray (http://biowww.dfci.harvard.edu/_gray). All reported p values are two-sided.

30.6.4 Patient Population and Tumor-Related Characteristics

A total of 113 patients were included in this analysis. Demographic and clinical characteristics of the groups according to type of surgery are shown in Table 30.1. Mastectomy was treatment of choice in 36 patients while BCS was performed in 77. In 70 patients out of 77, some type of RT was added during or after BCS. In particular, WBRT was performed in 18 patients while IOERT in 52. WBRT consisted of 50 Gy administered in 5 weeks followed by a boost of 10 Gy on the tumor bed in all the patients. In case of IEORT, we treated two patients with a total dose of 17 Gy (prescribed at 100% isodose) and three patients with 18 Gy (prescribed at 90% isodose). The remaining 47 patients (91%) received 21 Gy (prescribed at 90% isodose). The median interval time between diagnosis of lymphoma and the occurrence of breast cancer was 19 years (range 1–46 years). Median age at diagnosis of lymphoma was 25 years (range 11–66 years) and 46 years (range 29–73 years) at breast cancer diagnosis. As expected, there were significant differences between the BCS and mastectomy cohorts regarding tumor size ($p < 0.001$), nodal status ($p = 0.003$), expression of Her2 oncoprotein ($p = 0.046$), PVI ($p = 0.028$), and nuclear grade ($p = 0.031$) (Table 30.2). Median follow-up for the entire population was 7.3 years (range: 6 months to 18 years).

30.6.5 Survival Outcomes for the Entire Population

Although both groups of treatment were not comparable because of heterogeneity, a comparative analysis of survival outcomes was performed (Table 30.3). The 5- and 10-year OS rates were 94% and 86.7%, respectively, in the BCS group vs. 74.1% and 68%, in the mastectomy group. Log-rank tests indicated significantly different survival curves at the 5- and 10-year points ($p = 0.022$) (Fig. 30.2a). The 5-year disease-free survival rates for patients who underwent BCS and mastectomy were 79.2% (95% CI 67.2%–87.2%) and 57.9% (36.4%–74.4%), respectively. The 10-year DFS rates for patients treated with BCS and mastectomy were 65.9% (50.3%–77.6%) and 45.6% (23.8%–65.1%), respectively. Log-rank tests indicated significantly different survival curves at the 5- and 10-year points ($p = 0.039$) (Fig. 30.2b).

The number of observed events according to primary local treatment is shown in Table 30.4. In the total population, 12 patients developed locoregional recurrence (LRR) (10.6%). Eleven patients had a LRR (14.2%) in the BCS group and 1 (2.7%) in the mastectomy group. Local recurrence (LR) as first event occurred in 11 patients (91.6%), while 1 patient (8.3%) developed regional recurrence (RR). There was no significant difference in the cumulative incidence of locoregional recurrence events among BCS and mastectomy groups ($p = 0.124$). Distant metastasis occurred in ten patients, four of whom were treated with BCS and six patients received a mastectomy. The 10-year cumulative incidence of distant metastasis was 5.2 (95% CI 1.7–16.1) for BCS and 20.5% (95% CI 9.7–43.2) for patients treated with mastectomy ($p = 0.015$). Overall, 19 of 113 patients (16.8%) died, 13 due to BC (19.4 in the mastectomy group and 7.8% in the BCS group), 2 due to other tumors, and 4 from other/unknown causes. No several early or late side effects were reported.

30.6.6 Survival Outcomes Comparing BCS Plus Re-irradiation Versus Mastectomy in Patients with T1 Tumor

A subgroup evaluation on 73 patients with tumors smaller than 2 cm (T1) who had not been previously treated with neoadjuvant chemotherapy was performed. The majority of patients were treated with BCS ($n = 57$) plus RT and the others were treated with mastectomy ($n = 16$). A comparative analysis between the two groups of patients did not show any statistically significant difference in terms of OS ($p = 0.5$), DFS ($p = 0.25$), cumulative incidence of locoregional events ($p = 0.835$), and distant metastasis ($p = 0.359$).

30.6.7 Survival Outcomes According to Type of Radiation Therapy After BCS

We also performed an analysis of survival outcomes for patients undergoing BCS plus RT, comparing WBRT

was therefore not prolonged. The cosmetic outcome was also very good in all patients. In an analysis comparing BCS plus WBRT or IORT, no differences were found in terms of late side effects related to RT in both groups of patients.

In conclusion, early breast cancer patients previously irradiated for lymphoma have similar survival outcomes independently if treated with BCS or mastectomy. Breast re-irradiation after BCS can improve the local control of the disease and doesn't increase local toxicity. In selected patients, IOERT can be a valid alternative to WBRT, without acute, intermediate, and late side effects and with an acceptable cosmetic outcome. A thorough discussion with the patient is needed, and the patient's preference should be carefully taken into account after receiving all the available information on the different treatment options.

Conclusions

The treatment of malignant lymphoma has improved over the past decades: more than 90% of patients with localized lymphoma are cured with modern therapies combining chemotherapy and RT. With improved survival rates, long-term toxicities, especially increased incidence of second malignancies, are a major concern for survivors. Several studies have reported evidence that female survivors of lymphoma treated with RT are at increased risk for breast cancer, especially women treated before the age of 20 years. In women with a history of malignant lymphoma, breast cancer is the most common second malignancy, with a standardized incidence ratio of approximately six compared with the general population. The cumulative incidence of breast cancer by the age of 40–45 years ranges, in these women, from 13% to 20%. Risk factors for subsequent breast cancer after lymphoma have been described and discussed by many authors: splenectomy, young age at supradiaphragmatic irradiation, long interval after lymphoma, higher dose and volume of irradiation, and chemotherapy. Only few data are available, however, regarding locoregional treatment for breast cancer occurring after lymphoma. Mastectomy alone is the standard treatment because a breast-conserving option would necessarily entail re-irradiation of tissues already exposed to a mantle or mediastinal RT field and therefore expose the patient to potentially high cumulative doses. Breast-conserving treatment can be an option for breast cancers that occur after lymphoma, despite prior thoracic irradiation. It should consist of tumor resection and adjuvant breast RT with use of adequate techniques, such as the lateral decubitus isocentric position, to protect the underlying heart and lung. In selected patients, PBI can be a valid alternative to whole breast RT, without acute, intermediate, and late side effects and with good cosmetic results. A thorough discussion with the patient is needed, and the patient's preference should be carefully taken into account after receiving all the available information on the different treatment options. In fact, for patients with newly diagnosed lymphoma, the risks of both radiation-related and chemotherapy-related late toxic effects must be carefully balanced against the risk of failing to control the primary disease. Awareness of the increased risk of subsequent malignant neoplasms remains of great importance for survivors of lymphoma and for their physicians.

Surgery of Metastases in Stage IV Breast Cancer

31

Elisabetta Pennacchioli, Gianluca Varano, Franco Orsi, Pierpaolo Prestianni, Gianmarco Orsolini, and Angela Cioffi

31.1 Introduction

Breast cancer is the most common cancer among women worldwide.

Mortality rates have been decreasing since the 1990s, as a result of earlier detection through screening, increasing awareness, as well as advances in adjuvant therapies. Nonetheless, 3–4% of patients show synchronous metastasis at time of diagnosis [1–3].

As a result, over three million women in the United States live with a history of breast cancer, representing 41% of all female cancer survivors [4] and 3.6% of the whole American population [4, 5].

In Italy, about 50,800 new cases are recorded every year (AIRTUM, Italian Association of Tumor Registry, 2015).

The prognosis of stage IV breast cancer patients is poor with a median survival of 18–24 months, but has improved due to advances in systemic therapy. Surveillance, Epidemiology, and End Results (SEER) analysis data supports the concept that surgery may contribute to a better outcome advantage by reducing the burden of disease [6].

Patients with a higher overall survival tend to be younger females with an excellent performance status and a limited metastatic disease, for whom an intensified multidisciplinary approach combining systemic therapies with local treatment may prevent local complications and prolong survival [7, 8].

Metastatic disease is normally treated with systemic therapy, but sometimes surgery may play a role in symptom management, on a case-by-case basis. Recurrences, when they do occur, normally do so within the first 5 years, particularly in hormone receptor-negative or human epidermal growth factor 2 (HER-2)-positive disease, but sometimes they tend to be more indolent (hormone receptor-positive or HER-2-negative disease) [9].

31.2 Selection of Patients

The selection of candidates for surgery requires a careful assessment of medical conditions, extent and clinical behavior of the disease, and feasibility of resecting the metastasis with a negative margin.

The relative risks and benefits of surgery must be weighed for each individual patient.

Predictive factors are described in Table 31.1, with identification of different determinants related to the patients and to the disease.

31.2.1 Clinical Determinants

- Static clinical determinants:
  - Performance status, comorbidity
  - Extent of disease (life-threatening organs, brain mets)
  - Tumor burden
- Dynamic determinants (before and during therapy):
  - Kinetics of the disease
  - Time to progression
  - Disease aggressivity

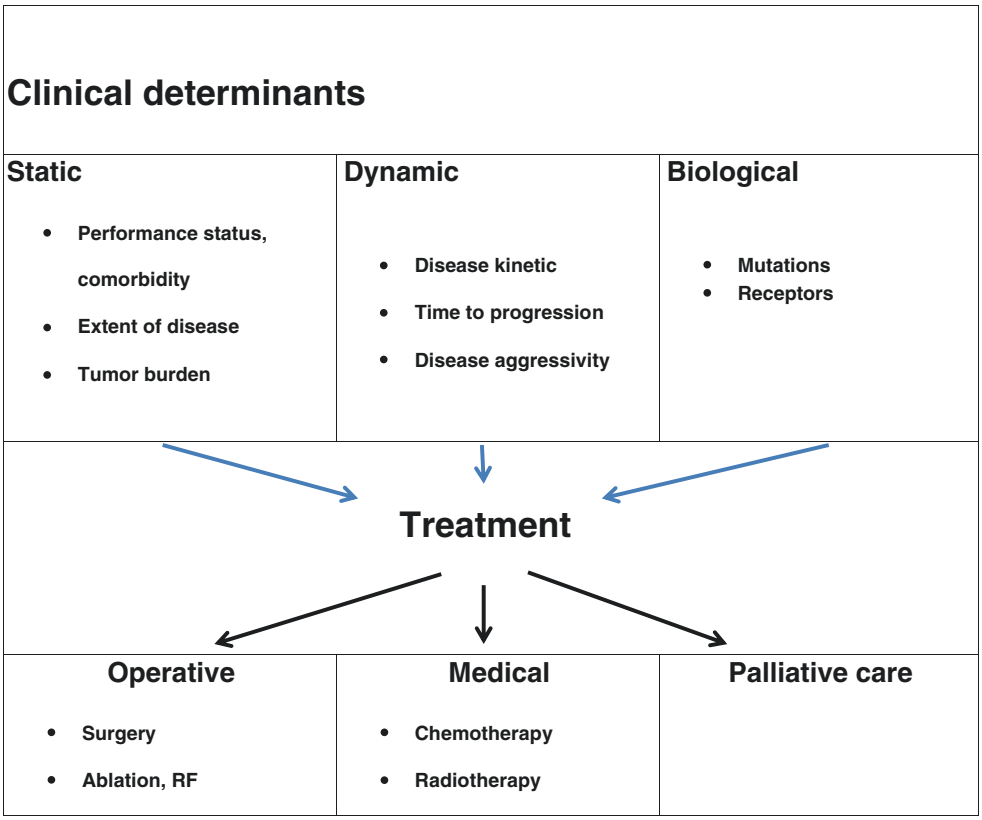
Table 31.1 Determinants which may help the selection of appropriate patients for surgical consideration



31.2.2 Biological Determinants

- Receptors
- Mutations

31.2.3 Treatment Strategy

- In fast disease kinetics (i.e., immediate danger), the first objective is to preserve life and relieve symptoms in the short term:
  - Fast-acting treatment.
  - Long-term survival is only a secondary objective.
- In intermediate disease kinetics, the first objective is to prolong survival:
  - The ideal strategy is to start with the treatment that will give the highest chance of a prolonged survival (3–5 years).
- In slow disease kinetics, the first objective is to prolong survival with the best possible quality of life:
  - The current strategy is to start with treatments such as surgery, radiosurgery, low toxicity, low morbidity, and some potential to preserve long-term survival.

31.2.4 Performance Status and Comorbidity

Perhaps the most important issues in choosing patients for local treatment of metastatic disease are the performance status and the estimation of the relative risks of a planned operation. Patients with an Eastern Cooperative Oncology Group (ECOG) performance status of 2 or worse or those with significant medical comorbidity should be considered carefully for local treatment, especially surgery, as they are likely to have high rates of postoperative morbidity and mortality.

31.2.5 Extent of Disease

Overall indicated as oligometastatic disease, disease extent is an important parameter which considers not only the number of metastatic sites but also the location in a single or multiple organs.

Multivariate analysis of local treatment outcomes suggests that those patients with limited metastatic disease, i.e., solitary or few detectable lesions, and limited to a single organ are more likely to benefit from local therapy than those with multiple metastases [10–14].

A small number of studies have reported no difference in long-term outcomes in patients undergoing hepatic resection in the presence or absence of extrahepatic disease (predominantly the bone) [15–17].

Successful surgery for metastatic disease is limited to patients with a single-organ involvement, as reported in some studies, even though there is a lack of experience in multi-organ resected patients.

31.2.6 Disease-Free Interval

A long disease-free interval (DFI) is associated with a better outcome with local therapy [18–20].

The specific cutoff value of DFI that best discriminates between favorable and unfavorable outcomes is unclear.

31.2.7 Complete Resection

Breast cancer has the potential to metastasize to almost every organ in the body. The most common sites of metastases are the bone, liver, and lung, while 15–40% of recurrences involve the chest wall and axillary or supraclavicular lymph nodes.

Approximately 50–75% of patients relapse distantly in a single organ, while the rest develop diffuse metastatic disease.

Fewer than 5% of patients manifest central nervous system (CNS) involvement as the first site of metastatic disease.

A careful preoperative evaluation is necessary to determine the feasibility of a complete resection of the metastatic deposit. The impact of positive margins is unclear, even though in some series they are associated with worse outcomes [10, 18, 20–22].

Surgical resection should be proposed when can be margin-free, alone, or in association with other means of local therapy (such as radiation therapy, radiofrequency ablation, or cryotherapy).

Several small studies have shown that treatment of isolated metastases is associated with a better progression-free survival and overall survival than oligometastatic cases.

However, with the exception of brain and spinal cord metastases, there are no prospective randomized clinical trials to determine whether or not such approaches really improve palliation and/or survival.

31.2.8 Resection of the Primary Tumor in Stage IV Breast Cancer

Management of the intact primary tumor in women presenting a stage IV breast cancer has classically been determined by the presence or absence of symptoms. However, multiple retrospective reviews suggest a survival advantage with resection of the intact, asymptomatic primary tumor in these cases [23]. Recently completed randomized trials (NCT00193778 [India] and NCT00557986 [Turkey]) do not support a significant survival benefit, although local control benefits may exist. The biases of the retrospective data include the use of surgery in younger women with smaller tumors, single sites of metastasis, and less visceral disease. Timing of surgery in relation to the diagnosis of metastases and use of systemic therapy has not always been specified in the published retrospective literature, although several authors have attempted to address this matter with varying conclusions [24–26].

Until additional unbiased data are available, surgery and/or radiotherapy should not be routinely recommended for patients with stage IV breast cancer with an intact primary tumor.

In particular, there is no basis for recommending surgery to women with distant disease if:

- The distant disease is not well controlled, and survival will likely not be long enough for the primary site to become a problem.
- Both local and distant sites are well controlled, in which case the primary site is likely to remain well controlled for the patient's life span.

The only possible exception to these general rules may be the patient with well-controlled or ablated oligometastatic distant disease, who would be rendered stage IV NED (no evidence of disease) through resection of the primary tumor.

For the patient whose distant disease is controlled but whose primary site is progressing, surgery provides a reasonable approach, although whether radiotherapy following surgery is beneficial is unproven; its use may be justified if the risk is high of early local recurrence and uncontrolled chest wall disease.

Locoregional therapy for the primary tumor should be offered to patients only with full disclosure of the lack of evidence of a survival benefit.

31.2.9 Lung Metastases

Isolated lung metastases occur in 10–25% of patients with metastatic breast cancer [11, 19] (Fig. 31.1). While pulmonary metastasectomy is a commonly performed operation, belief in its effectiveness is based on tumor registry data and surgical follow-up studies.

The necessity to rule out lung cancer in a breast cancer patient presenting with pulmonary nodes is clear; pulmonary resection may be diagnostic as well as therapeutic, since a significant number of solitary pulmonary nodules are primitive lung cancer [27–30].

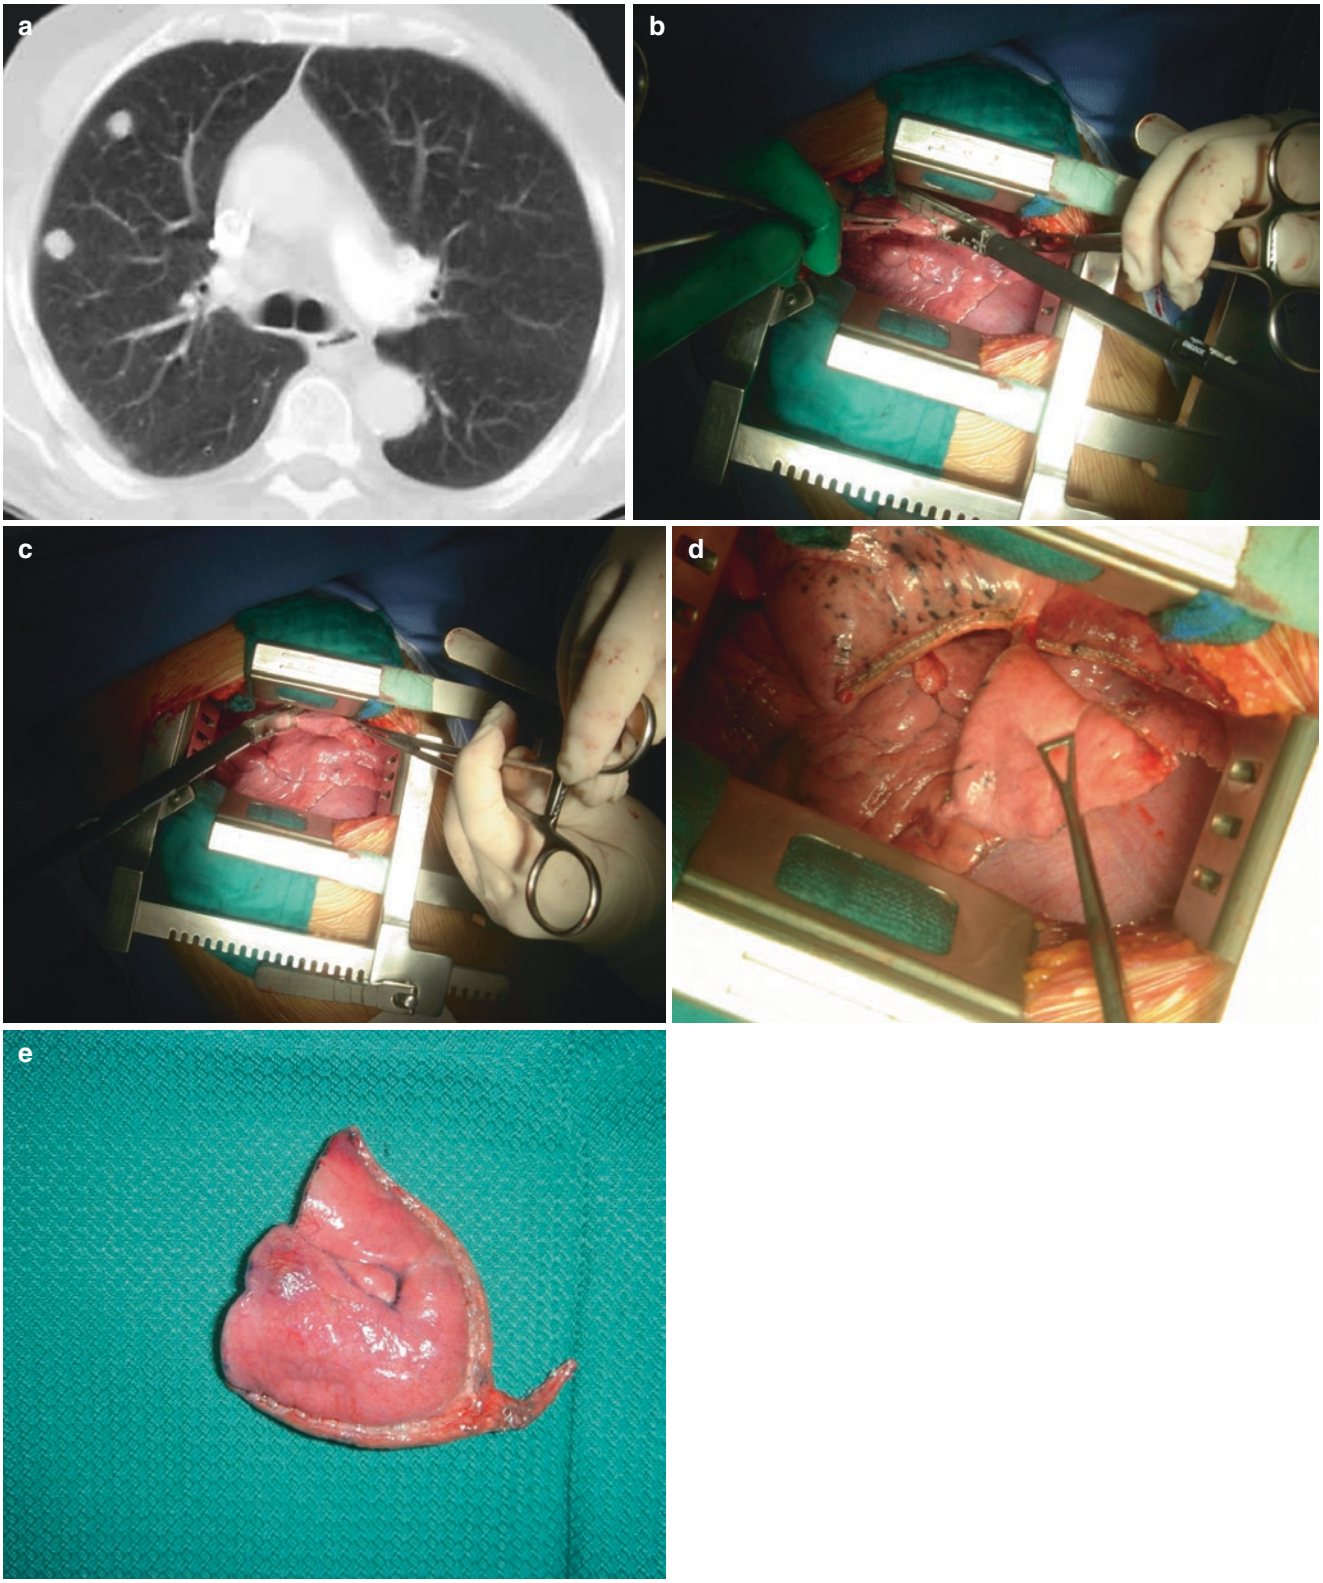


Fig. 31.1 (**a**) Monolateral lung metastases, amenable to surgical resection. (**b**) Identification and resection planning of a peripheral lung nodule. (**c**) Wedge resection using a surgical staple. (**d**) Result of lung resection. (e) Specimen with the evidence of a metastatic node

Pulmonary resection or metastasectomy offers an opportunity for long-term survival in highly selected patients with metastatic breast cancer, with case series demonstrating 5-year overall survival ranging from 30% to 80% and median survival duration ranging from 40 to 100 months [10, 19, 21, 27]. Based upon these observations, aggressive resection of isolated pulmonary metastases has become a widely accepted treatment for appropriately selected patients. The decision to proceed with pulmonary metastasectomy requires a multidisciplinary approach (a medical oncologist and thoracic surgeon). The goal is to offer surgery only to those patients who are most likely to benefit, to optimize the timing of surgical intervention. Patients who experience long-term survival after metastasectomy are those with solitary metastases and a disease-free interval greater than 36 months. In one report, the most important factor that influences survival is the positivity to HER-2; the 5-year survival moves from 12.1%, HER-2 negative, to 76%, HER-2 positive. Other prognostic factors may include size of metastases, unilateral disease, completeness of resection, and use of anatomic resection (as opposed to wedge resection) [10, 12].

31.2.10 Liver Metastases

Hepatic metastases occur in over half of patients with metastatic breast cancer, are commonly associated with disseminated disease, and result in a poorer prognosis than bone or soft tissue metastases.

Only 5–12% of patients have isolated liver involvement [31–33].

Only appropriately selected patients with breast cancer metastases may have an advantage from hepatic resection.

In a systematic review of 19 studies involving 535 patients who underwent hepatectomy for metastatic breast cancer, median overall survival was 40 months (range, 23–77 months) with a 5-year survival following resection of 40% (range, 21–80%) [34]. Postoperative mortality ranged from 0 to 6% and the complication rate ranged from 0 to 44%. Prognostic factors following hepatic resection were positive margins and hormone-refractory disease.

The ideal candidate has a solitary metastasis, no evidence of extrahepatic metastatic disease, normal liver function, a good performance status, and a long DFI [12, 14, 17].

An essential part of the diagnostic work-up in patients who are considered for hepatectomy is precise imaging of the liver (helical computed tomography scan or magnetic resonance imaging) to evaluate whether a complete resection can be achieved while retaining a sufficient volume of functional liver.

It is not clear whether multiple metastases are a negative prognostic feature for resection of liver metastases, as long as they can be completely resected [14, 15, 20].

Initial laparoscopic exploration may spare unresectable patients the morbidity of a laparotomy, since up to half of the patients considered for resection are discovered to have diffuse liver lesions or peritoneal dissemination at the time of laparotomy [35].

Hepatic resection is appropriate for highly selected patients, but alternative local therapies are being increasingly used to treat liver metastases.

Liver-directed therapy includes image-guided thermal ablation (radiofrequency ablation, microwave ablation, cryoablation, interstitial laser therapy), stereotactic body RT (SBRT), and intra-arterial therapies (selective internal RT and transhepatic arterial chemoembolization).

None of these methods has been directly compared to systemic chemotherapy in metastatic breast cancer, except in a recent paper addressing a cost-utility analysis of liver resection in breast cancer liver metastases. The authors compared postoperative conventional systemic therapy versus conventional therapy alone versus newer targeted therapy alone. The implications of using different chemotherapeutic regimens based on estrogen receptor and human epidermal growth factor receptor 2 status were also assessed. Liver resection in patients with breast cancer liver metastasis proved to be cost-effective when compared with systemic therapy alone, particularly in estrogen receptor-positive tumors or when newer agents were used [36].

31.2.10.1 Interventional Oncology

- Image-guided thermal ablation:

This category of local treatment includes modalities having the common aim of targeted tissue destruction by means of different forms of energy.

Those treatments can be used alone percutaneously, based on imaging guidance, or in combination with resection [31–34].

When radiofrequency energy is applied, an oscillating electrical current flows through the body inducing ionic agitation in tissues around the interstitial electrode. Resistive heating is produced in the areas closest to the interstitial probe [37] (Figs. 31.2, 31.3, 31.4).

Microwave (MW) ablation is based on electromagnetic energy, with frequencies greater than or equal to 900 MHz, which induces a vigorous movement of water molecules. This movement produces heat and thus tissue destruction and cell death via coagulative necrosis [38–41].

Cryoablation is based on alternating temperature decrease (−40 °C) and thawing. Rapid expansion of pressured gas within the probe creates a very low temperature and the formation of an iceball on the probe tip. Thawing of the iceball was achieved by insufflations of high-pressure gas. This system induces cell death by osmotic shock [42].

Fig. 31.2 CT scan portal venous phase: single metastatic lesion in segment II (pre)

Fig. 31.3 CT scan the day after treatment showing complete treatment: hypodense ablation area without suspicious contrast enhancement

Interstitial laser therapy (ILT) causes local tumor destruction by the application of laser light, delivered through quartz diffusing laser fibers which can be percutaneously placed within tumors [43–46].

- Intra-arterial therapies:

The rationale behind transarterial treatment is that liver tumors receive blood flow almost entirely from the artery, while normal liver tissue is supplied both by the portal blood flow and by arterial blood flow. Selective intravascular delivery of agents into arterial tumor-feeding vessels has the goal of inducing lethal damage to the pathologic tissue while reducing collateral injury to healthy liver tissue [47, 48].

Fig. 31.4 CT scan 5 years after treatment showing shrinkage of ablation area. Patient is still disease-free

Different materials have been used in past decades in the treatment of primary and secondary liver cancers.

Transarterial chemoembolization (TACE) is based on different drug carriers (Gelfoam, microparticles) that have a dual aim: to reach higher intrahepatic drug concentration than that in systemic therapy and occlude arterial vessel to induce tissue ischemia.

Selective internal RT (SIRT) is a procedure in which glass or resin microspheres incorporating the radioactive isotope 90Y are directly infused into the hepatic arteries feeding the tumor. This will allow the delivery of doses of ionizing radiation above 120 Gy to the tumor compartment without causing intolerable toxicity to the normal tissue [49].

- Stereotactic body radiation therapy (SBRT or fractionated radiosurgery) is a technique that delivers external beam radiation to the tumor.

31.2.11 Brain Metastases

Breast cancer is the second most common cancer associated with brain metastases in the United States. In a subset of women, progression in the central nervous system (CNS) has become the major life-limiting problem. The risk of central nervous system (CNS) relapse among patients with breast cancer varies significantly by disease stage. Among women presenting with early-stage breast cancer, less than 3% will

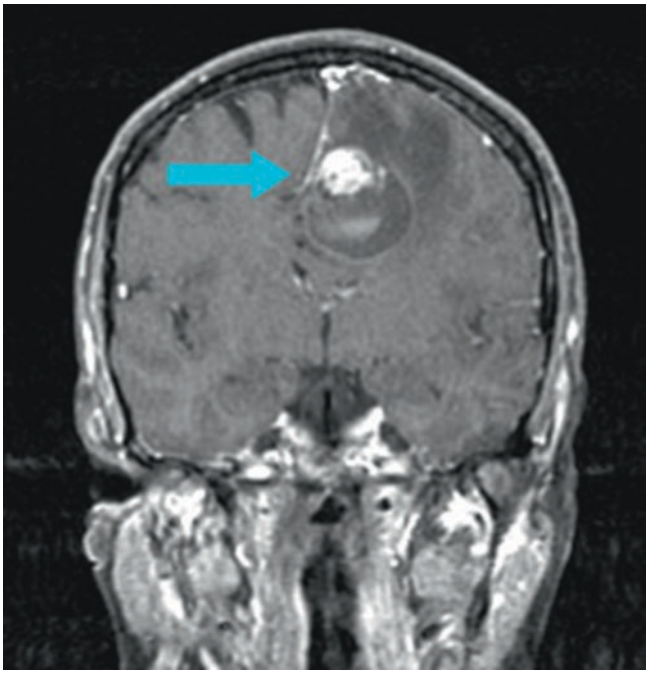

Fig. 31.5 Isolated brain metastasis

go on to develop brain metastases [1, 2]. In contrast, symptomatic brain metastases are diagnosed in 10–16% of patients with metastatic breast cancer [1, 3] (Fig. 31.5). Factors associated with an increased likelihood of CNS relapse include age under 40 years, pulmonary metastases, and African-American ancestry [1, 3–7].

In addition, the breast cancer subtype appears to be associated with the incidence of brain metastases [2, 6, 8–19]. In a cohort study of 1434 women treated with breast-conserving therapy plus systemic chemotherapy, brain metastases developed in 36 (2.5%).

For patients with a favorable prognosis (e.g., Karnofsky performance score [KPS] 70 or higher, age <65 years, controlled primary tumor, and controlled or absent extracranial metastases), aggressive treatment is indicated. For women with brain metastases from human epidermal growth factor receptor 2 (HER-2)-positive disease, the administration of systemic therapy may delay the use of whole-brain radiation therapy (RT) and the associated risk of neurologic toxicity.

Following initial treatment for brain metastases due to breast cancer, both surgery and stereotactic radiosurgery can be used to retreat patients who develop recurrent, symptomatic central nervous system (CNS) disease and have stable extracranial disease following their initial treatment for brain metastases. Careful selection of patients is critical in this setting. As with the initial evaluation, the absence of active systemic disease and a Karnofsky performance score of at least 70 are important. Factors indicating a probable poor outcome include a short time to recurrence and age less than 40 years.

Fig. 31.6 Pathologic fracture through a metastatic lesion of the distal femur (**a**). Resection of the metastatic lesion and distal femoral replacement (**b**)

31.2.12 Bone Metastases

The bone is the most common site of metastatic involvement in breast cancer and can be associated with significant morbidity and mortality.

Surgery, RT, and RFA can provide effective pain relief and prevent fracture (Figs. 31.6 and 31.7). Surgery and RT are also used for the palliative treatment of epidural spinal cord or nerve compression.

Bisphosphonates and other osteoclast inhibitors have been shown to reduce the morbidity of metastatic bone disease, in particular skeletal-related events (SREs), which include fracture, need for surgery or radiation to the bone, spinal cord compression, and hypercalcemia of malignancy.

Bone-confined metastatic breast cancer is usually characterized by an indolent course and good response to systemic therapy [50–52].

There is a limited role for resection as a curative option for the majority of bone metastases, except for selected patients with isolated spine or sternal involvement [53–57].

Sternal metastases may remain solitary for a long time, possibly because there is no communication with the paravertebral venous plexus through which cancer cells can spread to other bones [53, 55].

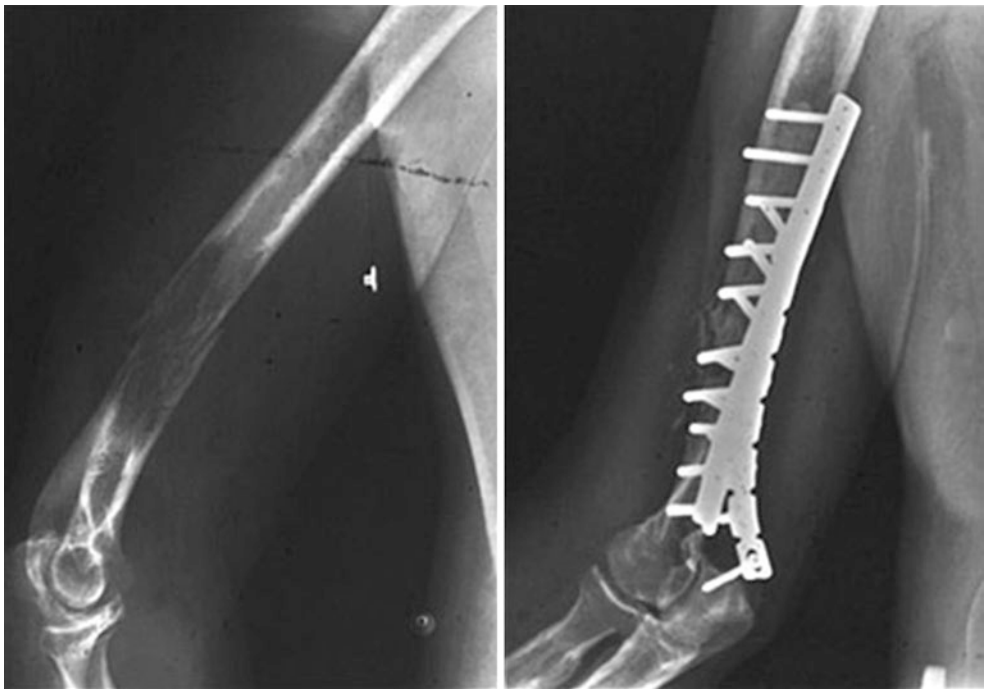

Fig. 31.7 Reconstruction of a pathologic fracture of the humerus with plates and screws

In other cases, isolated sternal involvement represents locoregional recurrence (i.e., direct extension from an internal mammary nodal recurrence) rather than true metastatic disease. Surgical resection of breast cancer confined to the sternum may improve quality of life and prolong survival.

When spine metastases become symptomatic causing severe pain, neurological deficit, and biomechanical instability, this may require surgical resection. The ideal approach is multidisciplinary and includes medical treatment (mostly for symptom control) radiotherapy, stereotactic radiosurgery, and surgery. The aim of surgery is to preserve or restore a neurological function in tumors that progress despite undergoing maximal radiation dosages and medical intractable pain. The treatment improves patient's quality of life; the indication for surgery should take into consideration anatomical location and the extension of disease [56, 58].

31.2.13 Abdominal and Pelvic Metastases

Limited data suggest that ovarian breast cancer metastases can appear many years following the initial diagnosis of breast cancer and tend to be hormone receptor-positive [59–62].

Surgical evaluation of an adnexal mass may be required to discriminate metastatic breast cancer from a primary ovarian cancer.

31.3 Summary and Recommendations

Local therapy may offer therapeutic benefits and the potential for long-term survival for highly selected patients with metastatic breast cancer.

Although most evidence exists in support of surgical resection, alternative approaches, such as radiofrequency ablation and stereotactic body radiation therapy, are gaining popularity.

Patient selection is crucial when considering local therapy. The best candidates are those with solitary metastases in a single metastatic site and a long disease-free interval.

Completeness of resection is a key factor when considering surgery.

Perhaps the main indication for resection of a new, isolated pulmonary, hepatic, or abdominopelvic lesion in a patient with a prior history of breast cancer is diagnostic, since some patients may have a new primary malignancy or a change in tumor marker status.

Part VI

Plastic and Reconstructive Surgery

Oncoplastic Surgery

32

Cicero Urban and Mario Rietjens

32.1 Introduction

Oncoplastic surgery (OP) represents an important evolution in breast cancer treatment. As a surgical method and a technical refinement, it allows better aesthetic and oncologic outcomes. In this way, as a consequence of a more individualized approach, it can positively influence psychological aspects of patients and broadens indications for breast-conserving treatment (BCT). Therefore, the emphasis of this new phase in breast cancer surgery is on immediate reconstruction and contralateral surgery for symmetry whenever necessary, synergistically combining oncologic and aesthetic concepts by the surgical team or by a single surgeon [1–18].

Around 20–30% of BCT has unsatisfactory aesthetic outcomes and 10–40% of reoperations due to compromised margins [2–20]. In addition, defects after BCT tend to accentuate with radiotherapy, increasing asymmetry, which usually require flaps or lipofilling to correct them in the future. But, unfortunately, aesthetic outcomes after delayed partial breast reconstructions are many times unsatisfactory [18–30]. Then OP is the way to reduce the conflict in BCT of performing resections with free margins even in large and multifocal tumors and does not remove so much breast tissue, which could result in major deformities and asymmetry between the breasts [3–8].

C. Urban (✉)

e-mail: cicerourban@hotmail.com

M. Rietjens
Plastic Surgery, European Institute of Oncology, Milan, Lombardia, Italy
e-mail: mario.rietjens@ieo.it

So, every effort should be made to identify better candidates to this surgical approach. If local-regional control represents the main target for oncologic surgeries, aesthetic outcomes and quality of life are also basic principles in BCT, from the very beginning [31, 32]. Then, in this chapter, it will be discussed OP history and evolution, and the indications and limits of Class I and Class II techniques in BCT.

32.2 History and Evolution

Historically it is difficult to precisely define the first time that a mammoplasty technique was used in BCT with the aim of reducing deformities and asymmetries. There were a number of nonacademic surgeons, in different countries, who were doing sporadically this kind of surgery, even before its appearance in the literature. One of its earlier applications was in the 1980s in France by Jean-Yves Petit (at that time at Institut Gustave Roussy), Jean-Yves Bobin (Centre Léon-Bérard), and Michel Abbes (Centre Lacassagne). Some years later, the OP concept was then originally coined by Werner Audrescht in German and posteriorly had a major diffusion after the publication of the classic paper from Krishna Clough and colleagues in 2003 (Fig. 32.1) [3, 9]. In Brazil, some breast surgeons like Antonio Figueira, Angelo Matthes, and Jorge Biazús were doing OP since the 1980s too. And, despite the lack of randomized trials, current evidence suggests at least equivalent oncologic outcomes, reduced re-excision rates, and superior aesthetic results when compared to lumpectomies (Table 32.1). Therefore, although it remains not a consensus, the original OP concept as "tumor-specific immediate reconstruction" [1] is not limited to BCT. Skin-sparing and nipple-sparing mastectomy techniques have incorporated OP principles doing a well-conducted oncologic resection followed by immediate breast reconstruction and contralateral symmetry in the same surgery.

32.3 Oncologic and Aesthetic Outcomes

Although there are no randomized trials comparing OP with standard BCT and many reported series are retrospective and noncontrolled ones, the current data is enough to incorporate OP in current BCT (Fig. 32.2) [1–29]. In addition, OP follows the same BCT oncologic principles (Fig. 32.3). Haloua [26], in their review of 11 prospective oncoplastic studies, found 7–22% positive margin rate in OP, compared to the 20–40% in standard BCT. This difference resulted in lower re-excision rate. Santos, in Brazil, did a comparison between quality of life and aesthetic outcomes in OP and lumpectomy and found that excellent aesthetic outcomes are more frequent in OP [4]. A recent meta-analysis by Losken [27] also demonstrated larger resection volumes, increased satisfaction with aesthetics, and decreased rates of positive margins, re-excisions, and local recurrences for OP. No significant delay in adjuvant chemotherapy and radiotherapy was related

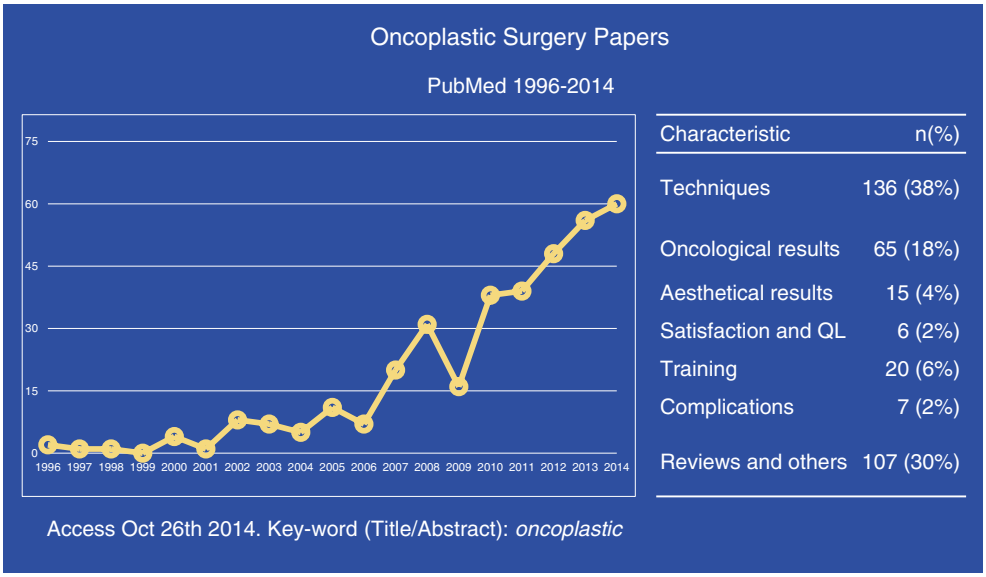

Fig. 32.2 Evolution and characteristics of oncoplastic surgery papers

despite the increased complexity of these surgeries [6–8, 26, 27]. Long-term survival has been equivalent to BCT series [26, 27]. A valid concern over the OP approach is the reliability of clips placed for the boost, although advances in intraoperative radiation therapy may make this less of an issue. Tissue rearrangement during oncoplasty might result in a larger, less exact boost during external beam radiation therapy, possibly resulting in a poorer aesthetic outcome and decreased local control of disease.

32.4 Patient Selection

Classically, the most frequent deformities after BCT are deficiency of glandular tissue and overlying skin retractions resulting from wide resections and late side effects after radiotherapy, deformity and/or retraction of the nipple and areola complex (NAC), and reduction of mammary ptosis and asymmetry of the inframammary crease as a consequence of fibrosis and retraction after radiotherapy. All these deformities are expected to be more evident when the relation tumor/breast is unfavorable, and they are also related to the tumor location and its proximity with the NAC and skin, and the boost. So, the most adequate technique for each patient should be determined according to the anticipation of the size and position of the future defect, tumor proximity with the skin and NAC, and clinical conditions of the patient [1–17].

Class II OP is more complex and time consuming than classic lumpectomy. Thus the selection of patients from oncological, aesthetical, and psychological point of view is critical. All attempts should be made to minimize the risk of positive margins, which are difficult and sometimes impossible to reassess in a second surgery [30], and to reduce and prevent complications that may delay adjuvant treatments. Therefore, there are some established indications for OP in BCT; the main ones are for patients with more than 20% of volume of mammary resection, and especially in the case of macromastia, where results from skin-sparing or nipple-sparing mastectomy are usually unsatisfactory, and OP approach may also favor radiotherapy planning.

Current indications and limits of Class II OP in BCT are in Table 32.2.

32.5 Preoperative Planning

Although the only significant element referred to as an aesthetical risk for BCT in Cochrane evaluation was the volume of mammary resection over 20%, in clinical practice there are many other risk factors that should be observed [8]. The choice of OP technique depends on tumor location and size, multifocality, multicentricity, bilaterality, breast size, ptosis, shape and symmetry, previous mammoplasties, and previous radiotherapy [8].

In some circumstances, some associated clinical conditions may also influence the choice of the most appropriate technique. Diabetic patients, obese patients, tobacco addicts, those with collagen diseases, and those above 70 years old are subject to risks concerning unsatisfactory aesthetic results, and skin healing complications are higher. Major resections and wide NAC dislocations may bring additional risks of fat necrosis and of partial or total NAC losses [8].

The ideal location for a tumor is within the mammoplasty area. When the tumor is close to the skin and out of this area, the OP procedure may be more complex, and it may require combined techniques, whose results are not

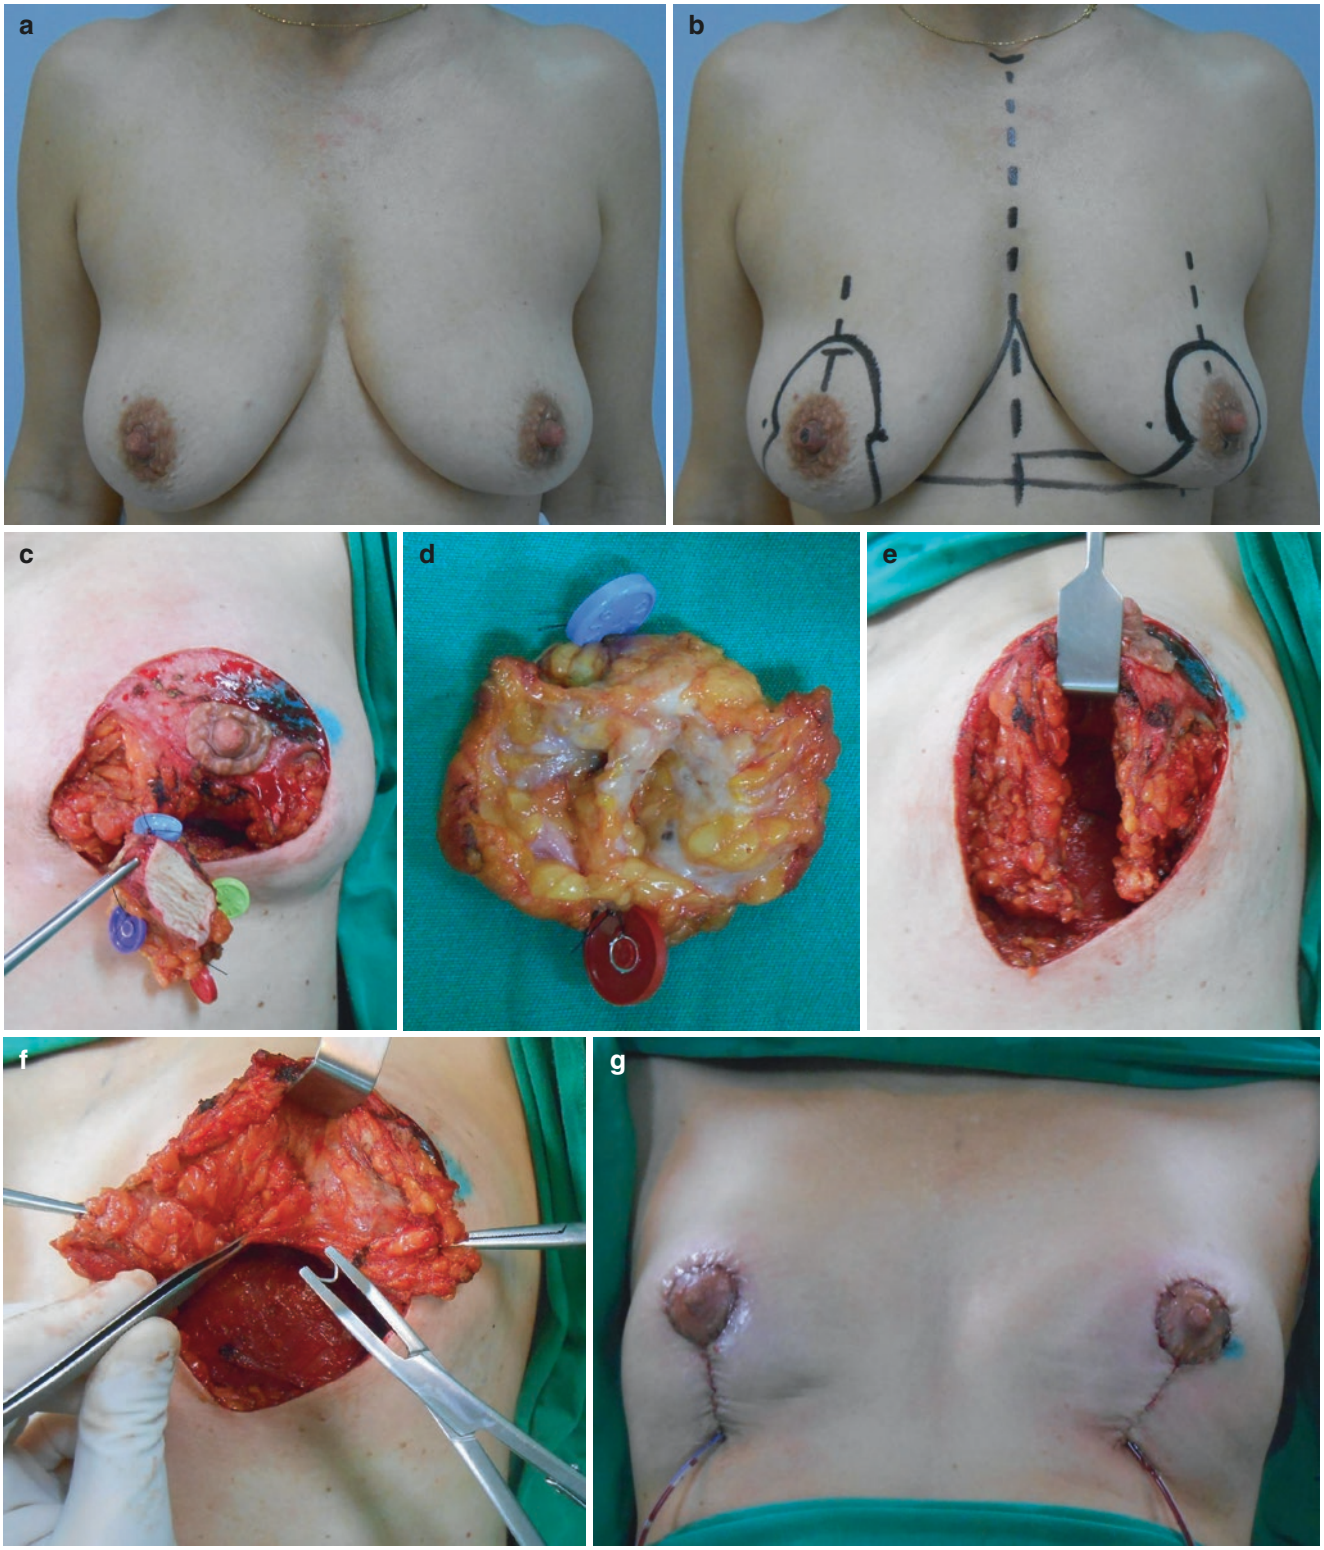

Fig. 32.3 Oncoplastic surgery step by step: (**a**) preoperatory view of a 50-year-old patient with T1cN0 breast cancer in the inferior quadrant of the left breast; (**b**) preoperatory draws for the surgical planning; (**c**) resection of the tumor (with skin over it); (**d**) tumor in the center and demarcation of the margins to guide the pathology; (**e**) the two pillars for partial breast reconstruction; (**f**) surgical clips for the boost; (**g**) final result with contralateral mammoplasty for symmetry

Table 32.2 Indications and relative contraindications for Class II oncoplastic surgery in breast-conserving surgery

Indications
• Resections over 20% of breast volume
• Macromastia
• Severe ptosis and asymmetry
• Need for large skin resections inside mammoplasty area
• Central, medial, and inferior tumors
• Previous plastic surgeries in the breast
Relative contraindications
• Extensive tumors located in medial regions
• Low-volume breasts, particularly those without ptosis
• Previously irradiated breasts
• Skin resections beyond mammoplasties zone in small-/medium-size breasts
• Tobacco addiction and uncontrolled diabetes
• Exaggerated patient's expectations with aesthetic outcomes

always satisfactory. In such cases skin-sparing or nipple-sparing mastectomy should be considered as an option. Flaps as the one from the *latissimus dorsi*, which has a different color and texture from the breast, usually bring unsatisfactory results and therefore should be considered as an exception [8].

High-volume breasts, with severe ptosis, allow for surgeries with wider margins and usually bring more satisfactory results. Patients with macromastias present a formal indication for OP due to better radiotherapy planning in a smaller and round breast. In cases of previous breast augmentation plastic surgery, it is necessary to take into consideration that the breast volume is not the real one, and consequently some considerable deformities may result. The biggest problem concerning OP is dealing with young patients, with conic breast, without mammary ptosis, and with low or medium volume. In such cases, according to the location or tumor size, local flaps offer a little chance of good results, so skin-sparing or nipple-sparing mastectomy with immediate reconstruction may be the best choice [8].

Basically, the flowchart for OP planning which we use in our practice takes into account both breast and tumor characteristics, and it is presented in Fig. 32.4.

32.6 Class I Techniques

32.6.1 Glandular Flaps

Class I techniques consists of moving glandular flaps around the defect caused by lumpectomies, in an attempt to cover it completely. It is preferentially indicated for premenopausal patients, when the glandular component of the breast is higher, therefore reducing the risks of liponecrosis in the postoperative period. This technique is also indicated in cases of tumors located in the upper quadrants, where the mammary gland is less thick; and even if there is a small filling defect, such a defect is not so visible. The opposite effect happens in the lower quadrants, where the mammary gland thickness is more evident and where adapted techniques are necessary. Glandular reshaping in lower portions of the breast is possible for small tumors and in a vertical or oblique way.

32.6.2 Central Quadrant Techniques

This represented a great innovation in early days of BCT, as up to some years ago having a retroareolar neoplasia was synonymous of mastectomy [17]. Immediate breast reconstruction techniques for central quadrant resections may vary according to breast volume, level of ptosis, and shape of ptosis (either vertical or lateral). Considering breast without ptosis or with slight ptosis, it is possible to use the glandular suture in tobacco pouch. Two or three layers of glandular suture in tobacco pouch allow for obtaining the central projection of the mammary cone, and the intradermal suture also in tobacco pouch would produce a residual scar within the area where the future NAC would be reconstructed, therefore causing the scar to disappear almost completely. The disadvantage of this technique is that there might be delay in the healing process. In medium- or large-size breasts with some degree of ptosis, it is possible to use Grisotti's technique, which is derived from the reduction mammoplasty techniques, with the rotation of infero-lateral glandular pedicle, preserving a coetaneous island that replaces NAC. This might be the first OP technique described in the literature, as it was a direct adaptation of plastic surgery technique to BCT [17]. For some large breasts, it is possible to do a reduction mammoplasty like Pitanguy's, but resecting the NAC.

32.7 Class II Techniques

The great diversity of mammoplasty techniques used in aesthetic surgery supports an increase in the indications of BCT. In most cases, reductive mammoplasties based on different pedicles can be transported to BCT. The level of mammary ptosis, differences of volume and shape detected in the preoperative stage, level of mammary liposubstitution, height, shape and size of the NAC, and mainly the size and location of the tumor are the most important factors to consider when choosing the technique of mammoplasty to be applied in BCT.

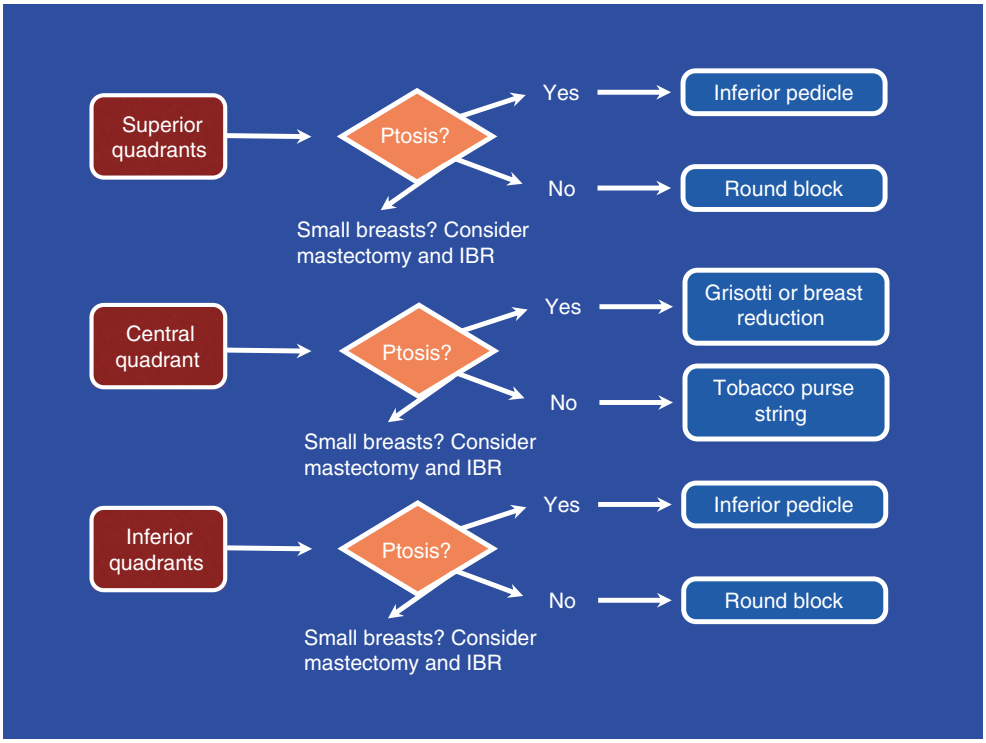

Fig. 32.4 Decision flowchart for Class II oncoplastic surgery in breast-conserving surgery

32.7.1 Periareolar Techniques

Class II techniques are inspired in reductive mammoplasty techniques proposed by Sampaio-Goes [33] and Benelli [34], in which a major glandular coetaneous undermining procedure for remodeling through a periareolar scar is performed. It is indicated for cases of non-ptotic (or with discrete ptosis) small- or medium-size breast. The great advantage of these techniques is that it allows lumpectomies in any part of the breast, except for the central quadrant.

32.7.2 Superior Pedicle Techniques

These techniques are based on superior vascular pedicles as those proposed by Pitanguy [35] and Lejour [36] in aesthetic surgery. They may be useful in cases of tumors situated in the lower quadrants and are appropriate for large and ptotic breasts or breasts medium size with some degree of ptosis. The decision whether perform only a vertical scar or an inverted "T" scar will depend on the level of hypertrophy and the level of ptosis. Considering smaller breasts and those with less ptosis, it is possible to perform only a vertical scar, and considering cases of larger breasts with a major ptosis, an inverted "T" scar will avoid the cutaneous excess. The format of the scar as vertical or inverted "T" can be central (more frequent), medial, or lateral, according to the location of the tumor and the need for skin removal.

32.7.3 Inferior Pedicle Techniques

These techniques are based on inferior-posterior vascular pedicles, as described by Ribeiro and Robbins, and they may be applied in cases of tumors situated in the upper quadrants of the breast [37, 38]. The preoperative drawing can be made in the same way and using measurements of Pitanguy's and Lejour's techniques, with a periareolar scar and inverted "T" or vertical/oblique inferior line. This is one of the most useful techniques, as there are many tumors in superior quadrants.

Conclusions

Surgeons play an influential role in the care of the breast cancer patient. OP allows for an oncologic-aesthetic-functional individualized surgical approach. Such an advance means a new philosophy in breast cancer surgery. It also brings new challenges for mentoring and training new generations of surgeons and opens new perspectives of research related to aesthetic results, quality of life, and local control of disease, as well as optimization of operative timing and reduction of both complications and costs. Finally, OP expertise is resulting in a higher standard of care for breast cancer patients.

Delayed Breast Reconstruction

33

Cicero Urban and Flavia Kuroda

33.1 Introduction

Delayed breast reconstruction is thought to be the first technique for restoring the physical integrity after mastectomy. Until some decades ago, breast reconstruction could not be performed until 2 or even 5 years after conclusion of oncologic treatment [1, 2]. Today, immediate breast reconstruction can be indicated for most breast cancer patients, but unfortunately the majority of them remain without their breasts. And there are different well-documented reasons for that, such as disparities related to race, sociodemographic factors, and financial and some cultural barriers. Then, delayed breast reconstruction is an option for many patients [3, 4].

Implants and autologous reconstructions are the most important options. Indications for them depend on patient's anatomy, previous radiotherapy, or patient's preferences. Both magnitude of the procedure in terms of invasiveness and morbidity in each individual case are important points to consider. Implant-based breast reconstruction is notable for its surgical simplicity, applicability, and faster recovery time, but it is not allowed in all cases [5]. Despite of that, there are some limitations for such an approach, like previous radiotherapy or Halsted's mastectomy. It is also important to take into account patient's expectations in order to better individualize the decisions.

So, the aim of this chapter was to cover the indications, preoperative evaluation, operative techniques, and complications related to delayed breast reconstruction.

33.2 Indications and Selection of Patients

33.2.1 Timing of Reconstruction

Delayed breast reconstruction can happen at any time, given that the wound has healed and adjuvant therapy has been already completed. But postradiation acute skin lesions and hematologic effects of chemotherapy should be completely ceased [6]. At the *Hospital Nossa Senhora das Graças* Breast Unit in Curitiba (Brazil), the routine is waited at least 6 months after the conclusion of adjuvant radiotherapy and 30–40 days after the end of chemotherapy. Different from the immediate approach, the delayed one can be indicated even for patients who had impaired perfusion of skin flaps after mastectomy [7]. Therefore, it is useful to be clear for patients who suffer from some medical comorbidities such as active smoking, diabetes, obesity, or cardiopulmonary disease that these conditions might predispose to some additional risks.

Delayed breast reconstructions have some facilities regarding the immediate ones because adjuvant treatment is already concluded. Moreover, there are series demonstrating that delayed has fewer complications [8]. However, the technique might entail other surgeries in order to ameliorate aesthetics, thus prolonging the overall time of treatment for patients, because it provides less cosmetic quality than the immediate reconstruction [7]. Furthermore, delayed reconstruction has limited reconstructive options following radiation therapy.

33.2.2 Implant-Based or Autologous Techniques

Delayed breast reconstructions can be implant-based or autologous-flap-based ones. The first technique involves the use of silicone-filled or saline-filled implants and definitive or temporary expanders beneath the remaining mastectomy skin flaps and the pectoralis major muscle, whereas the autologous reconstructions use musculocutaneous flaps, which consist of a segment of vascularized muscle with the overlying skin

U. Veronesi et al. (eds.), *Breast Cancer*, DOI 10.1007/978-3-319-48848-6_33

and fat, which are perfused by perforating vessels from the underlying muscle. It can be with pedicle or free flaps, and sometimes it is also necessary the association of an implant for better volume and projection, as it is the case with latissimus dorsi flap. While for some patients the overall result is more pleasing with musculocutaneous flaps [3, 4, 7], there are some disadvantages, which include longer surgical length and prolonged postoperative recovery when compared to implant-based reconstructions. In Fig. 33.3 there is a nice example of this, in a patient with previous breast cancer and radiotherapy in the thoracic wall and neurofibromatosis. Moreover, with implants there is no donor-site morbidity, reduced operative time, and more rapid postoperative recovery when compared to autologous reconstructions [9, 10]. In addition, with the new generation of breast implants, particularly the anatomical ones, it is possible to achieve good aesthetic outcomes and high rates of patient's satisfaction [20].

33.2.3 Definitive Implants or Temporary Expanders

In patients who were not previously irradiated, the choice of the most appropriate technique requires some specific preoperatory clinical evaluations: skin and musculocutaneous conditions in the mastectomy flap, size and ptosis of the contralateral breast, and patient's expectations about her breast reconstruction. For instance, the complete absence of the pectoralis muscles due to Halsted's mastectomy is a contraindication to this approach [11, 12]. Using a definitive form-stable implant rather than a temporary expander is not frequent in delayed reconstructions. The ideal patient for this approach should have a non-tense cutaneous flaps, a good quality of her pectoralis major muscle, and a small contralateral breast.

The tissue expansion with a temporary expander before to change to a definitive form-stable implant is the most frequent indication for delayed breast reconstruction for non-irradiated patients—the two-stage techniques. The expander is used to distend the cutaneous flaps in order to facilitate the insertion of definitive form-stable implant in a second surgery. The choice of the temporary expander is in a similar way of the definitive ones—basis, height, and desired volume should be considered. Older patients, those with significant medical comorbidities, and women with minimal abdominal tissue in whom the autologous technique would be unsuitable also benefit from this technique. Besides, the expander/implant technique is to be indicated for those patients devoid of sufficient skin or preserved subcutaneous tissue in flaps resulting from mastectomy. This may occur when there is little elasticity of the cutaneous flaps from mastectomy or in the case of a contralateral breast presenting a rather large volume. In these situations, the two-stage implant reconstruction usually yields aesthetically superior outcomes.

There are some cases where two-stage approach is contraindicated, and they are basically the same ones as those for definitive implants, with even more emphasis on the risk of expanders after radiotherapy [13]. Many authors have realized that several postoperative complications can ensue when attempting to distend previously irradiated tissues [13–16], since the radiation decreases the tissue elastic distension capacity. In these cases, the most frequent complications are painful and difficult expansion with possible extrusion of the expansion device or periprosthetic capsule. Even though one achieves the final stage of expansion, the cutaneous coverage of the prosthesis becomes too thin and fragile to protect the definitive implant. Recently, the addition of lipofilling in breast reconstruction armamentarium is allowing to expand irradiated tissues in selected cases, but it is necessary to have more data in this specific approach.

A practical flowchart for decisions in delayed breast reconstruction is shown in Fig. 33.1.

33.3 Preoperative Evaluation

The aim of breast reconstruction is to obtain symmetry [17, 18]. For this reason, it is essential to carry out a preoperative plan that includes a detailed analysis of the healthy breast's characteristics in order to make the correct choice of the most suitable technique to reconstruct the other breast [19]. It is important to remember that the reconstructed breast, most of the times, will have low projection in the upper pole and no ptosis. With these characteristics in mind, the contralateral breast should be planned to have an intervention for symmetry in the same surgery or in a second one (after the change of the temporary expander for a definitive implant).

Clinical and radiologic preoperative evaluations are crucial in order to clarify the patient's risks for the surgery. Diabetes, hypertension, obesity, and tobacco-using patients have higher risks for bad aesthetic outcomes and for implant or expander's extrusions. It is also important that a detailed oncologic evaluation be performed, surveying the following topics of the past treatment: type, localization, and size of tumor; number of positive lymph nodes; type of surgical procedure performed; chemotherapy; radiotherapy; hormone therapy; follow-up period; and the most recently performed radiologic and blood exams. Furthermore, the evaluation of the contralateral breast is also mandatory in order to exclude bilateral neoplasm and should include mammographic and ultrasound exams. In high-risk patients with hereditary breast cancer syndromes such as BRCA 1/2 mutations, it is necessary to add breast MRI. These exams are important because contralateral breast surgery—a reduction mammoplasty, mastopexy, or augmentation mammoplasty—is frequently required to obtain a more pleasing symmetry.

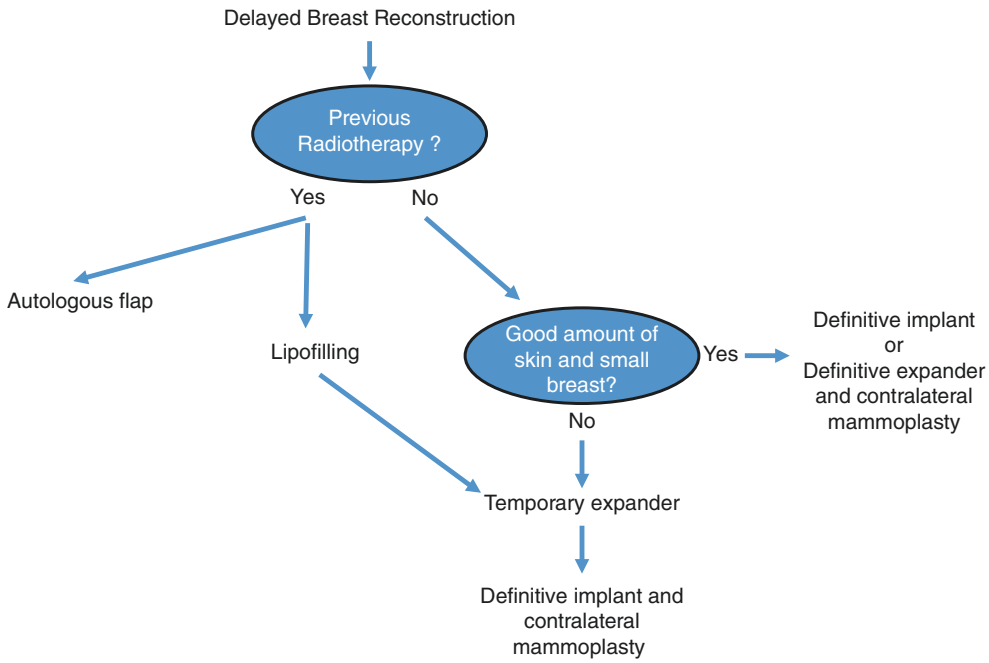

Fig. 33.1 A practical flowchart to guide decisions in delayed breast reconstruction

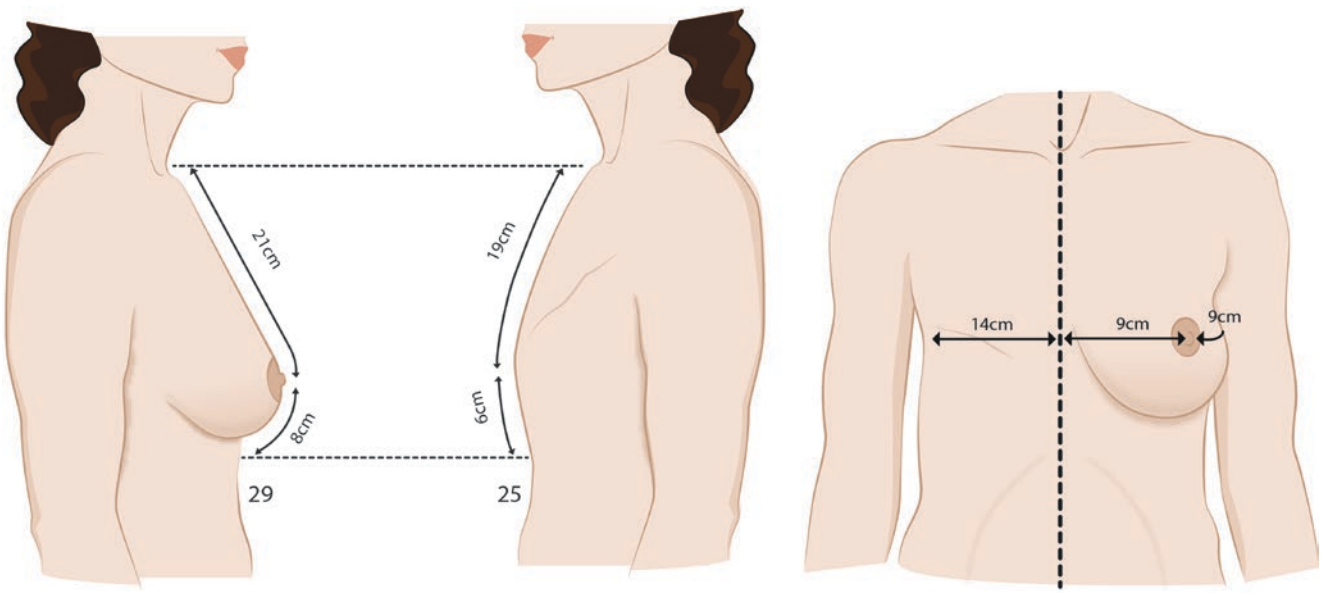

Fig. 33.2 Pre-operatory measurements for surgical planning and choice of the expander and implant

33.4 The Day Before the Operation

In the day before the operation, the whole procedure is explained to the patient again, and then the informed consent form is obtained. The patient is then placed standing, and photographs are taken in profile, in partial profile, and in forward-facing position. It is useful to make precise measurements of the contralateral breast in this occasion, such as base width, thickness of subcutaneous adipose tissue, and height as well as anterior projection (Fig. 33.2).

33.4.1 Choosing the Correct Expander and Implant

Concerning the decision as to which implant one should use, it is important to compare the contralateral breast with the future implant with regard to the parameters of base, height, and anterior projection. This is done during the preoperative period in order to choose two or even more models and sizes of implants that are most likely to be used during the surgical procedure. The final decision can be

made at the intraoperative stage, sometimes with the help of samples. Surgeons should pay attention to whether samples are prohibited in the country they work in. In Brazil there are some specific norms for that, and at the European Union, for instance, the re-sterilization of samples is strictly forbidden. Nevertheless, the non-sterilized implants can be thoroughly coated with a highly adherent and resistant sterile plastic envelope, therefore permitting their repeated usage. This technique for choosing the implants based on the aforementioned measures is precise and particularly useful in the cases in which it is necessary to use an expander/implant and, subsequently, perform a contralateral augmentation mammoplasty [20–22]. In cases of definitive implants with mastopexy or reduction mammoplasty in the contralateral breast, the decision as to the type and volume of the implant must also take in account the volume reduction, the change of shape, and the reduction of the breast base. These calculations can be based on augmentation mammoplasty papers [23, 24], which employ these methods to calculate the volume and shape of implants for aesthetic improvement, on samples, and in surgeon's personal experience (Figs. 33.3, 33.4, 33.5, and 33.6).

Fig. 33.6 Final outcome after definitive anatomical implant in the right breast and contralateral mammoplasty

33.4.2 Surgical Markings

Afterward, lines are drawn on the patient's chest to assure the correct understanding of the anatomic conditions. There should be drawn a median line from the sternal notch to the xiphoid appendix, and the inframammary fold should be placed at the same height and shape of the contralateral breast.

33.5 Surgical Technique

33.5.1 Before Skin Incision

In the operating room, patient is placed in supine position, keeping her arms parallel to the trunk. The operating table must be set in a way the patient can be placed in a 90-degree position, i.e., sitting, at the end of the procedure.

33.5.2 Skin Incision and Scar Excision

In cases of autologous flap delayed reconstruction, it is possible to remove part of the mastectomy flap, in order to replace that for the flap's skin and to shape the new breast. But with implants, the incision should be most of the times in the preceding mastectomy scar and, if possible, in the pectoralis major muscle. This technical detail allows for a safer suture of the prosthetic pocket in two layers, namely, the muscular and the cutaneous layers. Incision with either partial or complete removal of the scar is chosen based on three clinical situations:

- Wide scar with a good amount of skin in the mastectomy flap—in this case the exeresis of the scar is indicated.
- Narrow scar with little tense flap—here it is not necessary to remove the scar.
- Wide scars without much skin when it has already been decided to use an expander—scar can be removed completely or almost completely but extra care must be taken when expansion is performed, as a too sudden distension could widen the scar again.

33.5.3 Operative Technique

Autologous flap reconstruction is described in other chapters in this book. After incising the skin, an inferior and lateral subcutaneous undermining must be performed in order to do the contour of the inframammary fold. This is required to set the prosthetic pocket, which can be located subcutaneously in this region or under the serratus muscle, in case the skin or the adipose subcutaneous tissue in the inferior lateral region is too fragile. As a result of this maneuver, one can see the lateral edge of the pectoralis major muscle, which is then lifted to set the submuscular pocket. This pocket can be made via a digital undermining in the upper portion, where no perforating vessels are found. In the inferior and medial regions, a light retractor is required so that the efficient hemostasis of large internal mammary pedicles found in this region is performed. The pectoralis major muscle then must be completely detached from the costal plan about 4 or 5 cm above the medial extremity of the inframammary fold. This dissecting procedure is mandatory so that a nonaesthetic movement of the implant can be prevented when the pectoralis major muscle contracts. Preparation of the inframammary fold demands great technical attention, as it is an anatomic landmark crucial to the long-term aesthetic result [5]. There are two possible variants:

- Without an upper abdominal skin flap—It is used in cases either when there is great elasticity of the skin, which allows the insertion of a definitive prosthesis, or, if a decision has been made for a reconstruction in two surgical steps, of a temporary expander. In such cases, the subpectoral dissection must reach no more than the inframammary fold level, and then an incision into the aponeurosis of the rectus abdominis muscle must be performed to achieve a better projection of the lower mammary pole. There is no need for an undermining maneuver lower than the projection of the inframammary fold; otherwise, the prosthesis might end up being placed below the inframammary crease, producing asymmetry.
- Using an upper abdominal skin flap—This autogenous tissue reconstruction technique is recommended for those cases in which a definitive implant is applied and the skin flaps from mastectomy are not very elastic. A rectus abdominis muscle aponeurosis (made according to the projection of the inframammary fold) can be used if there is good elasticity of the skin in the upper abdominal area (just below the inframammary fold). The subpectoral dissection must reach the inframammary fold level followed by incision of the undermining of the supra-aponeurotic region 2–3 cm below the inframammary fold. A cutaneous advancement flap can be easily performed if the patient is placed in a semi-sitting position. The inframammary fold is reconstructed with spread stitches of nonabsorbable thread, suturing the superficial aponeurosis at the upper limit of the aponeurosis of the rectus abdominis muscle medially and laterally at the serratus muscle.

After the prosthetic pocket is set up, an internal irrigation is performed with either pure or with an antiseptic product-added saline solution. At this point, rigorous skin cleaning and change of gloves of the whole team before contact with the implant is mandatory. Such care helps to reduce the risk of microcontamination of the implants and therefore reduces the risk of postoperative infection or the formation and development of a peri-prosthetic capsule [25]. The implant, i.e., either the definitive implant or temporary expander, is carefully inserted into the prosthetic pocket.

Finally, a tubular multiperforated aspirating drain is inserted into the prosthetic pocket as a safety measure. Then, suture is done in two plans. The first suture is done in the subcutaneous tissue with absorbable monofilament stitches of 3-0, and the second is an intradermal cutaneous suture with absorbable monofilament stitches of 4-0.

33.6 Post-Operatory Care

Some surgeons apply a dressing with elastic straps, making a moderate compression for 3 days. Others choose a lighter dressing with no compression and also advise the patient to

wear a sports-type bra, medium compression, right on the first postoperative day. This second option allows an easier control of a possible postoperative hematoma and avoids risks of allergy and cutaneous lesions that might occur when adhesive elastic straps are used. The drain is removed when the drained fluid is serous and its volume is lower than 50 cc in the past 24 h. If a temporary expander is chosen, an expansion with a variable volume of saline solution is the usually recommended each 3 weeks. The correctly instilled volume should not cause tightness or erythema or disrupt the patient's comfort or skin quality. As the aim of the expansion is to surpass the quality of a one-stage definitive implant, an augmentation of 25% is needed to achieve this purpose, with ideal skin drape and recoil [5].

33.7 Association with Fasciocutaneous Thoracodorsal Flap

This technique was initially described by Holmstrom [10], who advocates the use of a rotational fasciocutaneous thoracic dorsal flap to improve the projection of the lower pole of the reconstructed breast. This technique can be applied in those cases of an oblique mastectomy scar, and the graft must be grounded on epigastric vascular pedicles, which cross the anterior aponeurosis of the rectus abdominis muscle. The flap must be designed with two thirds of the base above the future inframammary fold and a third below. After the preparation of the fasciocutaneous flap, an upper rotation of the flap is performed, and the donor zone is covered with the inferior rotation of the lateral triangular flap together with the advancing of the upper abdominal skin flap. The implant is inserted below the pectoralis major muscle in the upper internal region and below the flap in the inferior lateral region. This technique is not routine due to the vascular fragility of the flap. It can be used when applying more complex techniques such as when the latissimus dorsi or the transverse rectus abdominis myocutaneous (TRAM) flaps are contraindicated.

33.8 Complications

Complications related to breast reconstruction of any type can be classified into immediate (until 2 months after the surgery) or secondary (after the aforementioned period) [5]. The most frequent complications comprise hematomas, seromas, infection, flap necrosis, and capsular contracture. Capsular contracture rates may be lessened by the use of implants with a textured shell rather than a smooth shell, by placement of the implant in a submuscular rather than subcutaneous location, and by avoiding the use of this technique in women who need radiotherapy [26, 27]. Obesity, diabetes, age older than 65, smoking, and hypertension are risk factors for complications following breast reconstructions [28, 29].

Conclusions

Delayed breast reconstruction can achieve satisfactory cosmetic outcomes with low rate of complications. Temporary expanders and implants are surgical procedures that represent minor risks and, sometimes, can even be performed under day surgery. Overall, this is the most used technique due to its practicability, lower risk of complications than musculocutaneous flaps, and satisfactory aesthetic outcomes with the various anatomic implants available nowadays. Patients who were previously irradiated are better for autologous flaps or lipofilling.

Immediate Breast Reconstruction (Direct to Implant)

34

Mario Rietjens, Pietro Loschi,
and Leonardo Pires Novais Dias

34.1 Introduction

The treatment of breast cancer until the late nineteenth and beginning of twentieth century was highly mutilating for the patients, in order to have some possibility of cure [1]. The standard surgery, at that time, removed large amounts of skin and thoracic muscles [2], combined aggressive radiotherapy, and determined a significant tissue degradation. With all these sequelae due to the treatment, it was practically impossible to propose any type of technique for breast reconstruction. The evolution of our biological knowledge of the breast cancer [3, 4], in association with screening programs all around the world, provided an initial phase diagnosis [5–10] and consequently concedes a de-escalation of the mutilating treatment [11–21]. These factors contributed to preserve the patient's quality of life [22–24].

The development of a non-mutilating mastectomy, as skin-sparing mastectomy or nipple-sparing mastectomy, was the main factor to evolve indications of direct-to-implant reconstructions (DTIRs) [14, 15, 17, 18, 20, 21, 25–44]. The conservative mastectomy represents the main step on surgical technique by preserving more overall skin and surface area to place an implant and by helping to avoid some of the flattening associated with closure of skin-sparing incisions [30, 40, 41].

The implantable devices evolution was also very crucial to increase indications to DTIR. The first breast silicone implant was used in 1960, and since then, the medical industry invested massively on research and innovations, and the surgeon today has an arsenal of possibilities to use, especially prosthesis and meshes. There were improvements on several points: less capsule contracture, more resistant and durable materials, and better cosmetic results concerning the anatomical implants with different models, shapes, and dimensions [1, 28, 39–41, 44–62].

The aim of this chapter is to give an overview about patients and implant selections in cases of DTIR, focusing in surgical planning, technical aspects, and complication management.

34.1.1 Indications

The technique indications are related to two main variables: breast anatomy (volume and shape) and tumor characteristics (size, local extension, and muscles or skin infiltration) [17, 19, 63–68]. Following the patient individuality, different patterns of mastectomy can be applied.

34.1.1.1 Small or Medium Breasts

Nipple-sparing mastectomy: in cases of breast with minimal ptosis, small peripherally located tumors with nipple-areola complex distance >2 cm, and negative subareolar duct margins. In selected cases, larger tumors can be submitted. Contraindicated in patients with inflammatory breast cancer, clinical involvement of the nipple-areola complex, nipple retraction, Paget disease, bloody nipple discharge, or multicentricity (Fig. 34.1).

Skin-sparing mastectomy: in cases of tumors closer to the nipple-areola complex, positive subareolar duct margins and previous scars that compromise the nipple-areola complex blood supply. On this last situation, the nipple-areola complex graft can be performed after the intraoperative subareolar duct evaluation. Contraindicated in patients with inflammatory breast cancer and extensive skin involvement by tumor (Fig. 34.2).

34.1.1.2 Large Breast

Conventional total mastectomy: in cases of large breast with ptosis grade III or IV and large tumors near the skin. It is possible to remove a large amount of skin over the tumor and have enough skin to perform a DTIR (Fig. 34.3).

Fig. 34.3 Preoperative drawings for total mastectomy removing large amount of skin over the tumor located in the upper outer quadrant

Fig. 34.4 Preoperative drawings for a left skin-reducing mastectomy with a modified "Wise pattern"

Wise pattern mastectomy: in cases of large breast with ptosis grade up to II (moderate). It is possible to remove an amount of skin in order to have an adequate skin envelope to cover the implant. Contraindicated in patients with inflammatory breast cancer and extensive skin involvement by tumor (Fig. 34.4).

Skin-reducing mastectomy: in cases of large breast with ptosis grade III or IV (advanced or severe, respectively). It is possible to reduce the amount of the skin envelope with a lower pole skin deepithelialization and use the dermis to help the implant cover. Contraindicated in patients with inflammatory breast cancer and extensive skin involvement by tumor (Fig. 34.4).

34.1.1.3 Relative Contraindications

Advanced disease (stage III or higher)
Need for postmastectomy radiotherapy
Significant medical comorbidities such as active smoking, obesity, or cardiopulmonary disease

34.1.2 Planning

Optimal management requires a multidisciplinary approach between oncologic and reconstructive surgeons, radiologists, pathologists, medical oncologists, nurses, and physiotherapists. This allows providers to coordinate cancer and reconstructive procedures with postoperative recovery and adjuvant treatment. Also, the oncological multimodality access has been associated with a reduction in breast cancer

mortality [69]. A caring relationship is crucial to patient satisfaction with the reconstructive process and must be established early [70]. Therefore, it is important to embrace the patient with all endearment since the first interview. In-hospital is highly recommended to examine the patient the day before the operation and explain again the complete surgical procedure in order to have the patient's consensus.

34.1.2.1 Preoperative Evaluation

History and physical assessment should focus on the following factors: stage disease, oncologic treatment plan, past surgical history, comorbidities, volume and shape of contralateral breast, body habitus, smoking story, and potential donor sites for autologous reconstruction.

A past medical history of radiotherapy on the same site or current disease extent for which radiotherapy is mandatory influences reconstructive options. Radiotherapy leads to fibrosis, which compromises the quality of the skin and underlying tissue, resulting in a higher incidence of complications from the reconstructive procedure, and may produce a less esthetically pleasing result [28–31, 59, 71–80].

Comorbidities such as obesity [31, 53, 59, 76, 81, 82], insulin-dependent diabetes mellitus [53, 76, 82], chronic obstructive pulmonary disease, smoking [31, 53, 59, 76, 81–83], and connective tissue disease may impact also the patient's reconstructive options. When poorly controlled, these comorbidities may increase the risk for complications such as impaired wound healing, reduced tissue perfusion, and infection [76, 84]. In addition, past surgical history of coronary artery bypass grafting (with use of internal mammary vessels) may limit reconstructive choices because of their adverse effects on the breast tissue blood supply.

Tobacco use also poses significant risks [31, 53, 59, 76, 81–83]. Due to the nicotine effect, as well as generalized tissue hypoxia as a result of carbon monoxide, this can increase the risks of tissue necrosis, delayed healing, and infection [85, 86]. For these reasons, avoidance of smoking is recommended for at least 4 weeks prior to surgery and 2 weeks following surgery.

The physical examination of the breasts includes an evaluation for volume, ptosis, asymmetry, scars, and the axilla examined for palpably abnormal lymph nodes. The abdomen and back are evaluated, taking note of scars and patient's personal distribution of excess skin and fat. Technical details such as the type of incisions following the oncological and plastic goals and the need of a contralateral breast correction are also determined at this moment. The patient's wishes regarding scar location, tissue sacrifice, postoperative recovery, and esthetic outcome are also important in guiding the reconstructive surgeon. Finally, the evaluation of bilateral mammograms, bilateral breast and axilla ultrasound, and, in specific cases, breast magnetic resonance is also indispensable.

Photographs of the patient standing and preoperative drawings are performed after admission at the hospital. During the preoperative drawings, it is important to do specific breast measurements as base width and height, projection, and pinch test (to evaluate the skin and subcutaneous thickness). With all these parameters, it is possible to calculate the range of models and implant size to be used.

34.1.2.2 Intraoperative Evaluation

The initial evaluation consists of verifying the skin and muscles integrity, soft tissue blood supply, and inframammary fold preservation. The implant is chosen using preoperative measurements, mastectomy weight, and contralateral breast modifications (reduction or breast augmentation). The use of sterile sizers is helpful to select the best implant aiming good symmetry.

The advent of real-time perfusion mapping and similar technologies represents an important aid for intraoperative planning. Some models predicting the risk for mastectomy flap necrosis have surfaced [87]. Although simple in concept, the surgeon's intraoperative judgment may be one of the more challenging aspects of DTIR and should be a focus of the perioperative decision-making process [29, 31, 88–90]. The unpredictable nature of the defect after oncologic resection is a particularly limiting factor, as implant size depends on the available soft tissue envelope.

In cases of soft tissue commitment and impossibility to perform the programmed surgery, the surgeon can convert it into a two-step reconstruction, using a tissue expander. In these cases, it is not recommended to perform the contralateral breast symmetry. A new evaluation will be done at the end of the expander inflation, and the surgery must be integrated with the timing of oncological treatment.

34.2 Implant Pockets

Until some years ago, I did not recommend the insertion of definitive prosthesis in the same location of the removed breast. The complication rates are very high, and if, unluckily, a small skin necrosi arrives or a scar dehiscence emerges, an exposure of the implant can occur, and the implant removal is necessary. Even if there are no postoperative complications, the normal healing around the implant with the capsule formation gives a very bad cosmetic results, with an aspect of "ball attach to the thorax" with an unpleasant aspect.

Nowadays, different possibilities of implant pockets are available, due to the new materials evolution [43, 91].

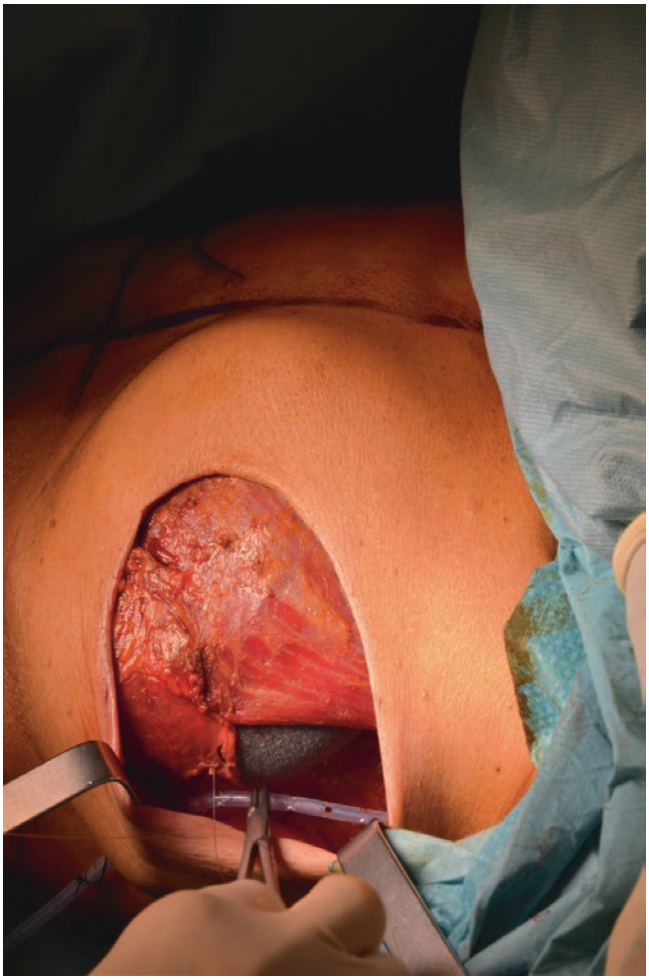

Fig. 34.5 Complete muscular pocket with pectoralis major muscle and serratus muscle

34.2.1 Total Muscular Pocket (Pectoralis Major and Serratus)

It was the first technique used in the past, when the mastectomy was less conservative. With this technique it was possible to cover completely the implant and avoid implant exposition in cases of skin necrosis. The cosmetic results were quite good when using small and round-shaped implants, but in cases of medium or large anatomical implants, it is difficult to cover completely the implant, and the cosmetic results are inferior because the lateral breast shape is compressed by the serratus muscle (Fig. 34.5).

34.2.2 Partial Muscular Pocket (Pectoralis Major)

This technique can be applied with safety in cases with a good lateral skin flap and when is possible to put all the mastectomy scar over the pectoralis major muscle, that one may have a good protection in cases of small skin necrosis or dehiscence. It is a very simple and quick technique and allows good results with anatomical or round implants. If the serratus muscle fascia is preserved during the mastectomy, it is also helpful to use it to cover partially the implant and avoid implant displacement, since it is the path of least resistance (Fig. 34.6).

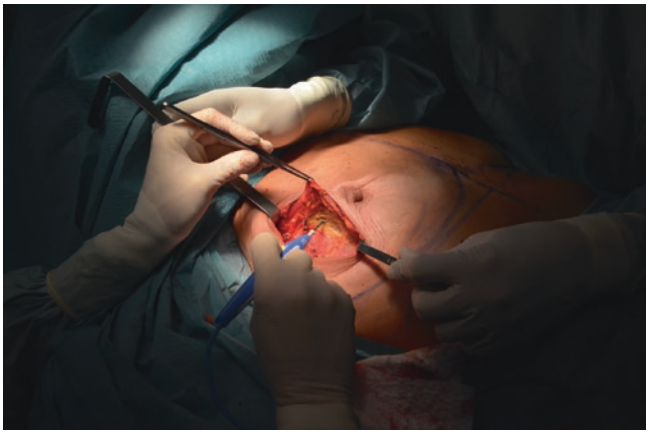

Fig. 34.6 Partial muscular pocket with only the pectoralis major muscle

34.2.3 Pectoralis Major Muscle and Synthetic Meshes

It is normally used in the outer lower portion of the breast, fixed to the lateral margin of the pectoralis major muscle and in the inframammary fold. The main indication of this material is mechanic, to maintain the implant at position and reduce the pectoralis major muscle retraction. The major problem with this material is the increase incidence of postoperative complications. The synthetic mesh is a low-cost alternative to biological matrices [35, 36, 39, 52, 57].

34.2.4 Pectoralis Major Muscle and Biological Meshes

The biological mesh is a collagen tissue matrix from which cell debris, DNA, and RNA are removed by complex proprietary process, leaving behind an acellular matrix [92]. This immunologically inert biological implant serves as scaffold necessary for tissue ingrowth, angiogenesis, and regeneration and can be integrated completely in few weeks. It is normally used in the outer lower portion of the breast, fixed to the lateral margin of the pectoralis major muscle and "wrapped" over the implant, not fixed to the inframammary fold. The major goal is to create a new tissue surface to cover the implant and reinforce the thickness in the outer lower portion of the breast [34, 53, 55, 61, 93, 94]. The material is

Fig. 34.7 Mixed pocket with pectoralis major muscle and ADM in lower outer quadrant

still very expensive [95, 96], and in our institute, the main indications are in cases with previous radiotherapy or complete inferior detachment of the pectoralis major muscle and rectus abdominis fascia. Using these material in these indications, it is possible to avoid a muscular flap, and it is also possible to reduce the capsule contracture after an implant breast reconstruction in cases with previous radiotherapy [55, 59, 61, 62, 97, 98] (Fig. 34.7).

A recent meta-analysis demonstrated that the risk of implant loss was not significantly affected by whether or not ADM was used. This result may be surprising given that the risk of infection, seroma, and mastectomy flap necrosis were significantly elevated in the ADM cohort. Although the use of ADM raises the risk of other complications including infection, they may not be that serious and can be clinically controlled without causing the implant removal [61].

34.2.5 Only Biological Mesh

Recent developments of this new technique showed that it is possible to do a breast reconstruction with implant without any muscle. The implant is completely covered with the biological mesh and implanted in the subcutaneous space. The cost is still very expensive and remains the main problem with this kind of technique [99, 100] (Fig. 34.8).

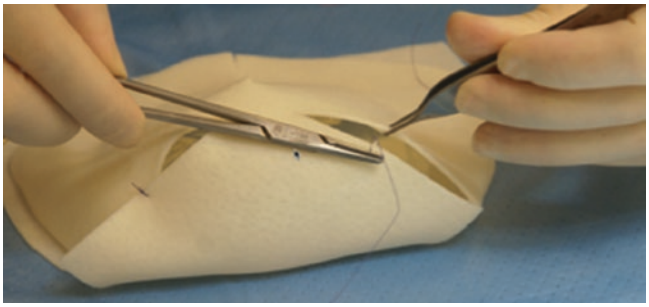

Fig. 34.8 Braxton® device consists in an ADM pocket with the implant inside, and it will be positioned in the subcutaneous space

34.3 Contralateral Breast Management

The goal of DTIR is an immediate reconstruction with definitive implant avoiding a second operation [1, 40]. For this reason, a contralateral breast mastoplasty is necessary in order to get an optimal symmetry [101–104] (Figs. 34.9, 34.10, 34.11, and 34.12). There are four main options for the contralateral breast.

34.3.1 Mastopexy

The DTIR allows a reconstructed breast without ptosis; for this reason, the contralateral ptosis should be corrected in order to get a good symmetry. Several techniques are available depending on the ptosis degree.

34.3.2 Reduction Mammoplasty

The DTIR is limited for the size of the breast to be reconstructed, because the maximum breast implant size available is around 700 cc. For this reason, in cases of large contralateral breast, a reduction mammaplasty should be performed in order to get a good symmetry. Several techniques are available depending on the breast shape, dimension, and ptotic degree.

34.3.3 Breast Augmentation

This technique is proposed for patients with small breasts and desiring a breast augmentation. The implant used is

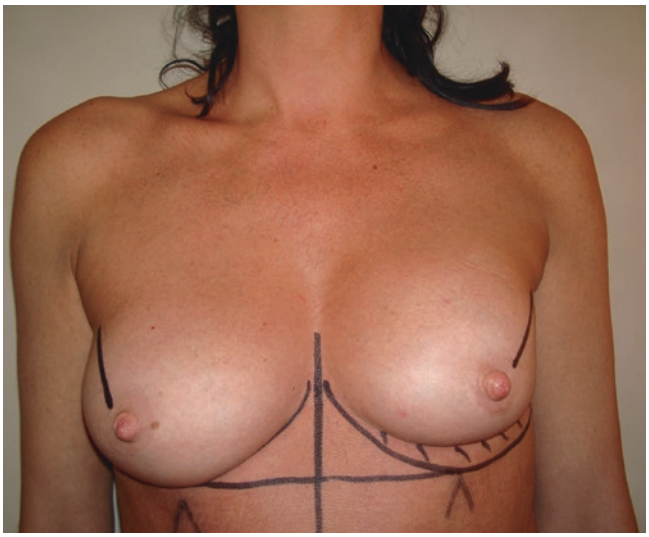

Fig. 34.9 Preoperative drawings for a bilateral nipple-sparing mastectomy with a radial incision and a DTIR

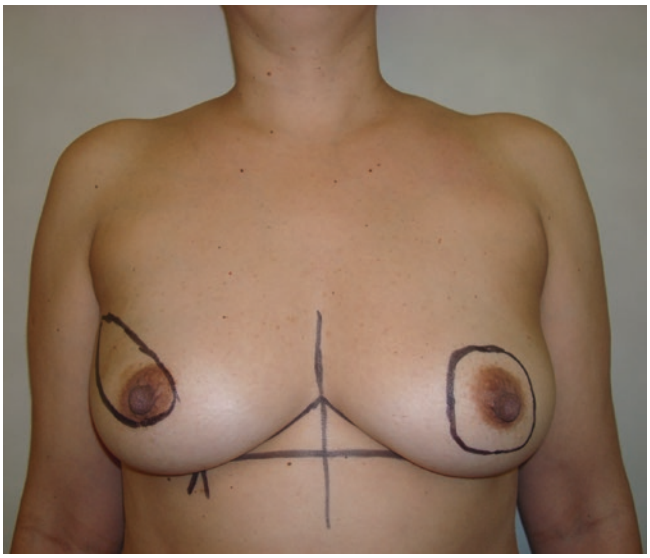

Fig. 34.11 Preoperative drawings for a right total mastectomy and DTIR and left periareolar mastopexy.

Fig. 34.10 Final results after 6 months

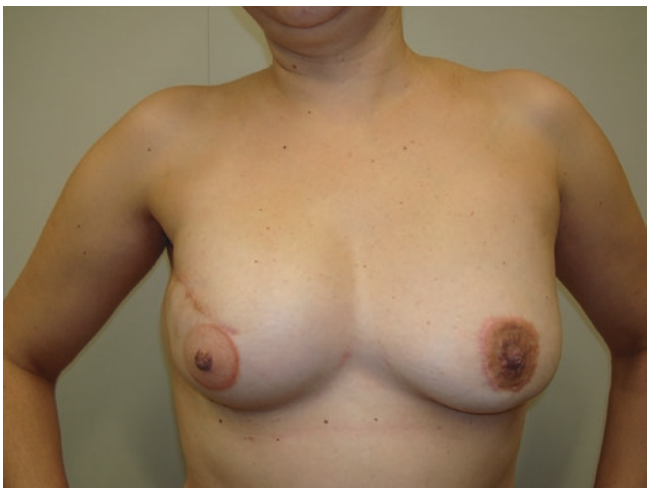

Fig. 34.12 Final results after 12 months.

frequently as a round-shaped implant positioned under the glandular tissue or under the pectoralis major muscle (dual plane technique).

34.3.4 Prophylactic Contralateral Mastectomy

This technique increased the indications in the last years after the possibility to diagnose a breast cancer familiarity with BRCA 1 and 2 genetic test [105]. Using the same technique and the same implant size and shape in both breasts, the breast symmetry is frequently optimal [106].

34.4 Technical Aspects

34.4.1 Cleaning and Arm Reposition

Once the mastectomy is finished, the skin is cleaned once again with chlorhexidine [107], and new sterile drapes are placed on top of the original ones. The arms are positioned along the body on arm boards, in order to promote a pectoralis major relaxation.

34.4.2 Skin and Muscle Evaluation After Mastectomy

The two main points are the coverage capacity, allowing the junction of tissue flaps without excessive tension on the suture, and the vascular supply of the mastectomy flaps that is evaluated by soft tissue thickness, color, and bleeding.

34.4.3 Pocket Dissection

The pectoralis muscle is elevated with a light retractor from lateral to medial; the lower muscle attachment is released with electrocautery from approximately 4–8 o'clock, preserving the rectus abdominis fascia, which is essential to have a complete pocket. The inferior dissection is performed until the inframammary fold level. The lower outer pocket dissection depends on the technical choice; the implant can be positioned subcutaneously, under the serratus fascia or under the serratus muscle.

34.4.4 Cleaning and Draining

The skin is cleaned once again with chlorhexidine, and internal pocket is irrigated with povidone solution [108]. One or two drains are inserted: one drain is in the submuscular pocket and, in cases of axillar lymphadenectomy, a second drain is placed in the subcutaneous space and axilla.

34.4.5 Implant Insertion

The operative team is also structured, so that there are no changes of surgical scrub technicians once the implant is opened until it is inserted in the breast pocket. The gloves are changed; only one surgeon handles the prosthesis and the implant is placed. The pocket is closed using monocryl 3.0 sutures.

34.4.6 Skin Closure and Dressings

The skin edges are trimmed and the skin is closed in layers with monocryl 3.0 and 4.0. Drains must be open at this time, to control the surgical site. Then Steri-Strips are positioned over suture site, and sterile gauze dressing is placed around the drains.

34.4.7 Post-op Cares

The patient stays in the hospital one or two nights. A sportif bra is placed prior to discharge from the hospital, after the prime dressing is pulled off, to help support the implant(s). Upon discharge, the drains, which are covered with and occlusive dressings, are maintained for 7–14 days, with removal determined by the amount and quality of their output, which should be less than 40 cc in 24 h.

34.4.8 Nipple and Areola Reconstruction

In cases of DTIR that the NAC was not preserved, the option of nipple-areolar reconstruction is proposed to the patients after 4 months. There are multiple techniques by which a nipple and areola can be recreated. Surgical methods involve local tissue rearrangement procedures or skin grafts [109]. These techniques are executed on day hospital, considering that it requires only local anesthesia. Once the projecting papilla has been created, the appearance of the entire nipple-areola complex can be enhanced by the use of tattooing. An alternative to surgical reconstruction of a nipple is three-dimensional tattoo. This is usually performed in a nonmedical setting by an experienced tattoo artist. The results have been excellent and patient satisfaction has been high.

34.5 Complication Management

34.5.1 Hematomas

It occurs usually in 1–5% [28, 29, 31, 55, 110] of the patients within 1–3 days after surgery. The symptoms are swelling of the breast and increasing pain that, sometimes, does not respond to pain reliefs. If the amount of blood is small, no treatment is required if the drains are still in place, but if the collection is moderate or large, a surgical revision is necessary to remove the coagulated blood, clean the cavity e insert new drains.

34.5.2 Skin Necrosis

The risk of skin necrosis is higher in DTIR compared with tissue expander reconstruction [37, 110, 111]. It occurs around 1.25–26% [28, 31, 55, 112]. Conservative wound care and a second intention healing can be used if the implant is completely covered by the muscles [82, 112]. In cases of skin necrosis with partial muscular pocket, the risk of implant exposure and an implant removal is very high. In these cases, the skin edge necrosis can often be managed with debridement and closure under local anesthesia. If the necrosis is more severe, the implant may need to be downsized or changed to a tissue expander [76, 83].

34.5.3 Seroma

34.5.3.1 Immediate

In the days following the surgery, fluid can collect around the implant, causing pain or swelling, if it is not adequately drained or if the drains are removed before the body can reabsorb the lymphatic fluid. It occurs in 1.5–7.5% of the cases [29, 31, 55, 56]. Removal of larger seromas is recommended since they can become infected. Usually, the fluid can be removed carefully with a puncture guided by an ultrasound and does not require additional surgery [56, 76].

34.5.3.2 Delayed

The etiology remains unclear; one supposed cause can be due to an internal tissue irritation with the textured implant surface in cases of an intense physical effort. Another possibility is a focal infection outside of the breast (oral, urinary, etc.) that can stimulate a fluid production around the implant. In cases of small seromas, only an oral therapy with antibiotics and anti-inflammatory for 10 days can solve the problem. Otherwise, in cases of large seromas, it is also necessary to aspirate the liquid to do bacterial analyses (antibiogram) and also cytology, for eventual diagnosis of anaplastic large cell lymphoma (ALCL) [113, 114]. In cases of frequent seroma recurrences, it is necessary to do an implant revision with large capsulectomy and implant change.

34.5.4 Infections

In cases of DTIR, it is around 1–5.2% of the cases [28, 29, 55, 115], and the most common organisms are *Staphylococcus aureus* and *Staphylococcus epidermidis* [115–117]. The main symptoms include pain, cellulitis, swelling, and fever. Initially, the treatment is based on oral antibiotics or, if the infection is severe, on intravenous antibiotics until the clinical and laboratory exams maintain stable for 48–72 h; then recommendation is return to oral antibiotics for 1–2 weeks more [76]. In severe cases, antibiogram is strongly suggested to guide the treatment. The presence of gram-negative rods or methicillin-resistant *Staphylococcus aureus* is relative contraindication to salvage attempts based on the poor success rate. The risk factors associated with postoperative infections after IBR are chemotherapy, smoking, radiation therapy, intraoperative lymph node dissection, and larger breast size [116]. In cases of severe infections, without positive response with antibiotics, the implant removal is indicated, clean and drain the breast, and reevaluate the local conditions after 4 months, in order to plan another breast reconstruction [76].

34.5.5 Implant Exposition

The implant exposition can be observed after skin necrosis or wound dehiscence. It occurs around 2% [28]. The decision to try to conserve the implant depends on the time between the exposition and medical evaluation (more time = more possibility of implant contamination) and the skin quality and elasticity or previous radiotherapy. A case with good local conditions and short time of exposition is indicated to make a debridement, new suture under local anesthesia, and antibiotic therapy. In the contrary, in cases with bad local conditions or previous radiotherapy and large time of exposition, the best solution is the implant removal and revaluation after 4 months for a new technique of breast reconstruction.

34.5.6 Implant Rotation

The main problem is due to a poor adhesion between the implant and the capsule, and the reasons can be thin capsula, periprosthetic fluids, or double capsulae. It occurs around 0.9% [55]. An implant surgical revision is indicated with a large capsulectomy to create a new adhesion area; try to close death spaces and also consider to change the anatomical implant with a round-shaped implant.

34.5.7 Capsular Contracture

This is the main long-term problem after implant surgery, and the rates are very different in the literature [28, 29, 55, 56]. The characteristics are pain, hardness, and changes on breast shape. The classification of Baker is useful to guide the treatment on this situation, and usually capsulotomy associated with implant replacement is reserved for Baker III/IV. A number of factors may reduce the occurrence of capsular contracture. These include submuscular implant location, use of textured implants, and prevention of postoperative infection or bleeding. Radiotherapy is closely connected with capsular contracture, because of its effects over the soft tissue [28–31, 53, 56, 71–75, 77–80].

34.5.8 Implant Rupture

The recent implant rupture is not detected by clinical examinations; for this reason, our follow-up protocol for patients with implant is a bilateral breast ultrasound each year and a breast MRI at 10–15 and 20 years of implantation [118–120]. In cases of implant rupture, an implant surgical revision with capsulectomy is indicated; remove the implant and all silicone inside the capsula and change the implant. In cases of axillar lymph nodes augmented after implant rupture, lymph

node removal is indicated only in cases presenting a very large and painful nodes. The others lymph nodes slightly augmented can be followed, and it will become normal few months after the implant change.

Conclusions

There are a number of potential advantages to single-stage DTIR as opposed to a conventional two-stage implant reconstruction. One benefit is avoiding a second operation and the expansion period necessary for tissue expander/implant reconstruction, allowing a shorter time to final reconstruction [28, 30, 37, 40, 110]. It improves patient quality of life and reduces the inconvenience of frequent clinical visits [28, 30, 37, 40, 110, 121]. The direct-to-implant procedure may have a higher risk of postoperative comorbidities and failure compared with two-stage reconstruction, so patient selection is an essential issue combined with a good surgical team experience [28, 29, 37, 40, 41, 55, 58, 60, 76, 81, 110, 122–125].

Breast Reconstruction with Tissue Expander and Definitive Implant Replacement

35

Thomas H.S. Fysh and R. Rainsbury

35.1 Introduction

For patients who are not suitable candidates for autologous breast reconstruction, the traditional approach has been a staged procedure, by first expanding the skin and chest wall musculature over a period of weeks and then exchanging the expander for a fixed volume implant. While this was conventionally a delayed procedure to be carried out once adjuvant treatments were completed, it is now routinely used in the immediate setting [1].

The use of silicone implants for breast augmentation was described as long ago as the early 1960s, but it was another decade before Snyderman published the technique for a rudimentary, single-stage immediate implant-based reconstruction [2, 3]. It was not until 1982 that Radovan first described formal tissue expansion after mastectomy followed by exchange for a fixed volume silicone implant [4]. Since then, the steady advances that have been made in implant technology and dermal substitutes, as well as the rising demand for reconstructive and oncoplastic breast surgery, have served to increase the popularity and improve the outcomes associated with two-stage, expander-based breast reconstruction.

35.2 The Rationale for the Two-Stage Breast Reconstruction

Each reconstructive option has its attractions, but while the aesthetic outcomes of implant-based reconstruction may be inferior to tissue-based techniques, high-quality series and national audits nonetheless report rising patient demand and high levels of satisfaction following this approach [5, 6]. Two-stage implant-based breast reconstruction is, in many respects, the simplest of options. As such, it has found favour where other approaches cannot be considered, either because of operative risk, resource limitations or patient preference.

35.3 Patient Selection and Relative Contraindications

Given that the maximum volume achievable in two-stage breast reconstruction is around 650 ml, the ideal patient is usually of slim to normal habitus or only mildly overweight. The pectoralis should be innervated and functioning, and the skin flaps should be healthy. Although contralateral symmetrising surgery is usually straightforward, it may be difficult to achieve significant ptosis with this approach, and some patients will go on to have a mastopexy or reduction either at the time of their reconstruction or later on.

Patients undergoing immediate breast reconstruction will usually be suitable for either a 'direct-to-implant' approach or an autologous tissue-based reconstruction with or without an implant. A two-stage approach, however, provides the patient and surgeon with more flexibility, and there are many examples of situations when it is an attractive option.

While the initial surgery is relatively simple and low risk, patients who choose to undergo two-stage breast reconstruction must be advised that they are likely to require adjustments or revision of their reconstruction at a later stage. Leading manufacturers of cohesive gel implants generally advise that after 10–15 years, more than half the number of implants will have been replaced. Furthermore, several high-volume case series have shown that almost half of patients who have a planned 'two-stage' breast reconstruction actually go on to have three or more procedures [7, 8]. It is also clear from these and other reports that patients who have postmastectomy radiotherapy are particularly at risk of complications and have poor aesthetic outcomes. But while radiotherapy is often regarded as a contraindication to implant-based breast reconstruction, this view is currently being questioned as discussed below.

35.4 The Operative Approach

35.4.1 Marking Up

With the patient standing up, her feet a comfortable distance apart and her shoulders relaxed with arms by the side, the midline is marked, starting at the sternal notch. The breast meridian is marked on the normal side, as is the inframammary fold (IMF), with its most dependent point marked in the midline. The planned IMF is then marked on the operative side, with the most dependent part marking the intersection of the planned new breast meridian. The upper and lateral borders are matched with the normal side, and so a new breast 'footprint' is marked and the base width noted. Some manufacturers provide transparent plastic templates for this purpose. The skinfold thickness is taken away from the base width to give an expander base-width measurement. The exact choice of the expander will depend on the manufacturer and familiarity with use, but in general, the choice of devices is smaller than that of the fixed volume implants. The height of the device is only relevant in anatomically shaped 'adjustable implants', which are usually more expensive than 'true' tissue expanders and used in situations where they are unlikely to be exchanged (their use is discussed below). As a rule, we suggest ordering two expanders of the measured base width, two of the size above and two of the size below, which allows for size discrepancy and accidental contamination or damage.

35.4.2 Antisepsis Measures

- Screening for methicillin-resistant and methicillin-sensitive *Staphylococcus aureus* (MRSA and MSSA).
- When screening is positive, implement a clearance regimen (e.g. nasal mupirocin and chlorhexidine body washes) for 5 days before surgery.
- Where possible, a 'clean air' theatre is used (e.g. laminar flow).
- Passage of staff in and out of theatres is restricted.
- Single dose of IV antibiotics should be administered on induction according to local policies, to reduce the risk of post-operative infection, and repeated in procedures lasting more than 4 h.
- The skin should be prepared with a single wash of 2% chlorhexidine in a 70% solution of isopropyl alcohol and allowed to dry. Povidone Iodine is less effective [9].
- The pocket is prepared as much as possible prior to implantation, even with the use of an ADM.
- All operating staff put on a second pair of gloves prior to opening the expander (or wear two pairs, taking the outer pair off at this stage).
- The authors favour a 'minimal or no touch' technique, whereby the expander is opened immediately before implantation and bathed in a betadine/antibiotic mixture [10] or aqueous chlorhexidine. High-quality evidence confirming that this measure reduces implant loss is lacking and there is some concern that betadine may cause local tissue trauma, increasing capsule formation; some favour saline washes only.
- Contact between the skin and the implant should be avoided.
- Time between implantation and skin closure should be minimal; consultants should determine how much time to allow trainees with this in mind since operating time is directly related to surgical site infection rates.
- The pocket is thoroughly washed prior to implantation, with special attention given to removing loose fat and necrotic tissue, which could provide a nidus for infection.
- The use of special devices such as plastic sleeves to deliver the prosthesis into the pocket is largely untested, but is conceptually attractive as they allow for a true 'no touch' approach.

35.4.3 Intraoperative Technique

The procedure is undertaken under general or regional anaesthesia such as paravertebral blockade and sedation, with the patient in the supine position and arm abducted.

In the delayed setting, the incision is made usually via the previous mastectomy wound, but there is the opportunity to redefine the new IMF if necessary at this stage. Alternatively, this can be considered at the time of implant exchange. The techniques for redefining the IMF are described below; this is generally more important in patients who have undergone chest wall radiotherapy, since nonirradiated skin should expand without difficulty. It is preferable to excise as much irradiation-damaged and scarred skin as possible at this stage.

In the 'immediate reconstruction' setting, the mastectomy is most commonly performed using a skin-*reducing* pattern, since a total skin-*sparing* approach is usually more appropriate for a 'direct-to-implant' reconstruction. While it is technically possible to retain the nipple in a skin-reducing pattern, the vasculature of the nipple-areola complex is extremely precarious, and patients must be advised of the greater risk of ischaemic complications, especially when adjuvant therapies may be required. The template for the skin-reducing approach is a modified 'Wise' pattern, whereby the T junction is raised a little and the angle of the apex made more acute than for a breast reduction. As such, the final incision takes on more of a 'Mercedes' sign appearance than the classic 'inverted T'. The surgeon's aim is to be able to drape

the skin over the reconstruction 'mound' such that it is not under tension but in such a way that it remains 'smoothed out'. In both the immediate and delayed setting, the skin is elevated from the chest wall musculature about 1–2 cm beyond the superior and lateral boundaries of the planned breast 'footprint'. Care should be taken to preserve the perforating intercostal branches medially, and some surgeons like to mark these preoperatively using a handheld Doppler device.

The pectoralis major is then elevated and detached from the chest wall at its costosternal origin as far as the level of the planned maximum breast projection (usually the fourth intercostal space). It is crucial NOT to over-dissect the submuscular pocket superiorly or laterally. It is all too easy and tempting to do so, since this is a natural tissue plane, but the expander will follow the path of least resistance once in situ and will tend to migrate in this direction.

In its lower pole, the expander must be covered either with an ADM and/or chest wall fascia/musculature. Using the former approach, the IMF and lateral border can be easily defined by carefully suturing the lower border of the ADM to the anterior rectus sheath inferiorly and to the serratus fascia laterally; indeed this is the main reason for using an ADM in this context. Since the ADM itself cannot be expanded, a small a piece as possible should be used and attached to the pectoralis muscle with interrupted absorbable sutures. At the time of implant exchange, the incorporated ADM can be incised radially to improve its compliance and shape. When using the skin-reducing approach, the lower pole breast skin can be de-epithelialised, forming an 'inferior dermal' or 'lipodermal' sling. This avoids the cost and risks associated with ADMs and is sutured to the pectoralis to provide implant cover (Figs. 35.1, 35.2, 35.3 and 35.4).

Fig. 35.1 Mark-up for skin-reducing mastectomy and inferior lipodermal sling with Becker™. *Inferior shaded area* is de-epithelialised and skin template cut quite loosely compared to a cosmetic breast reduction

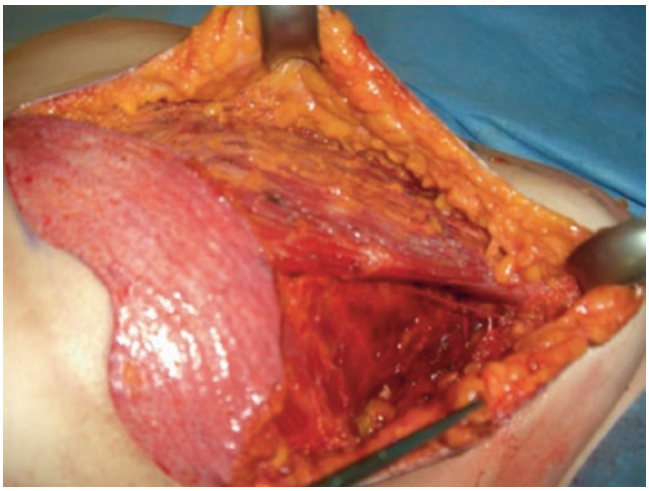

Fig. 35.2 The de-epithelialised inferior sling is sutured to pec major superiorly and serratus laterally to form the expander pocket. The skin is draped over the top without undue tension

Fig. 35.3 Early post-operative appearances (bilateral procedure), Becker™ adjustable implants 70% filled

Fig. 35.4 Three months post-operative left skin-reducing mastectomy and lipodermal sling with Becker fully inflated (with prior right augmentation mastopexy many years ago). This patient unexpectedly required postmastectomy radiotherapy and the implant extruded 12 months later

It is the authors' preference to use a single suction drain at closure, which can be fed into the expander pocket and through the skin via the mastectomy pocket. It is important for any dead space to be drained long enough for the ADM or lipodermal sling to incorporate into the skin envelope. Typically, this means the drain is left for 1–2 weeks. As with any immediate reconstruction, it is preferable to stage the axilla beforehand or intraoperatively. This not only avoids unnecessary early reoperation, risking exposure of the expander, but may also influence the timing and type of any reconstruction. There is a lack of evidence to demonstrate that skin necrosis rates are higher when accessing the axilla via the mastectomy incision. Some surgeons prefer to minimise traction and trauma to the skin envelope by accessing the axilla through a small separate incision, thereby keeping the axillary and mastectomy pockets separate. If required, the use of high-intensity illumination and careful exposure with atraumatic retractors can provide excellent axillary access even through a small circular mastectomy incision.

35.5 Radiotherapy in Two-Stage Implant-Based Breast Reconstruction

It has long been held that postmastectomy radiotherapy is a relative contraindication to two-stage implant-based breast reconstruction. Ideally, it would be preferable to replace the irradiated skin with fresh tissue from elsewhere. Sometimes, however, this may not be an option because patients are not willing or able to consider autologous reconstruction. When two-stage implant-based breast reconstruction is undertaken either after chest wall radiotherapy or before planned chest wall radiotherapy, it must be on the understanding that the rates of all complications, including reoperation, implant extrusion and reconstructive failure, are much greater, often quoted as high as 50% [7, 11]

35.5.1 Patients with Planned Radiotherapy

In the immediate setting, it may be appropriate to use a two-staged approach to implant-based reconstruction in patients for whom the adjuvant treatments are unclear. This is sometimes referred to as 'skin-banking' or a 'delayed-immediate' approach. Common reasons for adopting this approach include:

- When it is unclear preoperatively whether or not patients will require or accept postmastectomy radiotherapy. Few would disagree that it is preferable to avoid any implant-based breast reconstruction when radiotherapy is being considered. The value of 'skin banking' is this context is questionable since healthy skin can usually be transferred along with an autologous flap later, and so the simpler approach of a well-executed, IMF-based mastectomy is often the preferred option.
- For patients who have not yet decided what kind of definitive reconstruction they would like, but who will not accept being flat chested at any point.
- For patients who need cancer surgery soon and do not want to be flat chested, but who can wait for definitive reconstruction for other reasons, such as buying time to stop smoking, attending important personal engagements or when there is lack of access to specialist services.
- For patients who have had a previous augmentation and who need the existing implant to be removed as part of their cancer surgery. In these patients, the implant pocket (or parts of it) can usefully be retained, but often needs to be expanded to make up for the volume lost to the mastectomy.

35.5.2 Adjustable Implants Versus Tissue Expanders

Most tissue expanders are constructed from a solid state silicone shell surrounding a saline chamber that is accessed via an integrated metallic port on the anterior surface of the device. Most ports have a magnetic location system, which allows the clinician to cannulate the port transcutaneously without sonography. They are relatively cheap but are not designed to be left in situ. Moreover, the integrated port means that they are often unsuitable for patients likely to require MRI scanning or radiotherapy.

Adjustable implants such as the Becker™ expander series (Mentor, Johnson and Johnson) can provide an elegant solution for patients who are suitable for implant-based reconstruction but who are not suitable for either the "direct-to-implant" approach or in whom a two-staged "exchange approach" may not ultimately be necessary. These implants contain a variable volume of cohesive silicone gel (between 25% and 50%, depending on the type) with an adjustable inner saline chamber accessed via a remote subcutaneous injection port. Typically the port is removed under local anaesthetic, once the final volume has been achieved, and the adjustable implant is left in situ without being exchanged. These gel/saline implants are more expensive than traditional saline expanders or fixed volume gel-filled implants, and so their use should reflect the likelihood that they will remain in situ. In one case series reporting the outcome of >300 Becker™, 74% remained in situ >5 years following implantation, avoiding the cost and morbidity of exchange for a fixed volume device [12]. Examples of patients who might be suitable for an adjustable implant include:

1. Those for whom postmastectomy radiotherapy is dependent on histopathology findings, but may not be necessary.

2. Those who require contralateral reduction simultaneously. Since shape and volume match in such patients is difficult to predict, final adjustments may be needed.
3. Patients in more remote communities where access to a large implant bank is not possible.
4. Patient groups with poorer-quality skin flaps, but who would otherwise be suitable for the 'direct-to-implant' approach (such as the growing number of older patients requesting breast reconstruction). In such women, the pressure on the skin can be easily reduced if necessary without exposing the patient to further surgery (Figs. 35.5 and 35.6).

Fig. 35.5 78 year old with prior left mastectomy requesting reconstruction (preoperative). A single operation was desirable, and so a Becker™ adjustable prosthesis was used with a non-biological ADM (TiLOOP™)

Fig. 35.6 Three months post-operative. Left delayed Becker™/ADM reconstruction in older patient. She underwent a single operation lasting approximately 1 h. She had good symmetry in a bra and declined contralateral reduction/mastopexy

5. Women with a very small (100–150 cc), somewhat flat breast mound who choose implant-based reconstruction but decline contralateral augmentation. The use of a slightly underinflated small (150–200 cc) Becker™ expander will achieve a breast shape which is as close as possible to the remaining breast. The base width is wider than a gel implant of equivalent volume, and the somewhat unnatural projection associated with smaller fixed volume implants can be avoided.
6. Patients undergoing bilateral immediate or delayed reconstruction after risk-reducing mastectomy who are uncertain about the most appropriate final volume. Becker™ provides considerable flexibility in relation to both volume and projection while avoiding the inconvenience and risks of subsequent exchange.

35.5.3 Timing of Radiotherapy in the 'Delayed-Immediate' Approach

For patients awaiting radiotherapy and not requiring chemotherapy, the expander is inflated fairly rapidly 2–3 weeks after surgery, provided wound healing is normal. This is usually straightforward because these patients do not require very much (if any) true skin expansion in the early stages due to the skin-sparing approach of the mastectomy. The aim is ultimately to 'overexpand' the skin envelope in order to preempt the fibrosing effects of radiotherapy. Most manufacturers of tissue expanders favour overexpansion and exchange to a fixed volume implant prior to radiotherapy. Overexpansion volumes are given in the manufacturers' leaflets, and while the actual tolerance tends to be well in excess of the advised overfill volume, most advocate an overfill of about 20% of the intended final volume.

Given that it is desirable to deliver postmastectomy radiotherapy within 4–6 weeks of surgery, this approach can lead to delays in order to accommodate hospitalisation and healing times. Although long delays can worsen outcomes, excellent loco-regional control is still achieved when radiotherapy is delivered within 8 weeks of surgery [13, 14]. Delay is seldom a problem since most patients with a disease profile warranting postmastectomy radiotherapy will also require post-operative chemotherapy. In this situation, expansion is carried out during chemotherapy, and exchange is carried out 3 weeks after the last cycle of chemotherapy and 3 weeks before the start of radiotherapy. These timing issues will become more common as the use of neoadjuvant chemotherapy continues to rise.

An alternative strategy is to delay implant exchange until *after* completion of radiotherapy. This may seem to be an attractive approach, as operative scheduling is simplified and irradiation of the final implant is avoided.

Recent evidence suggests however that this approach is associated with poorer outcomes, including high rates of capsular contracture and reconstruction failure and is best avoided [15].

35.5.4 Patients with Prior Chest Wall Radiotherapy

When patients present with an irradiated chest wall, but who have otherwise completed their adjuvant treatment, the basic approach to the reconstruction differs to that in nonirradiated patients. Only rarely will such patients end up having an implant-based reconstruction, and it is fair to say that these patients are extremely challenging. Most are suitable candidates for an autologous reconstruction, combined with an implant/expander or subsequent lipofilling if further volume is required, or an external prosthesis should be considered. For those wanting an implant-based reconstruction, several issues arise:

- The irradiated skin is less elastic, and the underlying pectoralis is often somewhat fibrotic, rigid and resistant to stretching. These factors combine to make expansion a much more challenging and time-consuming process. The number of expansions required will usually be greater, in smaller increments (e.g. 50 ml per expansion), with longer periods between each expansion.
- It is wise to be modest in terms of the final reconstruction volume. Attempting to use a large volume expander may preferentially depress the chest wall, causing a 'saucer' deformity of the rib cage, rather than expanding the skin. This can happen with smaller expanders too and should be anticipated and suspected in those patients who fail to achieve satisfactory projection despite numerous expansions.
- The expander will tend to migrate upwards or laterally towards the axilla, following the plane of least resistance. It is crucial to avoid over-dissection of the pocket in the first instance, although migration may still occur during the phase of overinflation (Figs. 35.7, 35.8, 35.9 and 35.10).
- Subcutaneous autologous fat grafting to improve the quality of irradiation-damaged skin has been shown to improve patient-reported outcomes in this context [16]. This may need to be repeated until visible improvement takes place, prior to delayed reconstruction.
- Nonirradiated skin will tend to expand preferentially compared to irradiated skin. Accurate placement of the tissue expander directly beneath the irradiated mastectomy flaps is important to avoid the creation of a 'double bubble' breast mound, due to differentially greater expansion of the unirradiated peripheral tissues.

Fig. 35.7 50 year old requesting delayed reconstruction 5 years post-mastectomy and chest wall radiotherapy and axillary clearance

Fig. 35.8 Pt in Fig. 35.7, 4 weeks postoperatively. A planned LD was aborted intraoperatively, since the LD pedicle was destroyed by previous surgery and radiotherapy. An expander was inserted with and inferior non-biological ADM (TiLoop™) and filled with 60 ml initially

- Irradiated skin and muscle is unlikely to yield sufficiently to provide good projection even after expansion. This can be addressed in a number of ways
  - At the time of exchange to a permanent implant, a good volume of skin and subcutaneous fat can be recruited from the abdominal wall by dissecting beyond the IMF often as far as the umbilicus, in the plane of abdominal wall fascia. This 'abdominal advancement flap' can then be advanced into the lower pole of the new breast mound. It can then be secured in place with a line of sutures including the anterior rectus sheath and positioned to define the new inframammary fold. The imported, unirradiated abdominal tissue is then draped over the lower pole, providing ptosis and enhancing projection.

Fig. 35.9 Pt in Fig. 35.7. As expansion continues, the expander migrates along the path of elastic resistance, superolaterally. The radiotherapy damaged skin fails to expand

Fig. 35.10 Pt in Fig. 35.7. Upon exchange, an attempt to redefine the IMF by advancing abdominal wall tissue is only partially successful. The patient went on to have symmetrising reduction, however, and no longer needs an external prosthesis

  - At the time of expander placement and again at the time of exchange for an implant, the irradiated skin and fascia can be relaxed through multiple radial and horizontal 'capsulotomy' incisions, carried out from within the cavity (stopping before the dermis is reached). It is also safe to perform multiple capsulotomies following ADM-based procedures, as the dermal substitute should be fully incorporated into the surrounding tissues by the time of exchange.

- Because of resistance of irradiated chest wall tissues to expansion, clear definition and firm fixation of the IMF is crucial. This can be achieved in a number of ways.
  - At the time of expander placement, an ADM can be used to define the IMF, bearing in mind that the use of an ADM in this setting is associated with higher rates of infection and loss of both ADM and implant. The ADM will not expand itself and so in addition to fixation to the anterior rectus sheath and serratus fascia, it must be sutured to the lateral border of the pectoralis muscle with interrupted sutures; it may help to further shape it with radial incisions to encourage future expansion. Similarly, careful fixation of the ADM inferiorly prevents the expander from migrating downwards. This will not guarantee a well-defined IMF particularly in larger patients, or in those who have had an incomplete mastectomy leading to thick flaps.
  - At the time of replacement of an expander with a permanent implant, the IMF may require further definition. This can be achieved from within the implant pocket, and, here, the author's preference is to use several heavy PDS sutures to anchor the IMF from the deep dermis to the chest wall along a pre-drawn line corresponding to the level of the intended IMF. Forming the new IMF is facilitated by advancing the abdominal wall as described above, particularly when the soft tissues over the lower pole are tight and attenuated.
  - An alternative approach is to redefine the IMF by entering the implant cavity via an incision placed along the line of the planned IMF. A crescent of skin is then de-epithelialised, such that the full-thickness 'access' incision is in its centre. The upper part of this de-epithelialised crescent is then tacked to the chest wall with heavy interrupted PDS sutures. The abdominal wall is advanced to the same level and in a similar way is also tacked to the chest wall with heavy PDS sutures, since it will now be under some tension. The exact mark-up of the de-epithelialised section will vary and depend on skin laxity, thickness of the abdominal wall and degree of projection to be achieved after expansion. Contrary to traditional teaching, the authors have not found that fashioning these parallel 'tramline' incisions carries a risk of ischaemia, as long as the original mastectomy incision is mature, preceding the inframammary fold incision by at least 6 months.
- Patients with a with previously irradiated chest wall should be warned that, more than any other patient undergoing breast reconstruction, the likelihood of requiring further unplanned operations (for any reason, including repeated adjustments, implant exchange and revisional surgery) is very high [12].

35.6 Summary

Two-stage implant-based breast reconstruction is an attractive, relatively uncomplicated option, particularly for those women who are not suitable for other forms of breast reconstruction. Its appeal lies in its simplicity, low morbidity, short hospital stay and rapid recovery. Women should be informed that these shorter-term gains need to be considered carefully alongside the more favourable longer-term aesthetic outcomes associated with autologous tissue-based techniques. They should also understand that although the initial surgical episode is usually uncomplicated, they are likely to require long-term maintenance, with revision and possibly conversion of their reconstruction in the years which lie ahead.

The Pedicled TRAM Flap in Breast Reconstruction

36

Glyn Jones

36.1 Introduction

Breast reconstruction using autologous techniques [1] have undergone considerable change in recent years. Earlier implant and expander-implant reconstructions achieved mound creation, but a natural ptotic breast shape remained an elusive goal. Recent advances in implant shape and texture technology coupled with the use of acellular dermal matrices have done much to dramatically improve implant-based outcomes in reconstruction, constituting over 80% of all breast reconstructions performed in the United States at this time. Some surgeons find the attendant complication rates and need for long-term maintenance troubling. Distortion and capsular contracture did little to encourage reconstructive surgeons and may well have contributed significantly to Veronesi's successful focus on breast conservation therapy. While capsular contracture is no longer the major problem it used to be, implant-based reconstruction definitely requires ongoing maintenance in the long term. The advent of autologous techniques with the latissimus dorsi and then transverse rectus abdominis myocutaneous (TRAM) flap and its derivatives for breast reconstruction revolutionized breast reconstruction, enabling surgeons to create a breast that is soft, warm, and well integrated into a patient's psyche. The latissimus flap often requires an additional implant, but TRAM flap techniques enabled us to create a truly autologous breast reconstruction without the need for long-term maintenance or adverse events. The popularity of skin-sparing mastectomy (SSM) and nipple-sparing mastectomy (NSM) has made further landmark advances in breast reconstruction, attaining the goal of a natural, almost scarless reconstructed breast. These oncologically safe procedures do not compromise mastectomy outcomes [2–4]. Combined with TRAM flap reconstruction whether pedicled or free, the technique offers potential for increasing patient acceptance of mastectomy as an alternative to breast conservation therapy (BCT). In our practice, 95% of patients undergoing mastectomy select immediate reconstruction with skin- or nipple-sparing mastectomy, while a minority present for delayed reconstruction.

36.2 History of the Pedicled TRAM Flap

Millard described the use of a tubed lower abdominal pedicled flap in reconstructing the radical mastectomy defect in 1976 [5]. The flap was transferred onto the chest via the forearm, using a waltzing technique, achieving a successful autologous tissue reconstruction for the time. In 1979, Robbins used a vertical rectus abdominis flap for breast reconstruction [6]. Independently, Drever, Dinner, and Sakai all refined variations on the use of vertical rectus abdominis myocutaneous flaps for breast reconstruction [7–10]. Hartrampf and Scheflan took the bold step of changing the skin island orientation to a transverse one across the mid-abdomen, making a more sizeable volume of tissue available for breast reconstruction with a cosmetically desirable donor site [11–14]. Scheflan confirmed the dominant deep inferior epigastric arterial supply to the lower abdominal skin and fat. Blood supply was most reliable directly over the designated rectus muscle from which perforators were most abundant, while the periphery of the flap relied on the capture of successive angiosomes through the subdermal plexus. Milloy had documented the blood supply of the rectus muscles in 1960, and these findings together with Scheflan's dissections found their culmination in the lead oxide injection studies of Taylor, Moon, and Palmer. Their publication of the angiosome concept was an extension of Michel Salmon's anatomic studies [15–17]. From these beginnings, the TRAM flap became the gold standard procedure for breast reconstruction and remains in widespread use today. In the interim, free flap options have arisen as refinements of the original pedicled technique, including the free TRAM (FTRAM), the muscle-sparing free TRAM, and the deep inferior epigastric

artery perforator (DIEP) flaps, as well as the superficial inferior epigastric perforator (SIEA) flap. While the younger generation of plastic surgeons is rarely trained to perform pedicled TRAM flaps, they are still widely performed in the United States as well as in Europe at this time. Part of this relates to the dramatically shorter operating times, easier technical procedure, and lack of potential total flap loss in the pedicled flaps. Physician reimbursement has certainly impacted the nature of autologous reconstruction in some areas where perforator flaps are consistently rewarded with higher payment schedules.

36.3 The Vascular Anatomy of the Pedicled TRAM Flap

The skin and fat of the lower abdomen and periumbilical area are supplied by perforators arising from five major sources:

- Superior epigastric vessels arising from the termination of the internal mammary vessels
- Deep inferior epigastric vessels
- Superficial inferior epigastric vessels
- Intercostal segmental vessels
- Terminal branches of the superficial and deep circumflex iliac vessels

Of these, only the superior epigastric vessels are utilized when raising a pedicled TRAM flap. The predominant blood supply of the lower abdominal tissues is, however, unquestionable from the deep inferior epigastric system [14, 16, 17]. The vessels from both epigastric systems penetrate the rectus muscles on their deep surfaces and travel as single or duplicated vessels up and down the flap to anastomose in the periumbilical region through a system of choke vessels described by Taylor [17–19].

Three vascular patterns have been identified within the rectus muscles:

Type I (29%) had a single superior and inferior arterial supply.
Type II (57%) had a double-branched system from each source artery.
Type III (14%) had a triple-branched system from each vessel.

Bilateral vascular symmetry was noted in only 2% of patients.

Moon and Taylor proposed three variations in skin island design: the upper, mid-abdominal, and lower abdominal flaps. Vessels injections studies suggested increasing paucity of inflow the lower the skin paddle was placed on the abdominal wall in the case of a pedicled flap. This finding was corroborated by Harris [20] and has led to most surgeons designing the flap from just above the umbilicus to above the pubic crease and not below it.

Macroscopic communication between the two systems is present in only 40% of cases, while 60% of patients have choke vessels of microscopic caliber [16, 21]. These choke systems allow for reversal of flow to open up between the two systems to provide increased blood flow to the tissues. The superior vessels pass into the muscle from the deep aspect of the costal margin and run inferiorly. The deep inferior epigastric supply enters the posterolateral aspect of the muscle below the arcuate line and passes up to anastomose with the superior vessels in the periumbilical area. It provides significantly more circulation to the flap and is accompanied by two large venae comitantes which drain into the iliac circulation [14, 19]. These venae comitantes are usually larger than the superior veins, which partially explains the improved venous drainage associated with the free TRAM. The most dominant venous outflow is often supplied by the superficial inferior epigastric vein, the basis of the SIEA flap. This fact can lead to venous congestion in free flaps requiring decompression through the superficial inferior epigastric vein (SIEV). The periumbilical anastomosis has a bidirectional venous outflow confirmed by Taylor. Following elevation of a pedicled TRAM flap, distal venous flow has to reverse, following the drainage pattern of the superior veins. In order to achieve this, the venous flow pressure has to overcome the venous valves within the choke system described by Taylor [16, 17]. Arterial perforators arise from both systems and run in two roughly parallel lines on either side of the linea alba. The lateral row lies 2–3 cm within the lateral border of the rectus sheath, while the medial row lies 1–2 cm from the linea alba [17]. These vessels vary significantly in both size and number; their caliber may be miniscule to several millimeters in diameter.

The anterior rectus sheath is densely adherent to the muscle at the tendinous inscriptions. During flap elevation, a gently tapering cuff of this fascia is left on the muscle with its apex toward the costal margin helping to maintain the integrity of the muscle, thereby reducing the risk of injury to the pedicle. It also aids in reducing tension during closure [22]. A muscle-sparing technique can be used to leave a strip of muscle laterally and/or medially to assist in maintaining abdominal wall strength, but the rationale for this is flawed as it is poorly vascularized (if at all) and probably just contributes some fibrous scar to the long-term abdominal closure. The intercostal nerves and vessels penetrate the posterior aspect of the rectus muscle at the junction of the mid and lateral thirds of the muscle and not in the lateral third. Any lateral segment is probably devoid of neurovascular input [23, 24]. Harris demonstrated an 80% reduction in intraoperative blood flow when clamping the medial and

lateral thirds of the rectus muscle to simulate muscle-sparing harvest [20]. Consequently, there seems little value to incorporating muscle-sparing surgery into TRAM flap harvest.

36.4 Vascular Zones in TRAM Flap Blood Supply

Two major vascular classifications exist for TRAM flap blood supply. The best known and earliest description was that of Hartrampf (Fig. 36.1) who divided the supply into four zones:

Zone I overlying the muscle pedicle
Zone II lying across the midline, immediately adjacent to zone I
Zone III lying lateral to zone I on the ipsilateral side
Zone IV lying lateral to zone II on the contralateral side from the pedicle

Historically, zone I is the most reliable portion of the flap. This was followed by the medial portion of zone III. The end of zone III becomes increasingly unreliable as one moves toward the tip of the flap and it is wise to discard it in most patients. The medial portion of zone II is also usually reliable, but the lateral part is less predictable followed by zone IV which should be discarded routinely. Taylor documented the anatomic theory behind this approach in his paper on the angiosome concept [16]. It is his belief that a single adjacent vascular territory could be captured relatively reliably, but more than one angiosome capture becomes increasingly unpredictable, particularly once the midline is crossed. These observations led Taylor to popularize the concept of TRAM flap delay in an effort to bolster the blood flow to the flap prior to elevation.

Ninkovich and Holm [25] performed dynamic indocyanine green perfusion imaging of DIEP flap blood supply in vivo. They reached the conclusion that while zone I remains the most reliably perfused portion of the flap, any flow across the midline is more precarious than ipsilateral flow. The Ninkovich classification proposes that Hartrampf's ipsilateral zone III should be renamed zone II, while Hartrampf's zone II should be renamed zone III with a less reliable flow due to its cross midline location (Fig. 36.2). One of their DIEP flaps is shown in Fig.

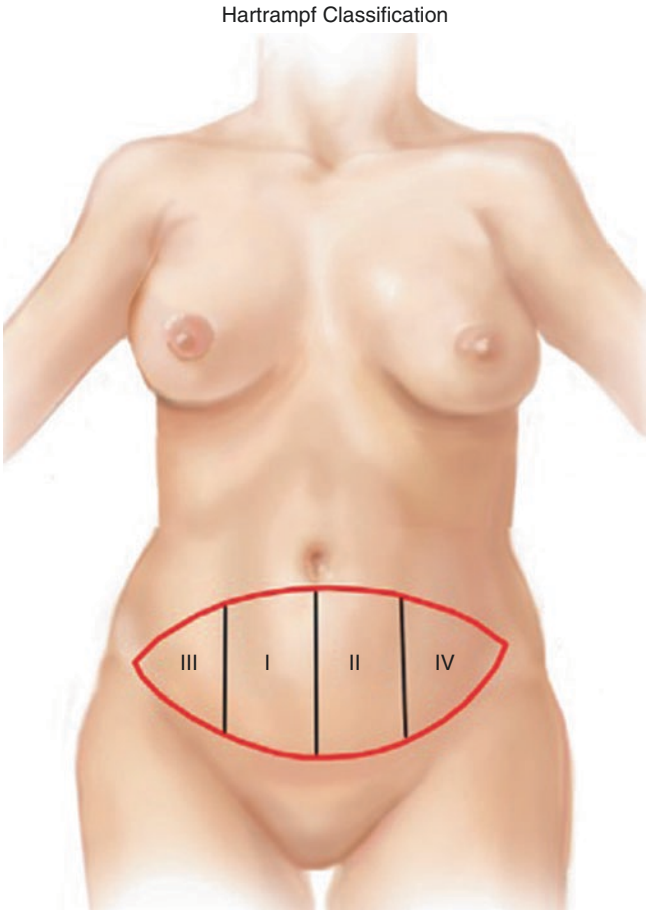

Fig. 36.1 Hartrampf's classification of TRAM flap blood supply zones

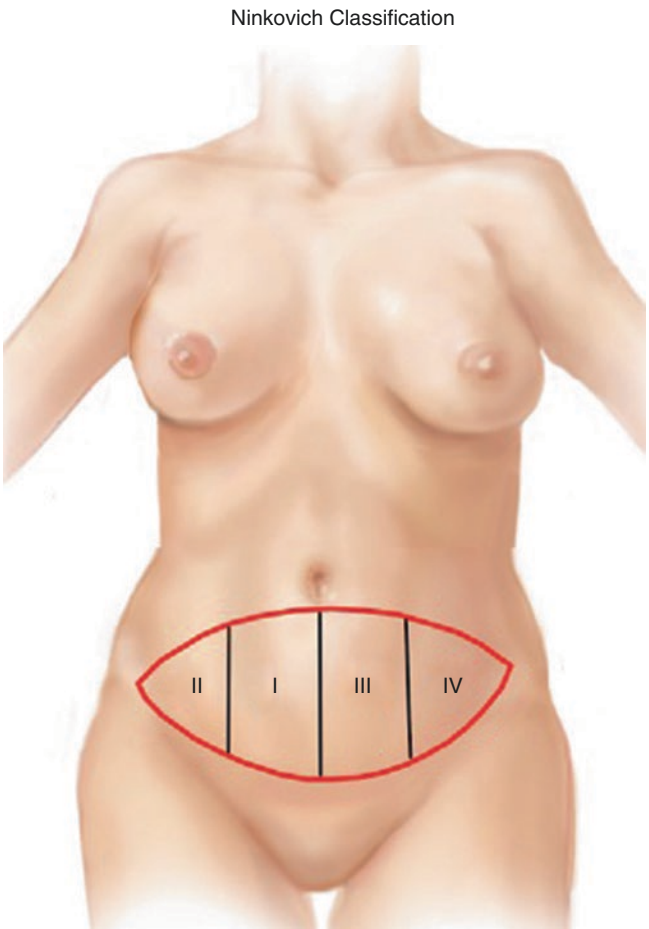

Fig. 36.2 Ninkovic's classification of TRAM/DIEP flap blood supply zones

(Fig. 36.2) clearly illustrating this phenomenon with all of the cross midline tissue showing signs of ischemia, while the ipsilateral tissue remains well perfused. These findings are borne out by both reperfusion times and the rate of flow in each zone. There is an increasing trend among both pedicled and free flap surgeons to rely more on the ipsilateral side than any cross midline tissue in an effort to reduce flap necrosis.

36.5 The Anatomic and Physiologic Basis of TRAM Flap Vascular Delay

Vascular delay is a historic concept, the efficacy of which was documented during the era of tube pedicled flaps for general reconstruction [26]. Moon and Taylor recommended surgical delay of the TRAM flap 1 week prior to definitive elevation. The procedure focused on ligation of the superficial and deep inferior epigastric systems in an outpatient setting. Although timed for 1 week prior to flap elevation and breast reconstruction, Taylor believes the delay phenomenon reaches its functional peak at 72 h after surgery rather than the classic 10-day window suggested in past literature [26]. The procedure is effective but adds another step to the operation with added costs incurred. One creative approach used by Rezai is to perform a contralateral breast reduction at the time of vascular delay, coming back several days later to transfer the vascular-delayed TRAM flap to the fresh mastectomy site. This maximizes operating room time utilization. Codner demonstrated a statistically significant rise in vascular inflow to the pedicle after delay with improved perfusion pressures in the vascular-delayed cases [27]. This was corroborated by Restifo and Ribuffo [28, 29]. Restifo demonstrated a flow in the superior epigastric vessels similar to that of the inferior system once delay had been performed. He was also able to demonstrate no additional benefit to waiting longer than 1 week after delay prior to formal flap elevation. Ribuffo used color Doppler studies to demonstrate increased caliber of, and flow within, the superior epigastric system after vascular delay [29]. The indications for delay can be summarized as follows:

- An alternative for plastic surgeons not comfortable with microsurgical reconstruction
- Useful for the higher-risk patient—obesity, smoking, and prior radiation to the proposed TRAM flap pedicle

36.6 Abdominal Anatomy and the Use of Pedicled TRAM Flaps

Competent rectus sheath closure is an essential element to success with any TRAM flap procedure, be it pedicled or free [22, 30, 31]. Laterally the rectus sheath consists of two fascial components derived from the external and internal oblique muscles. These blend into a confluent anterior sheet which fuses at the linea alba with the contralateral sheath. It is imperative that *both* lateral components be incorporated into the fascial closure when closing the donor defect if hernias or bulges are to be prevented [22, 32]. Nerve supply to the muscle is segmental and must be divided when raising the flap. It is essential to denervate the eighth intercostal nerve at the costal margin as this maneuver causes the muscle to atrophy so as to prevent muscle bulging at the costal margin tunnel when the patient sits up.

36.6.1 The Case for Delayed or Delayed-Immediate Reconstruction

Immediate breast reconstruction is the most favorable context in which to perform breast reconstruction as it offers the benefit of retaining the natural breast skin envelope's shape and consistency. It also retains the natural location and composition of the inframammary fold, assuming that the breast surgeon has not violated this critical structure. This leaves behind the patient's natural skin brassiere together with a defined inframammary fold [2] to help mold the newly reconstructed breast. While this is most valuable in immediate reconstruction, it does offer maintenance of the inframammary crease for delayed reconstruction. The original breast shape may be more readily matched as a consequence [33].

Traditional mastectomies leave a large skin defect making access to the chest wall, axilla, and TRAM flap tunnel communicating with the abdominal dissection very simple. In skin-sparing mastectomy, the excision usually incorporates a peri-areolar biopsy if this has been performed and axillary dissection is either done through the nipple-areola complex (NAC) wound or through a separate axillary incision [3]. The closer an excised skin biopsy site is to the excised nipple-areola disk, the greater is the risk of skin bridge necrosis. Skin incisions for the procedure have been suggested by Carlson, Toth, and Skoll, all of whom highlight the risks of the Wise pattern approach for ptotic patients [3, 34, 35]. Skin flaps must be handled gently in order to minimize the risks of skin necrosis. Every attempt should be made to preserve the inframammary fold as Carlson has shown that this does not

compromise the oncologic safety of the procedure and it greatly enhances the ultimate appearance of the reconstruction [36] . Although skin-sparing mastectomy may be used without immediate reconstruction, the retention of the additional breast skin does little to ease the reconstructive surgeon's task when delayed reconstruction is finally performed. This is particularly true of radiated patients. Data published by Kronowitz [37] has supported the concept of immediate-delayed reconstruction. In this process, mastectomy flaps may be held out to size by an immediately placed expander which can be inflated and then deflated during radiation if reconstruction is to be delayed, followed by re-expansion and either implant or free flap insertion. This approach has been given the label of "immediate-delayed" reconstruction but has a reputation for 35% complication rates from seromas and infection. Andree has more recently proposed the IDEAL concept of delayed reconstruction in which an implant and not an expander is placed and used as a spacer until radiotherapy has been completed, followed by early DIEP flap substitution. It does allow the surgeon to take advantage of nipple- or skin-sparing mastectomy in the face of delayed reconstruction.

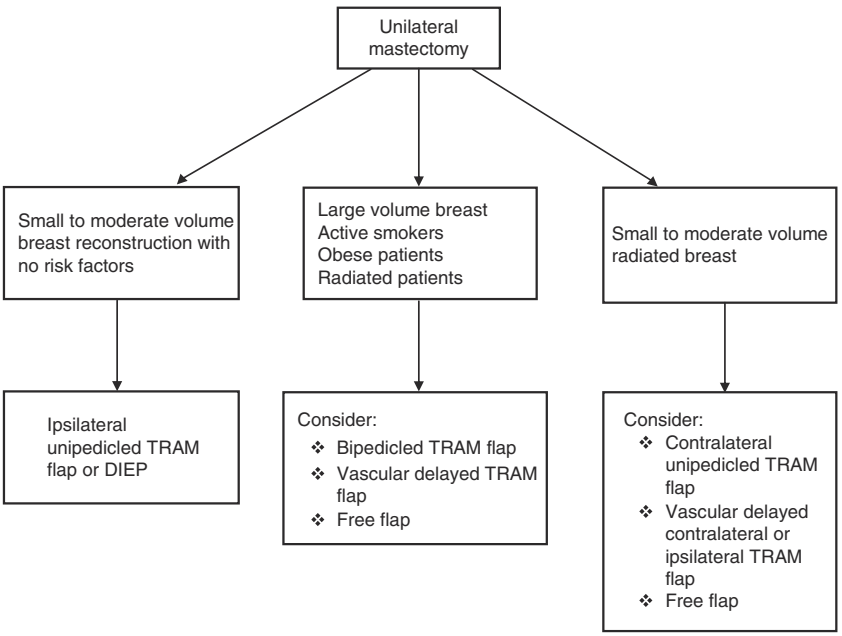
36.7 Patient Selection for TRAM Flap Breast Reconstruction

The first prerequisite for this procedure is a patient healthy enough to undergo a 2–3-h operation, a 3–5-day hospital stay, and a 4–8-week recovery period before the patient begins to feel that life is returning to some degree of normality. The second major requirement is an available donor site. The patient should have a thorough history taken including an evaluation of comorbidities such as gastroesophageal reflux disease (GERD), irritable bowel syndrome, lumbar spine problems, smoking history, and cardiovascular risk factors. We did not find diabetes mellitus to be a risk factor in TRAM flap usage [32] although Hartrampf has assigned it a significant value [11]. Collagen vascular disease is potentially problematic although we have performed the procedure safely in patients with systemic lupus erythematosus and mild rheumatoid arthritis. Scleroderma would present more of a risk if anterior chest tightness were present as this could compromise abdominal skin closure. Considerable caution should be exercised in deciding to operate on a patient with Ehlers-Danlos syndrome. A history of prior abdominoplasty or abdominal liposuction represents relative contraindications to the procedure in theory (although we have successfully performed the procedure in a patient with complete abdominal wall undermining 20 years previously as well as in patients with conservative liposuction). Preoperative CT or MR angiography is not particularly helpful in pedicled TRAM flap planning, but delineation of perforator location is helpful in planning perforator flaps. Intraoperative indocyanine green perfusion assessment is more helpful in this author's experience. Clinical examination should be performed noting body habitus and weight. The abdomen should be examined for old scars, particularly cholecystectomy scars or vertical midline incisions [38]. Pfannenstiel incisions are not a risk factor. Laparoscopic incisions are rarely a problem, but port sites may injure the vessels within the rectus muscle in the upper abdomen, and Doppler evaluation is probably prudent during surgery. It is unwise to operate within 6 weeks after laparoscopic surgery. A final factor in flap selection is that of the patient's occupation and lifestyle. Very active, young individuals are better served by a DIEP or SIEA flap, and patients engaged in musical careers occasionally express concerns about the impact of muscle loss on their ability to sing. This does not appear to be a significant issue in practice.

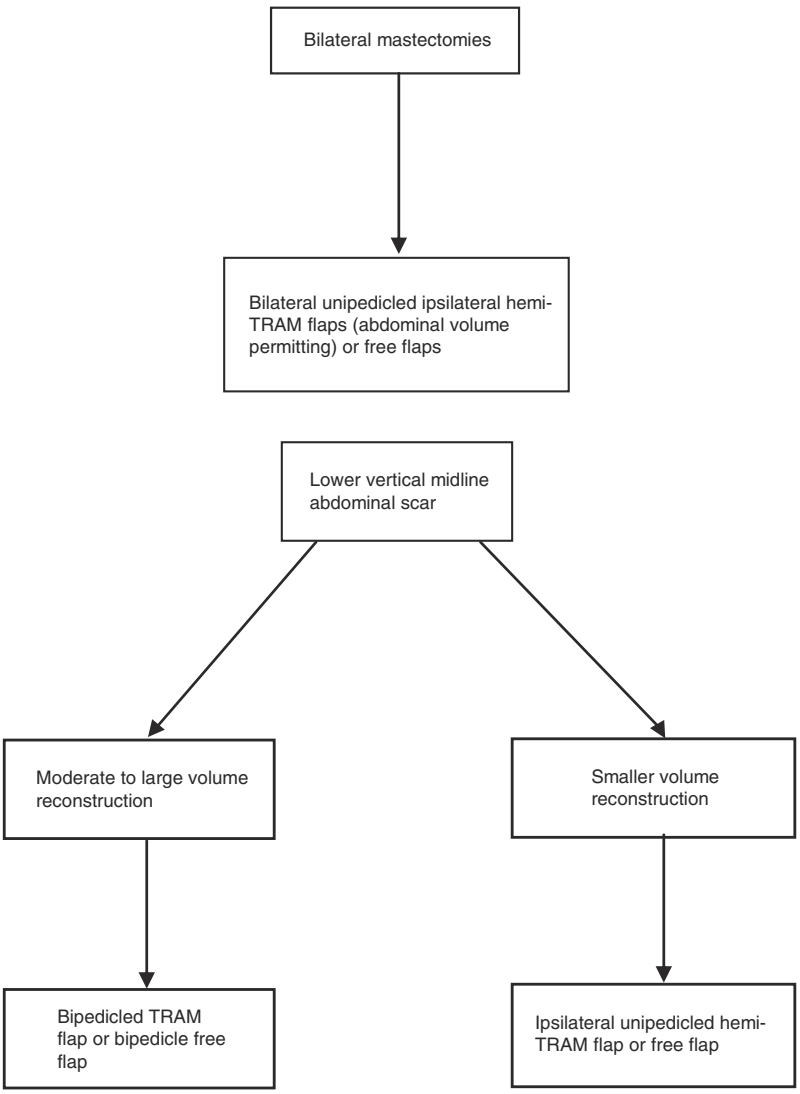
Hartrampf attempted to assign risk scores to patients in order to determine their eligibility for TRAM flap reconstruction [11]. Risk factors included smoking, obesity, psychological instability, autoimmune disease and diabetes mellitus, severe systemic disease, and surgeon inexperience. Using this rating system, a patient with two risk factors or a score of <5 represented a borderline risk, while patients with three or more risk factors or a score of >5 were considered a poor candidate for surgery [11]. In our own series, diabetes did not correlate well with complications, but obesity, smoking, abdominal scars, and prior radiation therapy did [31, 32]. The following algorithm is an attempt at simplifying flap choices for patients with differing risk factors as well as including the surgeon's preference and level of comfort with microsurgery.

36.7.1 TRAM Flap Selection Algorithms

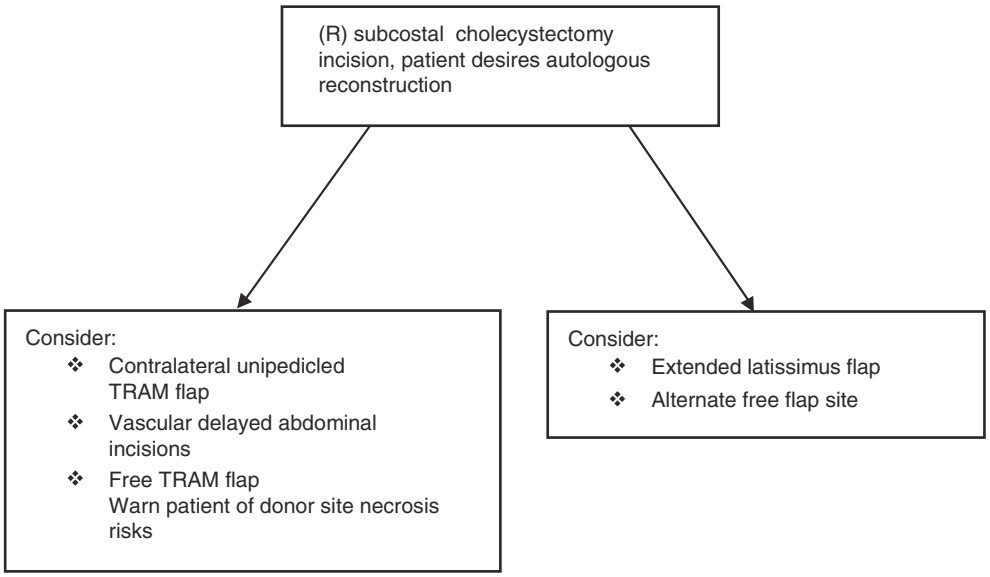
1. Small- to moderate-volume breast reconstruction with no risk factors—ipsilateral unipedicled TRAM flap or DIEP flap
2. Large-volume breast, active smokers, obese patients, and radiated patients—bipedicled TRAM flap, vascular-delayed TRAM flap, and free flap (excluding DIEP)
3. Small- to moderate-volume radiated breast—contralateral unipedicled TRAM flap (or ipsilateral TRAM flap if radiation injury appears mild) or free flap



Unilateral mastectomy
Small to moderate volume breast reconstruction with no risk factors
Large volume breast
Active smokers
Obese patients
Radiated patients
Small to moderate volume radiated breast
Ipsilateral unipedicled TRAM flap or DIEP
Consider:
Bipedicled TRAM flap
Vascular delayed TRAM flap
Free flap
Consider:
Contralateral unipedicled TRAM flap
Vascular delayed contralateral or ipsilateral TRAM flap
Free flap



Bilateral mastectomies
Bilateral unipedicled ipsilateral hemi-TRAM flaps (abdominal volume permitting) or free flaps
Lower vertical midline abdominal scar
Moderate to large volume reconstruction
Smaller volume reconstruction
Bipedicled TRAM flap or bipedicle free flap
Ipsilateral unipedicled hemi-TRAM flap or free flap



36.8 Anesthetic Requirements

Patients are kept warm and well hydrated to provide robust circulation [11]. Urine output should be high throughout the procedure. Nitrous oxide administration can cause small bowel distention resulting in potential difficulties with abdominal wall closure; nitrous oxide inhalation is not used at all in our practice. Intraoperative body-warming blankets are used routinely as are leg compression stockings. We use prophylactic heparin therapy or low molecular weight enoxaparin as these drugs do not appear to increase the risk of hematomas. Intravenous ketorolac for postoperative pain has not been shown to increase hematoma rates [39, 40]. The reported incidence of deep venous thrombosis complicated by pulmonary embolism in our series was just under 0.006%, while the incidence of fatal pulmonary embolism is approximately 0.1% [31, 32].

36.9 Unipedicled Operative Procedure

The upper abdominal incision is made first and the upper abdominal skin flap is elevated over the costal margins laterally and to the xiphoid centrally. The patient is flexed to assess the adequacy of closure to the inferior incision line. The inferior incision may need to be elevated slightly to allow for a less tense suture line in patients with a long narrow torso. Tight closure can seriously compromise blood flow to the skin edges causing skin necrosis. Obese patients are particularly at risk. Pfannenstiel incisions are routinely ignored. The distal incision is then made, and TRAM flap is elevated from lateral to medial identifying the lateral row of perforators and the lateral border of the rectus abdominis muscle. The decision as to which side to base the flap depends upon abdominal anatomy and surgeon preference. In the unscarred abdomen, either side may be used and I prefer the ipsilateral pedicle (Figs. 36.3 and 36.4a, b). Ipsilateral

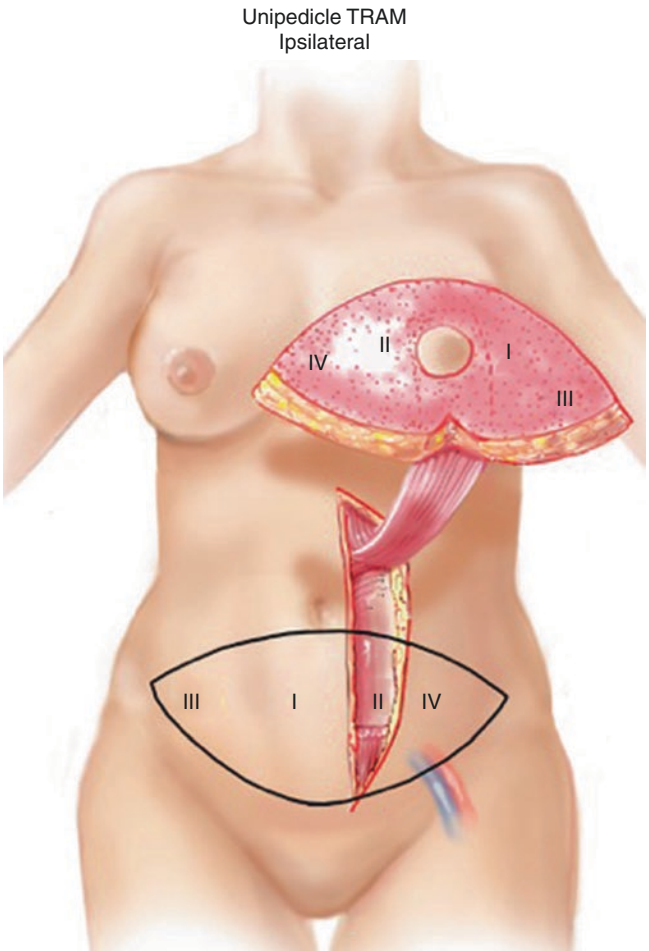


Fig. 36.3 Ipsilateral unipedicled TRAM flap with 180° flap rotation

transfer reduces initial intermammary bulging, and the definition of the ipsilateral inframammary crease tends to be excellent. Pedicle tension is reduced and flap positioning is easier. Venous drainage of the flap appears better with ipsilateral transfer [41]. The contralateral pedicle (Fig. 36.5) tends to create more blunting of the medial inframammary crease and limits the ease of flap positioning laterally.

Radiation to the affected breast necessitates either a contralateral unipedicled flap (with or without surgical delay) or preferably a bipedicled or free TRAM flap. While the ipsilateral radiated pedicle can be used in many patients, it may be unreliable and I always use Doppler to assess the ipsilateral pedicle signal and compare it to the non-radiated side. We have clearly shown a higher fat necrosis rate in patients with preoperative radiation to the internal mammary supply [42]. A contralateral pedicle is useful in such cases but tends to cause some degree of blunting of the medial inframammary fold and softens the depth of the intermammary cleavage, although careful denervation of the pedicle may ameliorate this problem**.** A surgical delay performed 5–14 days previously improves TRAM flap blood supply and may be considered for a pedicled procedure if a large breast is to be fashioned [26, 27, 43, 44]. If vascular delay is performed, it should include an incision right across the lower inferior end of the TRAM flap with elevation of the flap tips as described by Taylor [26, 45] and not just two small groin incisions to give access for vascular

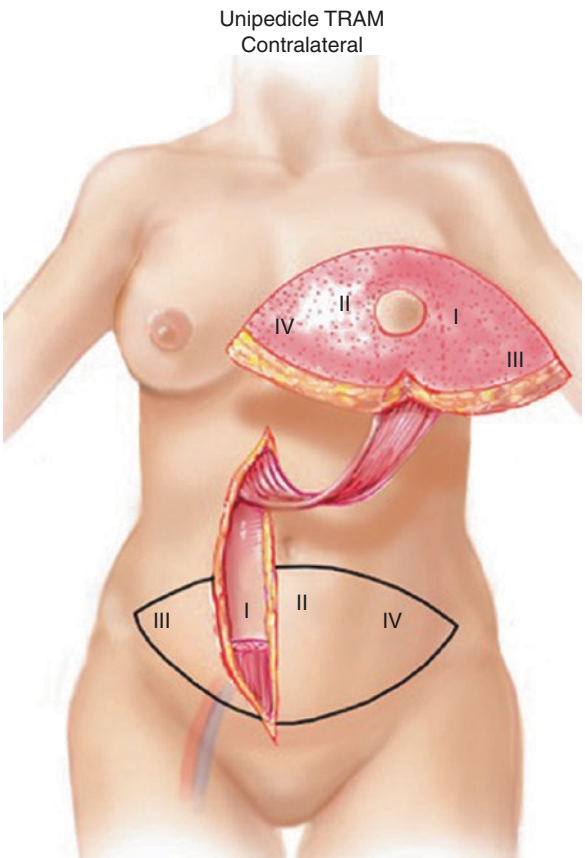

Fig. 36.5 Contralateral unipedicled TRAM flap with 180° flap rotation

division. The rectus fascia is incised as a long ellipse to facilitate closure and maintenance of muscle integrity at the inscriptions and is freed from the underlying rectus muscle. Care must be taken not to penetrate the muscle while separating the tendinous inscriptions. The muscle can be elevated in its entirety or using a muscle-sparing technique (Fig. 36.6). Muscle sparing involves identifying the intramuscular course of the superior epigastric vessels with a Doppler probe and then leaving a lateral strip of muscle some 2 cm in diameter. Theoretically, this leaves muscle innervated and vascularized by the intercostal vessels and nerves for further abdominal wall competence postoperatively. In practice, however, the intercostal supply penetrates the rectus muscle in its middle third, thereby leaving no innervation and probably little, if any, blood supply to the lateral muscle strip. A medial strip of muscle may also be left but its functional value is also questionable. As noted earlier, Harris demonstrated an 80% reduction in pedicled blood flow by clamping the medial and lateral thirds of the rectus muscle intraoperatively [20]. Suominen's data on the diminishing size and strength of residual upper rectus muscle left after free TRAM flap harvest calls into question the validity of performing muscle-sparing procedures [24]. The rectus muscle is divided distally, and the deep inferior epigastric vessels are ligated with LIGACLIP®. These vessels should be dissected out with the flap just in case they are needed for conversion to a free flap in the event of vascular compromise of a pedicled flap.
